RESEARCH INSTITUTE, NEW DELHI.

JOURNAL

OF

THE CHEMICAL SOCIETY.

Committee of Publication:

H. E. ARMSTRONG, Ph.D., F.R.S.
WYNDHAM R. DUNSTAN.
F. R. JAPP, M.A., Ph.D., F.R.S.
H. F. MORLEY, M.A., D.Sc.
HUGO MÜLLER, Ph.D., F.R.S.
W. H. PERKIN, Ph.D., F.R.S.
W. RAMSAY, Ph.D., F.R.S.
W. J. RUSSELL, Ph.D., F.R.S.
J. MILLAR THOMSON, F.R.S.E.
T. E. THORPE, Ph.D., F.R.S.
W. P. WYNNE, B.Sc.

Editor:
C. E. GROVES, F.R.S.

Sub-Editor:
A. J. GREENAWAY.

Abstractors:

[illegible] B. ASHER ARON.
C. F. BAKER, B.Sc.
D. BENDIX.
A. G. BLOXAM.
C. H. BOTHAMLEY.
B. BRAUNER, Ph.D.
B. H. BROUGH.
H. G. COLMAN, Ph.D.
H. CROMPTON.
W. D. HALLIBURTON, M.D., B.Sc.
F. S. KIPPING, Ph.D., D.Sc.
J. W. LEATHER, Ph.D.
D. A. LOUIS.
P. MAXWELL, M.D., B.Sc.
N. H. J. MILLER, Ph.D.
G. T. MOODY, D.Sc.
J. M. H. MUNRO, D.Sc.
T. G. NICHOLSON.
E. W. PREVOST, Ph.D.
R. ROUTLEDGE, B.Sc.
M. J. SALTER.
JAMES TAYLOR, B.Sc.
L. T. THORNE, Ph.D.
J. B. TINGLE, Ph.D.
H. K. TOMPKINS, B.Sc.
G. W. DE TUNZELMANN, B.Sc.
J. WALKER, D.Sc., Ph.D.
W. C. WILLIAMS, B.Sc.
W. P. WYNNE, B.Sc.

Vol. LVIII.

1890. ABSTRACTS.

LONDON:
GURNEY & JACKSON, 1, PATERNOSTER ROW.

LONDON:
HARRISON AND SONS, PRINTERS IN ORDINARY TO HER MAJESTY,
ST. MARTIN'S LANE.

CONTENTS.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS:—

General and Physical Chemistry.

PAGE

Landolt (H.). Molecular Refraction 1
Petersen (E.). Heat of Neutralisation of Fluorides 1

INSTRUCTIONS TO ABSTRACTORS,

GIVING THE

NOMENCLATURE AND SYSTEM OF NOTATION

ADOPTED IN THE ABSTRACTS.

1. Before beginning to write an abstract, it is desirable to read through the whole of the original paper, in order to form a judgment as to its importance, and as to the scale on which the abstract should accordingly be made.

2. The abstract should mainly consist of the expression, in the abstractor's own words, of the substance of the paper.

3. The abstract should be made as concise as possible, consistently with a clear and accurate statement of the author's results or theories, due regard being paid to their import.

4. If an abstract of a paper on the same subject, either by the author of the paper abstracted, or by some other author, has already appeared, note should as a rule be made of this fact. Important references to the researches of others quoted by an author should be reproduced in the abstract. Always employ figures instead of Roman numerals for references, thus:—*Annalen*, **221**, 92, instead of ccxxi, 92.

5. If an abstractor is acquainted with papers previously published by other authors containing statements either practically identical with, or opposed to, those in the paper abstracted, and to which no reference is made, he should notice their agreement or contradiction in a foot-note.

6. As a rule, details of methods of preparation or analysis, or generally speaking of work, may be omitted, unless such details are essential to the understanding of the results, or have some independent value.

Nomenclature.

7. Employ names such as *sodium chloride*, *potassium sulphate*, *ethyl acetate*, and use the terminals *ous* and *ic* only in distinguishing compounds of different orders derived from the same elementary radicle; such, for instance, as mercurous and mercuric chloride, sulphurous and sulphuric acid.

8. Term compounds of metallic and alcoholic radicles with the group OH, *hydroxides* and not hydrates; for example, potassium hydroxide, phenyl hydroxide, the name hydrate being reserved for compounds supposed to contain water of combination or crystallization. Compounds such as CH_3ONa, C_2H_5ONa, $C_7H_{15}ONa$, &c., should be termed sodium methoxide, ethoxide, heptyloxide, &c.

9. Apply the term *acid* only to compounds of hydrogen with negative radicles, such as HNO_3, H_2SO_4, H_3PO_4, and denote the oxides which form acids by names such as sulphuric anhydride, carbonic anhydride. Term salts containing an amount of metal equivalent to the displaceable hydrogen of the acid, *normal* and not neutral salts, and assign names such as hydrogen sodium sulphate, hydrogen disodium phosphate, &c., to the acid salts. Basic salts are as a rule best designated merely by their *formulæ*.

10. Use names such as *methane*, *ethane*, &c., for the normal paraffins or hydrocarbons of the C_nH_{2n+2} series of the form $CH_3{\cdot}[CH_2]_5{\cdot}CH_3$, &c. The isomeric hydrocarbons are usually most conveniently represented by names indicating their relation to methane; for example, $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_3$ = propylmethane; $CH_3{\cdot}CH(CH_3)_2$ = isopropylmethane or trimethylmethane; or, although less frequently, by names such as diisopropyl.

11. Term the hydrocarbons C_2H_4 and C_2H_2 *ethylene* and *acetylene* respectively (not ethene and ethine). Distinguish the homologues of ethylene, whenever possible, by names indicating their relation to it, such as methylethylene, dimethylethylene, &c., denoting the di-derivatives of the form $C_nH_{2n+1}{\cdot}CH{:}CH{\cdot}C_nH_{2n+2}$ as α-, and those of the form $CH_2{:}C(C_nH_{2n+1})_2$ as β-compounds, thus: $CH_3{\cdot}CH{:}CH{\cdot}CH_3$ = α-dimethylethylene; $CH_2{:}C(CH_3)_2$ = β-dimethylethylene. Similarly, use names such as methylacetylene and dimethylacetylene for the homologues of acetylene of the form $CH{\vdots}C{\cdot}C_nH_{2n+1}$ and $C_nH_{2n+1}{\cdot}C{:}C{\cdot}C_nH_{2n+1}$. Adopt the same *allene* for the hydrocarbon $CH_2{:}C{:}CH_2$, and indicate the relation which its homologues bear to it in the same manner as pointed out for acetylene.

12. Distinguish all alcohols, that is, hydroxyl-derivatives of hydrocarbons, by names ending in *ol*; such as quinol, catechol, resorcinol, saligenol, glycerol, erythrol, mannitol, instead of hydroquinone, pyrocatechin, resorcin, saligenin, glycerin, erythrite, mannite. Compounds which are not alcohols, but which are at present distinguished by names ending in *ol*, may be represented by names ending in *ole*, if a systematic name cannot be given. For example, write indole instead of indol: furfuraldehyde instead of furfurol; fucusaldehyde instead of fucusol. Ethers derived from phenols, such as $C_6H_5{\cdot}OCH_3$, &c., hitherto called anisol, anethol, &c., may be distinguished by names ending in *oil*, as anisoïl and anethoil.

Alcohols should be spoken of as mono-, di-, tri-, or n-*hydric*, according to the number of OH groups.

13. Compounds analogous to the acids of the lactic series containing the group OH should be termed *hydroxy*-derivatives, and not oxy-derivatives; for example, hydroxyacetic and not oxyacetic acid. Compounds containing the analogous groups C_2H_5O, C_6H_5O, $CH_3{\cdot}COO$, &c., should in like manner be termed ethoxy-, phenoxy-, acetoxy- derivatives. Thus

ethoxypropionic acid instead of ethyl-lactic acid; 3 : 4 diethoxybenzoic acid instead of diethylprotocatechuic acid; and acetoxypropionic acid instead of acetyl-lactic acid. Terms such as diethylprotocatechuic acid should be understood to mean a compound formed by the displacement of hydrogen-atoms in the hydrocarbon radicle of protocatechuic acid by ethyl, viz., $C_6H(C_2H_5)_2(OH)_2 \cdot COOH$, and not $C_6H_3(OC_2H_5)_2 \cdot COOH$, just as dibromoprotocatechuic acid is understood to be the name of a compound of the formula $C_6HBr_2(OH)_2 \cdot COOH$.

14. The term *ether* should be restricted to the oxides of hydrocarbon radicles, and the so-called compound ethers should be represented by names similar to those given to the analogously constituted metallic salts (comp. 12).

15. Compounds of the radicle SO_3H should, whenever possible, be termed *sulphonic* acids, or failing this, *sulpho-compounds*: as benzenesulphonic acid, sulphobenzoic acid, and not sulfi-compounds. Compounds of the radicle $SO_2 \cdot NH_2$ should be termed sulphonamides.

16. Basic substances should invariably be indicated by names ending in *ine*, as aniline, instead of anilin, the termination *in* being restricted to certain neutral compounds, viz., glycerides, glucosides, bitter principles, and proteids, such as palmitin, amygdalin, albumin. The compounds of basic substances with hydrogen chloride, bromide, or iodide should always receive names ending in *ide* and not *ate*, as morphine hydrochloride and not morphine hydrochlorate.

Notation.

17. Equations should *be omitted* unless essential to the understanding of the results; they, as a rule, should *not* be written on a separate line, but should "run on" with the text.

18. To economise space, it is desirable: 1, that *dots* should be used *instead of dashes* in connecting contiguous symbols or radicles, whenever this does not interfere with the clearness of the formula; 2, that formulæ should be shortened by the judicious employment of the symbols Me for CH_3, Et for C_2H_5, Pr^α for $CH_2 \cdot CH_2 \cdot CH_3$, Pr^β for $CH(CH_3)_2$, Ph for C_6H_5, Ac for $CO \cdot CH_3$, and Bz for $CO \cdot C_6H_5$; and 3, that formulæ should be written *in one line* whenever this can be done without obscuring their meaning. For example:

$CCl_3 \cdot CH(OEt)_2$ instead of $CCl_3—CH<\genfrac{}{}{0pt}{}{OC_2H_5}{OC_2H_5}$

$[CCl_3 \cdot CH(OH)]_2S$ instead of $\genfrac{}{}{0pt}{}{CCl_3—CHOH}{CCl_3—CHOH}>S$

$CH_2 : CH_2$ instead of $CH_2{=}CH_2$

$CH \vdots CH$ instead of $CH{\equiv}CH$

$CH \vdots C \cdot CH_2 \cdot CH_2 \cdot C \vdots CH$ instead of $\begin{array}{l} CH_2—C{\equiv}CH \\ | \\ CH_2—C{\equiv}CH \end{array}$

$CHMe : CHPr^\alpha$ instead of $CH_2 \cdot CH{=}CH \cdot CH_2 \cdot CH_2 \cdot CH_3$

$COOH\cdot CH : CMe\cdot COOH$ instead of $\begin{array}{ccc} CH_3—C & = & CH \\ | & & | \\ COOH & & COOH \end{array}$

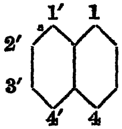
$CH_2Br\cdot CBrMe$ instead of 
$CEt_2Ac\cdot COOEt$ instead of 
$\left.\begin{array}{l}CH_2\cdot CHMe\\ CH_2\cdot CHMe\end{array}\right>O$ instead of 
$CHPh(OBz)\cdot CH(OBz)\cdot COOEt$ instead of
$C_6H_5\cdot CH(O\cdot CO\cdot C_6H_5)\cdot CH(O\cdot COC_6H_5)\cdot COOC_2H_5$.

19. In representing the constitution of benzene-derivatives, as a rule, merely indicate the relative positions of the radicles in the symbol of benzene by figures, instead of by means of the hexagon symbol, for example:—

Paradibromobenzenesulphonic acid, $C_6H_3Br_2\cdot SO_3H$[Br : SO_3H : Br = 1 : 2 : 4] instead of  the figures always being used in the order 
Relatively to the position 1, the positions 2 and 6 should always be spoken of as *ortho*-positions, 3 and 5 as *meta*-positions, and 4 as the *para*-position. It is better, however, in speaking of the derivatives of benzene, to express their constitution by giving them names such as 1 : 2 dibromobenzene, 1 : 3 dibromobenzene, &c., rather than by terming them ortho- or meta-dibromobenzene, &c.

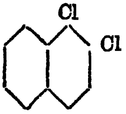
20. Moreover, in representing the constitution of derivatives of other "closed-chain" hydrocarbons do not, as a rule, employ graphic formulæ, but merely indicate the position of the radicles introduced in the following manner:—

In the case of naphthalene, express the position of the radicles introduced in place of hydrogen relatively to the carbon-atoms common to the two "rings," and number the positions in the one ring 1, 2, 3, 4, and those in the other 1′, 2′, 3′, 4′ in the order shown by the annexed symbol:—

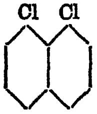


The dichloronaphthalenes, for example, are spoken of simply as 1 : 2 dichloronaphthalene, or dichloronaphthalene[Cl : Cl = 1 : 2], &c., thus:—

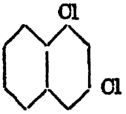
1 : 2 dichloro-naphthalene =



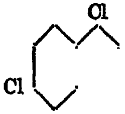
1 : 1′ dichloro-naphthalene =



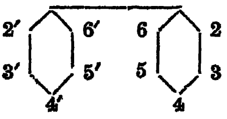
1 : 3 dichloro-naphthalene =



1 : 3′ dichloro-naphthalene =



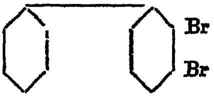
In the case of diphenyl, indicate the position of the radicles relatively to the carbon-atom of one C_6 group which is associated with the other C_6 group, and number the positions in the one group by the figures, 2, 3, 4, 5, 6, and the corresponding positions in the other group by the figures 2′, 3′, 4′, 5′, 6′. as shown by the following symbol:



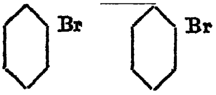
Thus the mono-derivatives, the bromodiphenyls, for example, are represented as

Bromodiphenyl [Br = 2]
" [Br = 3]
" [Br = 4]

and the two dibromodiphenyls

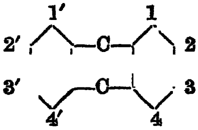


and



are respectively dibromodiphenyl [Br : Br = 2 : 3] and dibromodiphenyl [Br : Br = 2 : 6′].

In the case of anthracene, employ the following symbol, and indicate the position of the radicles relatively to the central C_2-group:



Examples:

Alizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 2].

Quinizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 4].

Anthraflavic acid, $C_6H_3(OH) : C_2O_2 : C_6H_3(OH)$ [OH : OH = 2 : 3′].

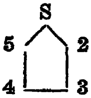
Purpurin, $C_6H_4 : C_2O_2 \cdot C_6H(OH)_3$ [OH : OH : OH = 1 : 2 : 4].

In speaking of compounds such as these, their constitution may be represented by the names

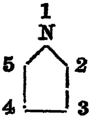
1 : 2 Dihydroxyanthraquinone	= Alizarin.
1 : 4 ,,	= Quinizarin.
2 : 3′ ,,	= Anthraflavic acid.
1 : 2 : 4 Trihydroxyanthraquinone	= Purpurin.

Always include the letters and figures indicating the constitution of derivatives of closed-chain hydrocarbons in square brackets.

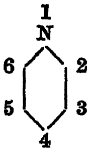
21. *In the case of thiophen*, express the position of the radicles introduced relatively to the sulphur-atom by numbers, as shown by the following symbol:



In the cases of pyrroline and pyridine, indicate the position relatively to the nitrogen-atoms as shown by the following symbols:

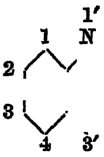


Pyrroline.

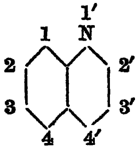


Pyridine.

In the case of indole, positions should be numbered as shown in the following symbol:—



In the case of quinoline, express the positions relatively to the carbon-atoms common to the two rings, and number the positions in the carbon ring 1, 2, 3, 4, and those in the nitrogen ring 1′, 2′, 3′, 4′ in the order shown by the annexed symbol:—



The Editor's decision, in all matters connected with the Abstracts, must be considered final.

JOURNAL
OF
THE CHEMICAL SOCIETY.

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN BRITISH AND FOREIGN JOURNALS.

General and Physical Chemistry.

Molecular Refraction. By H. LANDOLT (*Zeit. physikal. Chem.*, **4**, 413).—The author points out that Conrady's statements as to his method of determining the molecular refraction of the CH_2 group (*ibid.*, **3**, 212) are erroneous (compare Abstr., 1889, 661). H. C.

Heat of Neutralisation of Fluorides. By E. PETERSEN (*Zeit. physikal. Chem.*, **4**, 384—412).—The heats of neutralisation of the bases of the magnesium group, the alkali metals, and metals of the alkaline earths by hydrofluoric acid in solution are all equal, and for each molecule of hydrofluoric acid about 16300 cal. The above were determined by the interaction of the chlorides of the different metals with silver fluoride, and from the results the following heats of precipitation were also obtained: CaF_2, 2700 cal.; SrF_2, 2100 cal.; BaF_2, 1900 cal.; MgF_2 −2780 cal.; and AgCl 15900 cal.

The heats of neutralisation of the sesquifluorides of iron, chromium, vanadium, and manganese are—

$Fe_2(OH)_6$,	6HFAq.	3 × 15830 cal.	$V_2(OH)_6$,	6HFAq.	3 × 17410 cal.
$Cr_2(OH)_6$,	„	3 × 16780 „	$Mn_2(OH)_6$,	„	3 × 17210 „

With varying amounts of hydrofluoric acid up to 6 mols., the heat of neutralisation for the hydroxide of iron is proportional to the amount of the acid; for chromium and vanadium, it decreases slightly as the amount of acid increases. A further increase in the amount of acid produces a slight development of heat in the case of iron, vanadium, and chromium, but no effect whatever with manganese fluoride. The avidity of hydrofluoric acid towards ferric hydrate is three times as great as that of hydrochloric acid. H. C.

Exact Determination of the Melting Point of Organic Substances. By H. LANDOLT (*Zeit. physikal. Chem.*, **4**, 349—371).—

The author has made a comparison of the following methods for determining the melting point of organic substances:—

1. Melting and solidifying of large quantities of substance in which the thermometer is directly placed.
2. Heating the substance in a capillary tube.
3. Heating a platinum wire which has been covered with the substance in a mercury bath until, on melting, contact between the two metals is established, and an electric circuit thus closed.

The actual determinations made by the three methods were as follows:—

Method.	Naphthalene.	Mannitol.	Anthracene.
1. (Melting point)	80·04°, 80·10°	165·73°	200·61°
(Solidifying point)....	79·99°, 80·03°, 80·03°, 80·06°	165·64°, 165·69°	—
2. (Wide tube)	79·83°, 79·84°, 80·10°	167·54°	202·38°
(Narrow tube)	80·49°, 80·50°, 80·62°	—	—
3.	80·01°, 80·37°, 80·39°	165·77°, 166·92°	205·22°–207·62°
....	80·92°, 82·05°	167·04°	—

From the above results, more particularly those with naphthalene, the author concludes that the first method is the only one which will in all cases lead to accurate results. If this method is used, the solidifying point is most easily observed. The capillary tube method generally gives results that are too high, more especially when narrow tubes are used, and the electrical method is open to the same objection.

H. C.

Physical Constants of Halogen Substitution-products of Benzene and Toluene. By K. Seubert (*Ber.*, **22**, 2519—2524).—The author has determined the specific gravity of various halogen substitution-products of benzene and toluene, and the results are given in the following table as compared with water at 0°, 4°, and 20°, and in the last column as reduced by Winkelmann's formula for a temperature of 4° and a vacuum.

	t°.	0°.	4°.	20°.	4°. Reduced to a vacuum.
Chlorobenzene	20°	1·10726	1·10701	1·10855	1·10644
Bromobenzene...........	20°	1·49124	1·49095	1·49297	1·48972
Iodobenzene	20°	1·83247	1·83206	1·83460	1·82937
Orthochlorotoluene	20°	1·08198	1·08173	1·08323	1·08120
Metachlorotoluene........	20°	1·07242	1·07218	1·07367	1·07166
Parachlorotoluene	20°	1·06998	1·06974	1·07123	1·06923
Orthobromotoluene	20°	1·42252	1·42220	1·42417	1·42112
Metabromotoluene	20°	1·41019	1·40988	1·41183	1·40882
Parabromotoluene........	32°	1·39008	1·38977	1·39169	1·38832

The specific and molecular refractive power of these compounds was also determined with an Abbe's refractometer. The values obtained are given in a table, and agree very closely on the whole with those calculated from the values for the atomic refractive powers given by Conrady (Abstr., 1889, 661), but they are in all cases a little too low. The experimental results were in accordance with Brühl's value of the refractive power of the double linking, and also showed that place-isomerism has very little or no influence on the molecular refractive power. The ortho-compounds seem to have the smallest molecular refractive power, that of the meta- and para-series being somewhat larger, and probably the same for both.

Parachlorotoluene melts at 7·4°, parabromotoluene at 26·2°. Chloro-, bromo-, and iodo-benzene, orthochloro-, orthobromo-, and metabromotoluene solidify when cooled with solid carbonic anhydride; metachlorotoluene does not solidify until cooled with solid carbonic anhydride and ether, but it remains solid in carbonic anhydride alone.

F. S. K.

Reciprocal Influence on the Solubility of Salts. By W. NERNST (*Zeit. physikal. Chem.*, 4, 372—383).—The author regards the process of dissolution as being perfectly similar to that of vaporisation, the molecules assuming in both cases the gaseous state, in the one under the action of the osmotic pressure, in the other under that of the vapour-tension. On the Van't Hoff hypothesis it may, in fact, be shown that the work necessary to convert the gram-molecule of a salt into gas is equal to that required to bring the same amount of salt into solution. This work is the same for all substances, and hence it appears that the specific attraction between salt and solvent which has hitherto been assumed, does not exist, but that the process of dissolution is independent of such influences and similar in all cases.

The distribution of any vapour takes place in the atmosphere of an indifferent gas as in a vacuum, and in the same manner the solubility of a salt is not affected by the presence of a second salt in the solvent provided the two are without chemical action the one on the other. In the case of a dissociated vapour, however, Horstmann has shown that the addition of either of the products of dissociation will bring about an increase in the dissociation tension of that product, which causes a recombination and separation of a portion of the original substance, an effect which an indifferent gas is incapable of producing. In the same way the addition of either of the ions to an electrolyte in solution should bring about an increase in the osmotic pressure of that ion, and cause a separation of a portion of the salt from the solution, since an electrolyte in solution may be compared to a dissociated vapour. That this is the case is readily proved, for the addition of a concentrated solution of potassium chloride or hydroxide or of sodium chlorate to one of potassium chlorate immediately causes a separation of some of the latter salt, this being due in the one case to the presence of an excess of the positive, in the other to an excess of the negative ions. The amount of solid salt thus separated by the addition of a definite quantity of a second salt containing one of its ions, can be calculated from the dissociation theory, and the author shows the agreement between the calculated and observed quantities in the case of silver acetate.

H. C.

Sudden Changes in the Solubility of Salts caused by the Formation of two Layers in the Liquid. By H. W. B. Roozeboom (*Rec. Trav. Chim.*, 8, 257—272).—In studying the conditions of equilibrium between a dissolved salt and water, a disturbing influence may be introduced, owing to the separation of the liquid into two layers of different concentrations. Cases of this sort are of frequent occurrence with organic compounds, and have been noticed by Alexéeff (Abstr., 1886, 847). The formation of two layers in a liquid is a change that is conditioned by temperature, and at certain temperatures it might be possible for the solid salt and the two liquid layers to exist side by side in equilibrium with one another and with the vapour of the liquid. Such temperatures, at which the simultaneous existence of the four phases is possible. would be indicated on the pressure curves as quadruple points (Abstr., 1888, 1511). The author has endeavoured to obtain experimental evidence in this direction. but could find no salt suitable for the purpose. H. C.

Determination of Affinity Coefficients. By W. Hecht, M. Conrad, and C. Brückner (*Zeit. physikal. Chem.*, 4, 272—318).—Continuing their determination of affinity coefficients (Abstr. 1889, 931), the authors have examined the actions of sodium methoxide, ethoxide. and propoxide on the iodides of methyl, ethyl, propyl, and heptyl. The coefficients for methyl iodide are found to be in each case much greater than those of the other alkyl iodides, although the latter are also found to decrease somewhat with rising molecular weight. The relation between the coefficients of the iodides depends at the same time on the nature of the metallic salt, as may be seen by the following tables of these relations, in each of which the coefficient of heptyl iodide has been taken as unity.

	$C_2H_5 \cdot ONa$.	$C_3H_7 \cdot ONa$.	$CH_3 \cdot ONa$.
$C_7H_{15}I$	1·0	1·0	1·0
$C\ H_7I$	1·63	1·52	1·33
$C\ H_5I$	4·65	4·97	3·32
CH_3I	55·80	71·14	21·63

On the other hand, the influence of the metallic salt is greatest for the ethoxide and least for the methoxide. This is illustrated by the following table, in which the time in minutes which elapses before one half the active substance has been decomposed is given in each case.

	$C_2H_5 \cdot ONa$.	$C_3H_7 \cdot ONa$.	$CH_3 \cdot ONa$.
CH_3I	16	17	65
C_2H_5I	194	235	410
C_3H_7I	556	752	1053

In the case of the ethoxide, isopropyl iodide was also examined, and the coefficient found to be much lower than that of the normal compound.

In the latter part of the paper, methods of determining the relation between two affinity coefficients and the values of the coefficients from this relation are discussed. H. C.

Determination of the Affinity of Organic Bases. By J. WALKER (*Zeit. physikal. Chem.*, **4**, 319—343).—The author attempted to measure the affinities of the organic bases by studying the influence of their hydrochlorides in accelerating the decomposition of methyl acetate by water. Since the acceleration depends on the amount of free acid in solution, the amount of dissociation of the hydrochloride, and from this the relative affinity of the base for the acid, might be thus calculated. The results obtained were not, however, satisfactory except in the case of very feeble bases. The electrical conductivity was therefore resorted to, and from the conductivities of solutions of equal quantities of acid treated with equal quantities of different bases, the amount of salt formed in each, and from this the affinity of the different bases for the acid was deduced. Both sulphuric and hydrochloric acids were found to give good results by this method; and the results thus obtained for feeble bases agree with those obtained by the method first employed.

The dependence of the affinity of organic bases on constitution is to some extent rendered evident by the results. If methyl or ethyl is substituted for the hydrogen of an amido-group, the compound gains in basic properties. The same thing is also true in the case of the substitution of methyl for hydrogen in the carbon-ring of an aromatic base. On the contrary, the substitution of chlorine or a nitro-group for hydrogen in the carbon-ring considerably decreases the basic character of aniline, this effect being greatest in the ortho- and least in the para-position. H. C.

Apparatus for Evaporating by the Aid of Heat applied from above. By W. HEMPEL (*Ber.*, **22**, 2479—2481).—The author describes, with the aid of a diagram, an apparatus in which small quantities of a liquid can be evaporated by the aid of heat applied from above.

The source of heat is a large, inverted Argand burner, made either entirely of porcelain, or of steatite and metal cemented together with a mixture of soluble glass and finely-divided manganese dioxide. Through the centre of the burner passes a porcelain tube, the lower extremity of which projects a short distance through the flame, the upper extremity being connected with a glass chimney. The crucible or other vessel which contains the substance to be evaporated is placed on a piece of asbestos supported on a moveable iron plate. An inverted beaker, perforated with an aperture just large enough to admit the Argand burner, surrounds the vessel and serves to regulate the supply of heat; if the liquid is evaporated in a basin the employment of the beaker cover is unnecessary.

Clays or fluorides are readily dissolved by the aid of this apparatus. F. S. K.

Inorganic Chemistry.

Preparation of Chlorine in a Kipp's Apparatus. By J. THIELE (*Annalen*, 253, 239—242).—Chlorine may be conveniently prepared in a Kipp's apparatus by the action of hydrochloric acid on bleaching powder. By means of a handpress, the bleaching powder is compressed into a hard cake; this is broken into small lumps and used in this form. W. C. W.

Automatic Apparatus for Evolving Gases from Liquids. By J. THIELE (*Annalen*, 253, 242—246).—A convenient apparatus for preparing hydrogen chloride from commercial hydrochloric acid or sulphurous anhydride from a concentrated solution of sodium hydrogen sulphite may be made from a three-necked Wolff's bottle. This is provided with—(1) a delivery tube fitted with a stop-cock; (2) a small stoppered separating funnel with the stem drawn out to a fine point; and (3) a safety funnel with some mercury in the bend and a loose plug of cotton wool in the funnel. The Wolff's bottle is half filled with the solution of sodium hydrogen sulphite, for example, and the sulphuric acid is slowly introduced through the separating funnel. W. C. W.

Reciprocal Displacement of Oxygen and the Halogens. By BERTHELOT (*Compt. rend.*, 109, 546—548 and 590—597).—The author summarises his previous work on the reciprocal displacement of oxygen and chlorine and describes some later results.

Pure concentrated fuming hydrochloric acid is not decomposed by oxygen in presence of sunlight, but if some manganous chloride is present the liquid acquires a deep-brown colour, the atmosphere in the flask becomes charged with chlorine, and the liquid has bleaching properties. Oxygen is absorbed and hydrochlorides of manganese perchloride are formed. If the liberated chlorine is removed and hydrogen chloride and oxygen are introduced into the flask, a further quantity of chlorine is set free, and this process may be repeated several times. The decomposition ceases when the hydrates of the hydrochloric acid contain the maximum amount of water; dilute non-fuming hydrochloric acid is not decomposed even after long exposure in presence of manganese chloride. Ferric chloride behaves in the same manner as manganous chloride, but the phenomena are very much less distinct.

The heat of formation of dissolved hydrobromic acid is almost identical with that of water, and hence in presence of water, but under these conditions only, reciprocal decomposition may take place. In presence of excess of water, oxygen readily decomposes hydrogen bromide under the influence of light. Similar decomposition takes place at the ordinary temperature in the case of a fuming solution of hydrobromic acid, that is, hydrates of the free acid not saturated with water, but is arrested almost immediately by the formation of hydrogen perbromide, HBr_3; HBr conc. soln. + Br_2 gas = HBr_3 diss. develops +9·2 Cals., the total heat of formation, +43·5 Cals., being greater than the heat of formation of water. Oxygen does not decompose dilute hydrobromic acid, that is, the saturated hydrates of the acid, nor a solution of potassium bromide acidified with hydrochloric acid.

The formation of hydrogen perbromide explains the decomposition of water by bromine, but this change is limited by the dissociation of the perbromide in presence of water.

Dilute solutions of hydriodic acid are readily decomposed by oxygen under the influence of light at the ordinary temperature, the change corresponding with the liberation of 15·9 Cals. for each atom of gaseous iodine.

The heats of formation of dissolved potassium iodide and hydroxide are practically the same, and slight variations in the conditions serve to turn the reaction in one direction or the other. The combination of iodine with potassium iodide in concentrated solution to form potassium triiodide liberates +5·0 Cals. for each atom of gaseous iodine; the action of iodine on dissolved potassium hydroxide with formation of hypoiodite or iodate liberates +4·1 Cals. and +5·4 Cals. respectively for each atom of gaseous iodine. It follows that oxygen will not displace iodine from potassium iodide except under conditions in which potassium triiodide is stable, that is, in very concentrated solutions. Experiment showed that dilute solutions of potassium iodide remain quite colourless when exposed to light for a long time in presence of pure air; very concentrated solutions soon become orange and the colour deepens with prolonged exposure. The liquid then gives a blue coloration with starch and has an alkaline reaction; if, however, it is diluted, it rapidly becomes colourless, owing to dissociation of the potassium triiodide and the action of the liberated iodine on the potassium hydroxide which has been formed.

It is well known that even dilute potassium iodide solutions become yellow when exposed to ordinary air. This is due to the fact that the carbonic anhydride of the air takes part in the reaction. Carbonic acid does not displace hydriodic acid, but the simultaneous action of oxygen and carbonic anhydride on a dilute solution of potassium iodide produces potassium hydrogen carbonate and free iodine, the change being accompanied by the liberation of +13·5 Cals. for each atom of gaseous iodine. The colour of the liquid becomes deeper if the quantity of carbonic anhydride in the atmosphere above it is increased. The action of the oxygen is still greater in presence of acetic or hydrochloric acid, but in these cases the result is in part due to the displacement of some hydriodic acid. Acetic acid liberates very little hydriodic acid, but the action of the oxygen depends on the successive liberation of small quantities. Hydrochloric acid liberates more hydriodic acid and in this case the action of the oxygen is more marked. In presence of a large excess of air, a solution of potassium iodide acidified with hydrochloric acid is completely decomposed by the action of light in a few days.

If manganous chloride is added to a highly concentrated solution of potassium iodide and the mixture exposed to light, a higher oxide of manganese is precipitated and iodine is liberated; dilute solutions show the same phenomena in a lower degree.

All the reciprocal displacements of oxygen and the halogens under the influence of light are in agreement with the thermochemical determinations. C. H. B.

Simultaneous Synthesis of Water and Hydrogen Chloride.

By P. HAUTEFEUILLE and J. MARGOTTET (*Compt. rend.*, **109**, 641—644).—Mixtures which contained oxygen and hydrogen in the proportion required to form water, with varying proportions of chlorine; and mixtures of hydrogen and chlorine in the proportions to form hydrogen chloride, with varying quantities of oxygen, were exploded by means of a spark, and the residual chlorine was determined by means of standard sodium arsenite. If p represents the total hydrogen which enters into combination, and p' the quantity which combines with oxygen, $\frac{p - p'}{p'}$ gives the ratio of the hydrogen converted into water to the hydrogen which forms hydrogen chloride. This ratio is independent of the initial pressure, and of the nature of the spark. It is always less than unity if the proportion of chlorine is more than half the volume of the hydrogen, and it varies with every alteration in the proportion of chlorine. When the volume of chlorine present is double the volume of the hydrogen, the quantity of water formed becomes inappreciable. It is evident that the results do not agree with Bunsen's law.

With equal volumes of hydrogen and chlorine and varying proportions of oxygen, the ratio $\frac{p - p'}{p}$ is always less than unity and does not vary greatly when the ratio of oxygen to hydrogen varies from 0·25 to 3. With equal volumes of the three gases the change is represented by the equation $5Cl_2 + 5H_2 + 5O_2 = 8HCl + H_2O + Cl_2 + 4O_2$. C. H. B.

Equilibrium between Hydrogen, Chlorine, and Oxygen.

By H. LE CHATELIER (*Compt. rend.*, **109**, 664—667).—The author discusses the results of Hautefeuille and Margottet (preceding Abstract) from the point of view of his own laws of chemical equilibrium. The agreement between the observed and calculated numbers is very close. He points out that the degree of moisture of the gases, which is very important, is not specified. The formula shows that a reduction of initial pressure should be accompanied by a reduction in the proportion of water formed, and the fact that this is not observed indicates that the chlorine is partially dissociated. The varying effects of chlorine and oxygen depend solely on their relative volumes and not on their chemical properties. C. H. B.

Preparation of Oxygen in a Kipp's Apparatus.

By J. VOLHARD (*Annalen*, **253**, 246—248).—Small quantities of oxygen can be conveniently prepared in a Kipp's apparatus by the action of hydrogen peroxide on bleaching powder. Nitric acid is added in sufficient quantity to neutralise the lime in the bleaching powder. The oxygen contains a small quantity of chlorine. W. C. W.

Action of Sulphur on Solutions of Metallic Salts. By G. VORTMANN and C. PADBERG (*Ber.*, **22**, 2642—2644).—The authors find that with many proto-salts when their aqueous solutions are boiled with flowers of sulphur, about half the metal present is precipitated as sulphide, the remainder being oxidised to the per-salt. When a strongly acid solution of stannous chloride was employed, no stannous sulphide was precipitated, but hydrogen sulphide was evolved, and the whole of the tin oxidised to stannic chloride. With an aqueous solution of stannous chloride, and with an acid solution of cuprous chloride, rather less than half the tin was precipitated as sulphide, a little being oxidised in the same manner as with the strongly acid solution of tin. With mercurous nitrate, almost exactly half of the mercury was precipitated as sulphide.

Solutions of manganese, iron, nickel, zinc, and cadmium sulphates, and acid solutions of bismuth and antimonious chlorides, and of arsenious and arsenic acids, are not altered when boiled with sulphur. L. T. T.

Preparation of Nitric Oxide. By J. THIELE (*Annalen*, **253**, 246).—Nitric oxide is prepared in the apparatus previously described (this vol., p. 6) by adding a strong solution of sodium nitrite to a solution of ferrous chloride or sulphate in hydrochloric acid. If the sodium nitrite contains carbonate, it may be removed by precipitation with calcium chloride. W. C. W.

Phosphonium Sulphate. By A. BESSON (*Compt. rend.*, **109**, 644—645).—When hydrogen phosphide is passed into sulphuric acid at the ordinary temperature, there is considerable development of heat, sulphur separates, and sulphurous acid is formed. If the acid is previously cooled by means of ice and salt, the gas is somewhat largely absorbed, and the liquid remains limpid. After a time, however, it begins to decompose in the manner indicated, the temperature rises, and decomposition becomes very rapid. If the acid is cooled to −20° or −25° by the rapid evaporation of methyl chloride, a syrupy liquid is obtained, from which a white, crystalline, highly deliquescent, solid separates; this seems to be phosphonium sulphate. When thrown into water at the ordinary temperature, it dissolves with a strident noise, and hydrogen phosphide is evolved, but the sulphuric acid is not reduced. When exposed to air at the ordinary temperature, the phosphorus is oxidised to phosphoric, phosphorous, and hypophosphorous acids, whilst the sulphuric acid is reduced to sulphurous acid and sulphur, with a small quantity of hydrogen sulphide. The crystals may be dissolved in dilute sulphuric acid, and if the solution is electrolysed at −25° or −40° with a mercury cathode, there is only a very slight intumescence of the mercury, and hence, if phosphonium amalgam exists, it is very unstable even at the freezing point of mercury. The solution has a high resistance, and if the current is too strong the compound is decomposed with great rapidity in the manner already described.

Hydrogen phosphide has no action on nitric acid at −25°.

C. H. B.

Behaviour of Sodium Thiosulphate towards Acids and Metallic Salts. By W. VAUBEL (*Ber.*, 22, 2703—2704).—A reply to Vortman (Abstr., 1889, 1107) upholding the author's previous views (*ibid.*, p. 943).

Direct Production of Crystalline Sodium Carbonate and Chlorine from Sodium Chloride. By W. HEMPEL (*Ber.*, 22, 2475—2478).—In the electrolysis of metallic chlorides, which give readily soluble decomposition-products, the latter are further decomposed as soon as the quantity produced reaches a certain limit. When, however, the compound produced is only sparingly soluble, this secondary decomposition does not take place, and the whole strength of the current is utilised. Potassium chloride and sodium chloride, for example, can be converted into the corresponding chlorate; calcium chloride and magnesium chloride can be decomposed into chlorine and a solid hydroxide, by employing a diaphragm.

Marx (D. R.-P., No. 46318) has shown that alkaline chlorides can be directly converted into chlorine and an alkaline hydrogen carbonate, by passing carbonic anhydride through the solution during electrolysis, metal and liquid diaphragms being employed.

The author, who has been engaged independently in making similar experiments, describes, with the aid of diagrams, an apparatus in which sodium chloride can be directly converted into chlorine and crystalline carbonate. The cathode is a perforated iron disc, the anode a perforated carbon disc, the perforations being about 4 mm. in diameter, and bored in an upward direction to allow the gas to escape freely. A disc of ordinary asbestos-paper, placed immediately between the carbon and iron discs, serves as a diaphragm. The three discs are placed in the centre of a vessel made of porcelain and glass, which is thus divided into two chambers, each of which is provided with a conducting tube, in one case for carbonic anhydride, in the other for chlorine. If sodium chloride is added from time to time through a suitable aperture, and the water which is removed with the crystalline carbonate is replaced, the apparatus can be worked continuously, sodium carbonate and almost chemically pure chlorine being obtained.

A tension of 3·2 volts is required for decomposing the sodium chloride, and a tension of 2·5 volts to overcome the polarisation current; but the latter has only a slight tension when both electrodes are made of carbon. With a current of 1·73 ampères 0·93 gram of chlorine per hour was produced, so that if a dynamo were employed it should give 64·5 grams of chlorine and 259·8 grams of $Na_2CO_3 + 10H_2O$ per horse-power-hour.

F. S. K.

Preparation of Crystalline Normal Lithium Phosphate and Arsenate. By A. DE SCHULTEN (*Bull. Soc. Chim.* [3], 1, 479—480).—Fused lithium chloride dissolves the amorphous, normal phosphate, and on cooling and washing the melt, rhomboidal, tabular crystals of normal lithium phosphate, which have a sp. gr. 2·41 at 15°, and are infusible at a white heat, are obtained.

The normal arsenate is similarly prepared; it corresponds with the phosphate physically, and is of sp. gr. 3·07 at 15°. T. G. N.

Cadmium Phosphates and Arsenates. By A. de Schulten (*Bull. Soc. Chim.* [3], 1, 473—479).—The normal orthophosphate, $Cd_3(PO_4)_2$, falls as a voluminous, amorphous precipitate when normal sodium phosphate is added to the solution of a cadmium salt.

Hydrogen disodium phosphate throws down from a hot solution of cadmium chloride or sulphate an amorphous precipitate which quickly becomes crystalline. After purification by dissolution in phosphoric acid and cautious reprecipitation by alkaline hydroxides, it forms small, prismatic hexagons of sp. gr. 3·98 at 15°, having the composition $H_2Cd_5(PO_4)_4 + 4H_2O$; these, when dissolved in cold phosphoric acid (sp. gr. 1·1), are reprecipitated unaltered on warming or on heating in sealed tubes to 250°, but redissolve on cooling; as thus produced, their sp. gr. is 4·12 at 15°. This phosphate loses its water at a red heat, and fuses at a white heat; it is probably the compound described by Stromeyer as the normal phosphate.

Monocadmium phosphate, $H_4Cd(PO_4)_2 + 2H_2O$, crystallises out after slow evaporation of a saturated solution of the previous salt in cold dilute phosphoric acid at the normal temperature. It exists as large clino-rhombic prisms of sp. gr. 2·742 at 15°, which lose their water of crystallisation at 100°, and are decomposed by water to form a flocculent phosphate, $H_2Cd_5(PO_4)_4 + 4H_2O$.

Cadmium chlorapatite.—Normal cadmium orthophosphate and the second phosphate described above dissolve in fused cadmium chloride, and on slowly cooling the melt, long, hexagonal prisms of the salt, $3Cd_3(PO_4)_2,CdCl_2$, of sp. gr. 5·46 at 15°, separate.

A cadmium bromapatite, $3Cd_3(PO_4)_2,CdBr_2$, may be similarly prepared, but is always contaminated with cadmium pyrophosphate, from which it may be separated by cold, dilute nitric acid, which dissolves only the bromapatite; the cadmium pyrophosphate, $Cd_2P_2O_7$, exists as flattened oblique lamellæ of sp. gr. 4·965 at 15°.

Cadmium arsenates.—When the amorphous powder, $H_2Cd_5(AsO_4)_4 + 4H_2O$, which is precipitated on the addition of hydrogen disodium arsenate to the solution of a cadmium salt, is dissolved to saturation in a cold solution of arsenic acid of sp. gr. 1·3, and, subjected to heat, crystals of the salt $HCdAsO_4 + H_2O$, having a sp. gr. of 4·164 at 15° are deposited.

Monocadmium arsenate, $H_4Cd(AsO_4)_2 + 2H_2O$, crystallises out when a saturated solution of the compound $H_2Cd_5(PO_4)_4 + 4H_2O$, in arsenic acid solution (sp. gr. 1·3), is allowed to evaporate at the ordinary temperature. It forms large, clino-rhombic prisms of sp. gr. 3·241 at 15°, which are isomorphous with those of the corresponding phosphate. At 70—80°, they lose their water of hydration, and are partly decomposed; with excess of water, they form a flocculent substance, $H_2Cd_5(AsO_4)_4 + 4H_2O$.

Cadmium chlorarsenioapatite, $3Cd_3(AsO_4)_2,CdCl_2$, is produced by fusing either normal ammonium arsenate or the salt $H_2Cd_5(AsO_4)_4$ +

$4H_2O$, with excess of cadmium chloride. Its sp. gr. is 5·865 at 15°, and its physical properties correspond with those of the chlorapatite.

Cadmium bromarsenioapatite, $3Cd_3(AsO_4)_2,CdBr_2$, is similarly prepared, and exists as long yellow prisms of sp. gr. 6·017.

Cadmium pyroarsenate, $Cd_2As_2O_7$, is prepared by fusing a mixture of cadmium bromide (22 parts) with potassium bromide (5 parts), and adding to the fused mass normal ammonium arsenate (9 parts); after washing the melt, the colourless crystals of the pyroarsenate are separated from the yellow bromarsenioapatite by treatment with dilute nitric acid, which dissolves the latter compound only. This pyroarsenate forms crystals of sp. gr. 5·474 at 15°, corresponding in physical properties with the pyrophosphate. T. G. N.

Action of Sodium Thiosulphate on Metallic Salts. By G. Vortmann and C. Padberg (*Ber.*, 22, 2637—2641).—The authors have extended Vortmann's work on copper salts (Abstr., 1888, 787) to other metallic salts.

When a concentrated solution of sodium thiosulphate is added to a strong solution of lead acetate until the lead thiosulphate first precipitated has been just redissolved, and alcohol is then added, an oily liquid separates, which when rubbed with absolute alcohol solidifies to a crystalline mass of the formula $PbS_2O_3,3Na_2S_2O_3 + 12H_2O$.

Thallious sulphate under similar treatment yields small needles of the formula $Tl_2S_2O_3,2Na_2S_2O_3 + 8H_2O$.

When molecular proportions of cadmium sulphate and barium thiosulphate are rubbed together with a little water, the insoluble barium sulphate formed filtered off, and alcohol added to the filtrate, *cadmium thiosulphate*, $CdS_2O_3 + 2H_2O$, separates as an oil, which gradually solidifies to a yellowish-white, crystalline mass. When equal molecular proportions of sodium thiosulphate and cadmium nitrate in aqueous solution are mixed together and alcohol added, yellowish-white needles of the formula $2CdS_2O_3,Na_2S_2O_3 + 7H_2O$ are formed. If a large excess of the thiosulphate is used, the compound $CdS_2O_3,3Na_2S_2O_3 + 9H_2O$ separates as an oil. This gradually solidifies to small, yellow scales, which lose 4 mols. H_2O over sulphuric acid.

On mixing strong solutions of zinc iodide and sodium thiosulphate and adding alcohol, an oil separates, which after long exposure over sulphuric acid solidifies to a gum-like mass of the formula $2ZnS_2O_3,3Na_2S_2O_3 + 10H_2O$. It is deliquescent, and decomposes gradually with formation of zinc sulphide.

Ferrous thiosulphate, $FeS_2O_3 + 5H_2O$, forms green crystals easily soluble in water. A double salt, $FeS_2O_3,3Na_2S_2O_3 + 8H_2O$, was obtained by precipitating a mixed solution of ferrous iodide and sodium thiosulphate with alcohol. It forms bright-green crystals, soluble in water.

Manganese thiosulphate, $MnS_2O_3 + 5H_2O$, is crystalline but unstable. A pale, rose-coloured double salt, $MnS_2O_3,2Na_2S_2O_3 + 16H_2O$, was obtained.

The cobalt double salt, $CoS_2O_3,3Na_2S_2O_3 + 15H_2O$, forms a blue, gum-like mass, soluble in water. No corresponding nickel salt could be prepared, though a crystalline salt, $NiS_2O_3,6NH_3,3H_2O$, was obtained. L. T. T.

New Method of Preparing Anhydrous Aluminium Chloride. By C. F. Mabery (*Ber.*, **22**, 2658).—The author finds that dry hydrogen chloride extracts the whole of the aluminium from an alloy of copper and aluminium without attacking the copper. The reaction is most energetic a little below a red heat. The alloys containing 15 to 40 per cent. of aluminium are best powdered, mixed with powdered charcoal (to prevent the fusion of the remaining copper), put into a graphite retort, and when heated just below a red heat a current of hydrogen chloride is passed through. The aluminium chloride distils over, and may be condensed in suitable vessels, the liberated hydrogen passing on. L. T. T.

Alkali Aluminium Silicates. By A. Gorgeu *Zeit. Kryst. Min.*, **15**, 646, from *Bull. soc. fran. min.*, **10**, 278).—On melting kaolin with alkali haloid salts in the presence of moist air, silicates are formed, having the composition $AlR'SiO_4$. By melting kaolin with potassium carbonate or caustic potash at a dull-red heat, an amorphous salt, $AlKSiO_4$, is obtained, whilst at a more intense heat octahedra are obtained, having the composition $Al_2K_2SiO_6$, or else a more basic silicate also crystallising in the regular system. The sodium-compounds prepared in a similar way are always basic, and form doubly refracting crystals. B. H. B.

Mercuricobaltammonium Salts. By G. Vortmann and E. Morgulis (*Ber.*, **22**, 2644—2648).—When solutions of the mercuric double salts of cobaltammonium chlorides are treated with potash or soda, red precipitates are formed, which appear to be cobalt-ammonium chlorides, in which part of the hydrogen is replaced by varying proportions of the univalent radicles (HgCl) or (HgOH).

Luteocobalt salts. A solution of the salt $Co_2(NH_3)_{12}Cl_6,6HgCl_2$, or a mixture of one part by weight of luteocobalt chloride and three parts of mercuric chloride, when treated with 6 mols. of soda yields the salt $Co_2N_{12}H_{26}(HgCl)_6(HgOH)_2Cl_6$; or with excess of soda, the salt $Co_2N_{12}H_{28}(HgOH)_8Cl_6$. Both compounds are bright-red, and decompose quickly when moist, slowly when dry. Equal weights of luteocobalt chloride and mercuric chloride with excess of soda yield a slightly more stable, red salt, $Co_2N_{12}H_{32}(HgOH)_4Cl_6$.

Purpureocobaltdecamine salts.—1 mol. of purpureocobalt chloride, 6 mols. of mercuric chloride, and 6 mols. of soda yield a dark-red, flocculent salt, $Co_2N_{10}H_{22}(HgCl)_6(HgOH)_2Cl_6$; with excess of soda, the salt $Co_2N_{10}H_{22}(HgOH)_8Cl_6$ is formed.

Roseocobaltdecamine salts.—1 mol. of roseocobalt chloride, 6 mols. of mercuric chloride, and 6 mols. of soda yield a violet-red precipitate, $Co_2N_{10}H_{24}(HgOH)_6Cl_6$; with excess of soda, a salt,

$$Co_2N_{10}H_{24}(HgOH)_6Cl_4(OH)_2,$$

is formed. Both salts are very unstable.

Purpureocobaltoctamine salts.—1 mol. of purpureocobaltoctamine chloride, 6 mols. of mercuric chloride, and 6 mols. of soda yield the salt. $Co_2N_8H_{16}(HgCl)_4(HgOH)_4Cl_6$; with excess of soda, the salt $Co_2N_8H_{16}(HgOH)_8Cl_6$ is formed.

Equal weights of the cobalt and mercuric salts with excess of soda yield the salt $Co_2N_8H_{16}(HgOH)_8Cl_4(OH)_2$.

Roseocobaltoctamine salts.—Under like conditions as with the purpureo-salts, the three salts, $Co_2N_8H_{16}(HgCl)_6(HgOH)_2Cl_6$,

$$Co_2N_8H_{16}(HgOH)_8Cl_6,$$

and $Co_2N_8H_{16}(HgOH)_8Cl_4(OH)_2$, are formed. All three are violet-red, and decompose at ordinary atmospheric temperature, as do also the corresponding purpureo-compounds. L. T. T.

Cobaltoctamine Salts. By G. Vortmann and O. Blasberg (*Ber.*, **22**, 2648—2655).—When cobalt nitrate, sulphate, or chloride is dissolved in a small quantity of water and added to a mixture of ammonia and ammonium carbonate, violet-red solutions are formed. If these are oxidised by a current of air, decamine salts are formed, but on evaporation these are decomposed, octamine salts crystallising out. The following salts are described :—

$Co_2(NH_3)_{10}(NO_3)_2(CO_3)_2,2H_2O$	Crystalline.
$Co_2(NH_3)_{10}(SO_4)_2CO_3,4H_2O$	Crystalline.
$Co_2(NH_3)_8(NO_3)_2(CO_3)_2,H_2O$	Cherry red crystals.
$Co_2(NH_3)_8(SO_4)_2CO_3,4H_2O$..........	Long, thin needles.
$Co_2(NH_3)_8SO_4(CO_3)_2,3H_2O$..........	Dark red, prismatic crystals.
$Co_2(NH_3)_8Cl_4CO_3,2H_2O$.............	Crystalline.
$Co_2(NH_3)_8Cl_2(CO_3)_2,H_2O$	
$Co_2(NH_3)_8(NO_3)_2(SO_4)_2,2H_2O$	
$Co_2(NH_3)_8(NO_3)_6,2H_2O$.............	
$Co_2(NH_3)_8(NO_3)_2Cl_4,4H_2O$...........	
$Co_2(NH_3)_8(NO_3)_2I_4,2H_2O$	
$Co_2(NH_3)_8Br_2(SO_4)_2$	
$Co_2(NH_3)_8I_2(SO_4)_2$................	
$Co_2(NH_3)_8I_2Cl_4,2H_2O$	Brown scales.
$Co_2(NH_3)_8(OH)_2Cl_4,2H_2O$	Dark green powder.
$Co_2(NH_3)_8(OH)_2Cl_4,2HgCl_2$.........	
$Co_2(NH_3)_8(OH)_2Cl_4,PtCl_4,H_2O$	

L. T. T.

Action of Sulphurous Acid on Cobaltammonium Salts. By G. Vortmann and G. Magdeburg (*Ber.*, **22**, 2630—2637).—The authors have obtained the following compounds :—

$Co_2(NH_3)_8(SO_3Am)_6,10H_2O$	Yellowish-brown needles.
$Co_2(NH_3)_8(SO_3)_6Ba_3,7H_2O$...........	Golden-yellow scales.
$Co_2(NH_3)_8(SO_3)_6Ba_2Am_2,7H_2O$.......	Golden-yellow scales.
$Co_2(NH_3)_8(SO_3)_6Co_2^{vi},36H_2O$	Orange crystals.
$Co_2(NH_3)_8(SO_3)_6Co_2^{vi},24H_2O$	Orange crystals.

$Co_2(NH_3)_6(SO_3)_6(NH_3)_{12}Co_2^{vi},8H_2O$ ..	Orange powder.
$Co_2(NH_3)_9(SO_3)_2(SO_3Am)_2,4H_2O$.....	Yellowish-brown needles.
$Co_2(NH_3)_8SO_4(SO_3)_4Co_2^{vi},24H_2O$	Yellow crystalline powder.
$Co_2(NH_3)(NH_3)_8(SO_3)_2Cl_2,4H_2O$	Dark brown crystals
$Co_2(NH_3)_{10}(SO_3Na)_6,2H_2O$	Light brown crystals.
*$Co_2(NH_3)_{10}(SO_3)_6Co_2^{vi},8H_2O$	Brownish-yellow powder.
$Co_2(NH_3)_{10}(SO_3)_3,3H_2O$.............	
$Co_2(NH_3)_{10}(SO_3)_2Cl_2$................	Brown crystalline powder.
$Co_2(NH_3)_{12}(SO_3)_2Cl_2,6H_2O$	Yellow needles.

The authors consider that these salts show the existence of four series of salts.

1. $Co_2(NH_3)_{6-12}(SO_3)_3$.
2 $Co_2(NH_3)_{6-12}(SO_3)_2(SO_3R)_2$.
3. $Co_2(NH_3)_{6-12}(SO_3)(SO_3R)_4$.
4. $Co_2(NH_3)_{6-12}(SO_3R)_6$.

L. T. T.

New case of Isomorphism of Uranium and Thorium. By C. Rammelsberg (*Zeit. Kryst. Min.*, **15**, 640—641; from *Sitzber. preuss. Akad. Wiss*, 1886, 603).—The author shows that the thorium sulphate described by Nordenskiold and others, and the uranium sulphate hitherto regarded as rhombic, have a similar composition, namely:—

$$(SO_4)_2Th + 9H_2O,$$
$$(SO_4)_2U + 9H_2O.$$

The crystals of the latter are only seemingly rhombic in consequence of twin-formation; in reality they are monosymmetric, like the thorium sulphate. The axial ratios of the two minerals are: uranium sulphate, $a : b : c = 0·597 : 1 : 0·6555$, $\beta = 82° 11'$; thorium sulphate, $a : b : c = 0·598 : 1 : 0·658$, $\beta = 81° 50'$. B. H. B.

Fluorine-compounds of Vanadium and its Analogues. By E. Petersen (*J. pr. Chem.* [2], **40**, 271—296; compare Abstr., 1889, 107).—The following double salts of vanadium oxyfluorides and potassium fluoride have been obtained:—

$2KF,VOF_3$, a white, crystalline precipitate, is obtained by adding a solution of potassium fluoride to one of vanadic acid in hydrofluoric acid; when dried over sulphuric acid, it becomes reddish-brown, and has the above formula.

$4KF.VF_5,VOF_3$ separates as a white precipitate from the mother-liquor of the above salt.

$HF,3KF,2VOF_3$ crystallises from a hot solution of either of the preceding salts in hydrofluoric acid in beautiful, colourless prisms, which lose very little weight at 100°.

$3KF,VOF_3,VO_2F$ is the white, crystalline residue left when the precipitate obtained by adding a solution of vanadium pentoxide in hydrofluoric acid to a solution of potassium fluoride is treated with water at the ordinary temperature; if hot water is used and the solution is poured into a hot solution of potassium fluoride, a crystalline precipitate is obtained, of uncertain composition, but approaching the formula $4KF,VOF_3,VO_2F$: or if the first-mentioned precipitate is heated with water for some minutes, a salt having nearly the composition VOF_3,VO_2F is obtained.

---

* Probably Kunzel's pentaminedicobaltic sulphite.

$2KF,VO_2F$ separates from a warm solution of vanadium pentoxide in hydrofluoric acid when it is nearly neutralised with potassium hydroxide. It crystallises in yellow, six-sided, truncated prisms. When recrystallised from water, it yields the salt $3KF,2VO_2F$.

$3HF,9NH_4F,5VOF_3$, obtained by adding ammonium fluoride in slight excess to the solution of vanadium pentoxide in hydrofluoric acid, crystallises in large, colourless, four-sided prisms.

$3NH_4F,VO_2F$ crystallises from a solution of vanadium pentoxide in hydrofluoric acid when it is nearly neutralised with ammonia. The crystallography of the salt is given.

$HF,7NH_4F,4VO_2F$ separates in white crystals from the solution of the last-named salt in warm water.

$2Nb_2O_5,3KF,5H_2O$ is obtained by melting niobium pentoxide (1 part) with potassium fluoride (3 25 parts) and treating the melt with water, when the salt remains undissolved as a crystalline powder.

$Nb_2O_5,KF,3H_2O$ is a prismatic, crystalline powder, obtained by fusing niobium pentoxide (1 part) with potassium fluoride (1·3—1·5 parts).

The author reviews the work already done on the vanadium double fluorides, and concludes his paper with the following directions for extracting vanadic acid from the finery slag of Taberg:—300 grams of the finely-powdered slag is mixed with 400 c.c. of hydrochloric acid (sp. gr. 1·18) and shaken. After 24 hours, water is added to make the bulk up to 1½ litres, and the whole filtered through linen. Iron is then added, and, after the evolution of hydrogen has ceased, sodium acetate until the liquid is reddish-brown; finally, acetic acid and sodium phosphate are added until all iron, chromium, aluminium, and vanadium are precipitated as phosphates. The precipitate is mixed with sodium carbonate (0·5 part) and heated on an iron plate for ½—¾ hour; the mass is treated with water, hydrochloric acid added to nearly neutralise the solution, which is then heated, filtered, and made acid with acetic acid; solid ammonium chloride is now added, when a red, crystalline ammonium vanadate, $(NH_4)_2O,2V_2O_5,4H_2O$, separates; this is heated and the residual vanadium oxide treated with hot nitric acid at 110—120°, and converted into ammonium metavanadate by evaporating off the nitric acid, dissolving in ammonia, and crystallising; pure vanadic acid is obtained from this salt by igniting and repeating the nitric acid treatment. A. G. B.

Vapour-density of Antimony Pentachloride. By R. ANSCHÜTZ and N. P. EVANS (*Annalen*, **253**, 95—105).—By means of a modification of La Coste's apparatus, the authors have attempted to determine the density of the vapour of antimony pentachloride under reduced pressure. As antimony trichloride boils at 143—144° under 70 mm. pressure and antimony pentachloride boils at 102—103° under 68 mm. pressure, the determinations were made under 58 mm. pressure at a temperature of 218°. The mean of four determinations gave the value 10, the theoretical density being 10·33. It was impossible to exclude all traces of moisture from the apparatus and avoid the formation of minute quantities of the monohydrate of antimony pentachloride. W. C. W.

Atomic Weight of Palladium. By E. H. KEISER (*Amer. Chem. J.*, **11**, 398—403).—Attempts were at first made to use the double chlorides of palladium with ammonium and with sodium, but they had to be abandoned, as these compounds contain water, from which it is almost impossible to completely free them; moreover, the dried salts are very hygroscopic, and absorb water rapidly while being weighed.

Finally, the yellow, crystalline palladiodiammonium chloride, $PdN_2H_6Cl_2$, was used; this is formed whenever hydrochloric acid is added to a solution of palladium chloride in excess of ammonia; it is a stable compound, and can be obtained very pure. It contains no water of crystallisation, can be dried completely, and is not hygroscopic. When heated in a current of pure hydrogen, the colour changes from yellow to black, hydrogen being absorbed, and metallic palladium and ammonium chloride formed. On raising the temperature, the ammonium chloride volatilises, and spongy palladium is left behind; this is cooled below a red heat in a current of hydrogen, and then the hydrogen is displaced by air; in this way the occlusion of hydrogen is prevented. The weight of palladium obtained from a known weight of the chloride is thus ascertained, and from this the atomic weight of palladium is calculated, assuming N = 14·01, H = 1, Cl = 35·37. Two series of experiments were made; the palladammonium chloride used in the second series was prepared from the metallic palladium obtained in the first. The results give as mean value Pd = 106·35:—

		Atomic weight.		
Series.	Experiments.	Mean.	Maximum.	Minimum.
I.	11	106·352	106·459	106·292
II.	8	106·350	106·455	106·286

C. F. B.

Ruthenium Potassium Nitrites. By A. JOLY and M. VÈZES (*Compt. rend.*, **109**, 667—670; compare Abstr., 1889, p. 352).—If ruthenium chloride is added to a boiling solution of potassium nitrite until the precipitate which forms at first is redissolved, and the liquid is concentrated and allowed to cool, it deposits dichroic, orange-red, monoclinic prisms of 90° 10′. They are very soluble in water, can be purified by repeated recrystallisation without undergoing alteration, and have the composition $Ru_2O_2(N_2O_3)_4,4KNO_2$ or $Ru_2O_3(NO)_2,(N_2O_3)_2,4KNO_2$.

When the potassium nitrite is in excess, and prolonged ebullition is avoided, a pale-yellow, crystalline precipitate is obtained of the composition $Ru_2O_2,(N_2O_3)_2,8KNO_2$ or $Ru_2O_3(NO)_2,N_2O_3,8KNO_2$. Separation of the ruthenium is never complete, and the mother-liquor, on concentration, yields crystals of the first compound. The second salt is converted into the first by prolonged ebullition with water, and the reverse change is effected by the addition of potassium nitrite. At a low temperature, the second salt crystallises with 2 mols. H_2O. Other double nitrites seem to be formed, but are relatively very unstable.

If the double nitrites are heated with ammonium chloride and hydrochloric acid, only part of the nitrogen is evolved and one atom of the nitrogen remains in combination with each atom of ruthenium. The solution when concentrated yields the potassium ruthenium nitrosochloride previously described (*loc. cit.*).

No compound was obtained corresponding with that to which Claus attributes the formula $Ru(NO_2)_3,3KNO_2$. C. H. B.

Mineralogical Chemistry.

Glaserite from Douglashall. By H. Bücking (*Zeit. Kryst. Min.*, 15, 561—575).—In the astrakanite (bloedite) of Douglashall, crystals of potassium sodium sulphate have recently been found. The crystals vary from 5 to 20 mm. in length. They have a hardness of 2¾ to 3, and a sp. gr. of 2·650 to 2·656, the differences being due to small inclusions of rock-salt. The crystals belong to the hexagonal system, the axial ratio being $a : c = 1 : 1·2879$. These samples of crystals, easily soluble in water, gave on analysis the following results:—

	K_2SO_4.	Na_2SO_4.	$MgSO_4$.	NaCl.	Insol.	H_2O and loss.	Total.
I.	66·5	22·0	—	10·1	0·4	1·0	100·0
II.	67·3	18·2	—	11·6	—	2·9	100·0
III.	58·7	19·5	3·4	14·4	0·1	3·9	100·0

The author also gives crystallographical descriptions of bloedite, kainite, and boracite from the same locality. B. H. B.

Atelestite from Schneeberg, in Saxony. By K. Busz (*Zeit. Kryst. Min.*, 15, 625—627).—A specimen of this rare mineral from the Neuhilfe mine, at Schneeberg, gave on analysis results corresponding with the formula $As_2O_5,3Bi_2O_3,2H_2O$. The axial ratio was calculated by G. v. Rath to be $a : b : c = 0·869 : 1 : 1·822$, $\beta = 110° 30'$; whilst the author finds that it is

$$a : b : c = 0·92974 : 1 : 1·51227. \quad \beta = 110° 25'.$$

The hardness is 3½, and the sp. gr. 6·4. B. H. B.

Artificial Preparation of Wollastonite. By A. Gorgeu (*Zeit. Kryst. Min.*, 15, 646; from *Bull. Soc. fran. min.*, 10, 271).—One equivalent of $CaCl_2$ melted with one equivalent of precipitated silica, in the presence of steam, gives $CaSiO_3$, whilst two equivalents of the former give Ca_2SiO_4, which, however, cannot be isolated in distinct crystals. With a larger excess of calcium chloride, the compound $Ca_2Cl_2SiO_3$ is obtained in rhombic crystals and pseudo-hexagonal tablets, whose composition is probably $Ca_2Cl_2SiO_3$. If 1 gram of SiO_2, 15 grams of $CaCl_2$, and 3 grams of NaCl are melted for half an hour in a current of moist air there is obtained, besides small quantities of the chlorides mentioned above and of tridymite, long prisms of wollastonite exhibiting the optical properties of the natural mineral. B. H. B.

Anorthite and Enstatite. By K. v. Chroustschoff (*Zeit. Kryst. Min.*, **15**, 649; from *Bull. Soc. fran. min.*, **10**, 329).—The olivine inclusions in the basalt of Wingendorf, in Silesia, contain anorthite (I) and almost colourless enstatite (II). Both minerals were isolated and analysed with the following results:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	CaO.	Na_2O.	K_2O.	Ignition.	Total.
I.	44·68	35·32	0·41	—	1·13	17·45	1·33	0·45	0·33	101·10
II.	56·96	0·79	—	3·11	33·65	4·32	traces		0·26	99·09

B. H. B.

Minerals from Fiskernäs, in Greenland. By N. V. Ussing (*Zeit. Kryst. Min.*, **15**, 596—615).—1. *Sapphirine.*—The sapphirine-bearing rock belongs to the crystalline schist series. The sapphirine occurs in blue, tabular crystals, with distinct pleochroism. The axial ratio is calculated to be $a : b : c = 0·65 : 1 : 0·93$. $\beta = 79° 30'$. The hardness of sapphirine is 7½, and its sp. gr. is 3·486. Analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	Ignition.	Total.
12·83	65·29	0·93	0·65	19·78	0·31	99·79

Formula: $Mg_5Al_{12}Si_2O_{27}$.

2. *Kornerupine.*—This was described as a new mineral by Lorenzen. No crystallographical and optical examination has hitherto been made. The mineral belongs to the rhombic system, the axial ratio being $a : b = 0·854 : 1$. Its formula is $MgAl_2SiO_6$. It is perhaps identical with the prismatine of Sauer.

3. *Gedrite.*—This mineral is found at Fiskernäs in colourless grains or short prisms, having a hardness of 5·5 and a sp. gr. of 3·100. Analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	Na_2O.	H_2O.	Total.
46·18	21·78	0·44	2·77	25·05	2·30	1·37	99·89

Formula: $(NaH)_2SiO_4,6MgSiO_3,2Al_2O_3$. This variety of gedrite differs from all other rhombic amphiboles by its high percentage of alumina.

4. *Pargasite.*—This monosymmetric hornblende occurs in small, transparent grains, having a sp. gr. of 3·064, and giving on analysis—

SiO_2.	Al_2O_3.	Cr_2O_3.	FeO.	CaO.	MgO.	Ignition.	Total.
46·79	15·36	0·69	2·38	13·11	20·17	2·13	100·63

B. H. B.

Artificial Fayalite. By A. Firket (*Zeit. Kryst. Min.*, **15**, 652—653; from *Ann. Soc. géol. Belg.*, **14**, 196).—A slag from the Ougrée ironworks analysed by the author gave the following results:—

SiO_2.	FeO.	Fe_2O_3.	MnO.	S.	P.	Total.
28·00	62·00	9·30	0·97	0·14	0·50	100·91

The hardness is 6, and the sp. gr. 4·212. B. H. B.

Organic Chemistry.

Tetrabromides of Diallyl. By G. Ciamician and F. Anderlini (*Ber.*, **22**, 2497—2500).—A small quantity of an oily bromide, $C_6H_{10}Br_4$, is formed in preparing diallyl tetrabromide (m. p. 63°) by treating the hydrocarbon with bromine; when the crude product is crystallised from alcohol, the liquid bromide remains in solution. It boils at 135—140° (about 8 mm.) with slight decomposition, and its molecular weight, determined by Raoult's method in benzene solution, was found to be 325 as the average of two experiments.

F. S. K.

γ-Pentyleneglycol and its Anhydride (Tetrahydromethylfurfuran). By A. Lipp (*Ber.*, **22**, 2567—2573).—γ-Pentyleneglycol (Freer and Perkin, Trans., 1887, 836) mixes in all proportions with water, alcohol, and chloroform, is rather sparingly soluble in ether in presence of moisture, and is insoluble in light petroleum. At −18°, it is quite viscid. It boils at 219—220° (under 713 mm. pressure), and does not decompose at 236°. Sp. gr. = 1·0003 at 0° (water at 0° = 1). When heated with 35—40 per cent. hydrobromic acid for one hour at 100°, the anhydride is formed; this boils at 77—79°; sp. gr. = 0·8748 at 0° (water at 0° = 1). It is not changed when heated with water at 200—210°. Ammonia is also without action on it at 200°.

γ-Pentylene dibromide, $CHBrMe{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Br$, is obtained by heating the glycol or the anhydride with 3 to 4 parts of fuming hydrobromic acid for three hours at 100°. It boils at 200—202° with partial decomposition, is insoluble in water, readily soluble in alcohol, ether, chloroform, and carbon bisulphide. N. H. M.

Action of Lead Peroxide on Organic Substances in Alkaline Solution. By M. Gläser and T. Morawski (*Monatsh.*, **10**, 578—584).—When a mixture of glycerol (2 grams), sodium or potassium hydroxide (5—10 grams), and lead peroxide (25 grams) contained in water (100 c.c.) is gently heated, a vigorous evolution of hydrogen occurs, sodium or potassium formate being simultaneously formed, according to the equation $C_3H_8O_3 + 3O = H_2 + 3H{\cdot}COOH$. About 97 per cent. of the theoretical quantity of formic acid is produced.

Under somewhat similar circumstances ethylene glycol also yields hydrogen and formic acid (yield about 60 per cent.), $C_2H_6O_2 + 2O =$

$H_2 + 2CH_2O_2$. The authors intend to study the behaviour of lead peroxide with polyhydric alcohols in alkaline solution.

G. T. M.

Action of Ammoniacal Cupric Oxide on Carbon Compounds. By C. VINCENT and DELACHANAL (*Compt. rend.*, 109, 615—616).—Pure sorbite is completely precipitated by ammoniacal cupric oxide, and hence cannot be separated from mannitol by means of this reagent (compare Guignet, Abstr., 1889, 1133). C. H. B.

Action of Cuprammonium Sulphate on Sorbite. By C. E. GUIGNET (*Compt. rend.*, 109, 645).—Cuprammonium sulphate undoubtedly precipitates sorbite (preceding abstract), but it precipitates mannitol more rapidly, and by fractional precipitation the author has been able repeatedly to separate pure mannitol from liquids which also contained sorbite. C. H. B.

Sorbite. By C. VINCENT and DELACHANAL (*Compt. rend.*, 109, 676—679).—Sorbite exists in the fruit of all the rosaceæ, and especially in pears, cherries, and plums, which contain 0·7 to 0 8 per cent.

When heated with concentrated hydriodic acid, it yields β-hexyl iodide, which boils at 167° under a pressure of 753 mm.; when heated with alcoholic potash, it yields β-hexylene, boiling at 68·5 under a pressure of 735 mm., and acetic and butyric acids when oxidised. 90 c.c. of water and 35 grams of red phosphorus were gradually mixed with 150 grams of iodine in a capacious retort, 60 grams of crystallised sorbite was added, and the mixture gently heated. An energetic reaction took place, and β-hexyl iodide was obtained in almost theoretical quantity, no resinous products being formed.

Mannitol yields the same β-hexyl iodide when treated with hydriodic acid.

When heated with acetic anhydride and a small quantity of zinc chloride, sorbite yields a hexacetate, $C_6H_8(OAc)_6$, which is obtained as a very thick, colourless syrup, on washing the crude product with water, dissolving in ether, and evaporating the filtered ethereal solutions.

It follows from these results that the constitution of anhydrous sorbite is $C_6H_8(OH)_6$. C. H. B

Transformation of Cane Sugar into Dextrose. By J. BOCK (*Chem. Centr.*, 1889, ii, 30, from *Öster-ungar. Zeit. Zucker. Ind. Landw.*, 18, 194).—Cherries which had been preserved by heating with a hot concentrated solution of cane-sugar, and which had kept perfectly sound during the winter, were allowed to remain for four or five days in a loosely covered dish, when it was found that they were coated with a white, crystalline mass, which, after separation and recrystallisation, proved to be dextrose. Levulose was not found. The exact circumstances under which this change took place could not be determined. J. W. L.

Raffinose. By BERTHELOT (*Compt. rend.*, 109, 548—550).—The ordinary crystals of raffinose are generally regarded as having the composition $C_{18}H_{32}O_{16} + 5H_2O$, but raffinose from cotton seed separates from dilute alcohol in the form of a syrup, which gradually solidifies to lamellar crystals which contain 6 mols. H_2O and are different from the ordinary crystals. The rotatory power of their solution is, however, the same as that of a solution of the ordinary crystals.

The author confirms Tollens' observation, that good beer yeast ferments raffinose completely, but that weak yeast ferments only about one-third even after 48 hours, although during the same time it will completely ferment saccharose and glucose. It seems most probable that under these conditions raffinose splits up into glucose, which ferments, and either a saccharose which has a small reducing power like lactose, or a mixture of two glucoses only one of which has reducing power. C. H. B.

Fermentation of Raffinose by Beer Yeast. By D. LOISEAU (*Compt. rend.*, **109**, 614—615).—In a sealed paper, dated March 5th, 1888, the author described the following results. Raffinose is completely fermented by low beer yeast, but with high beer yeast only about one-third of the total possible alcohol is formed, whilst the solution has a reducing power equivalent to that of a quantity of glucose, equivalent to the amount of raffinose which has been fermented. It is probable that 2 mols. of raffinose are converted into 1 mol. of lævogyrate glucose, which always ferments, and twice the quantity of a dextrogyrate compound which is not fermented by high yeast. Prolonged contact with acids converts this compound into glucose, which is completely fermented by both forms of yeast.

This difference in behaviour with raffinose may be used as a means of distinguishing between high and low yeast (compare Berthelot, preceding abstract). C. H. B.

Lactose. By E. W. T. JONES (*Analyst*, **14**, 81—83).—Having obtained some very pure crystallised lactose, the author has redetermined the specific rotatory power and cupric reduction. For a solution of 5 grams of the crystals, $C_{12}H_{22}O_{11} + H_2O$, in 100 c.c., prepared hot, and of sp. gr. 1018·6 at 15·5°, the values obtained are:—

	For $C_{12}H_{22}O_{11} + H_2O$.	For $C_{12}H_{22}O_{11}$.
$[\alpha]_j$	$= 57{\cdot}5°$	$60{\cdot}5°$
$[\alpha]_D$	$= 51{\cdot}9$	$54{\cdot}6$

$$CuO \times 0{\cdot}5723 = C_{12}H_{22}O_{11}.$$
$$CuO \times 0{\cdot}6024 = C_{12}H_{22}O_{11} + H_2O.$$

The determinations were made by O'Sullivan's method, the cuprous oxide being converted into cupric oxide by careful ignition and weighed.

Lactose is not affected optically, or in reducing power, by heating with citric acid, whilst cane sugar is completely inverted. The crystals do not lose their water by 24 hours' heating in a water-oven, but if dissolved in water and re-dried, the anhydrous sugar is obtained in a few hours. M. J. S.

Methylhydrazine. By G. v. Brüning (*Annalen*, **253**, 5—14).—In order to prepare methylhydrazine, nitrosomethylcarbamide, $NO\cdot NMe\cdot CONH_2$, is first obtained by adding the theoretical quantity of solid sodium nitrite to a solution of methylcarbamide nitrate mixed with powdered ice. Not more than 50 grams of methylcarbamide nitrate should be used in each operation. The nitroso-compound forms small, yellow, crystalline plates, and melts at 123—124° with decomposition. It is soluble in hot water, alcohol, and ether. The aqueous solution is decomposed by prolonged boiling. *Methylhydrazine* is prepared by adding zinc-dust (4 parts) in small quantities to the nitroso-compound suspended in water (6 parts) and acetic acid (2½ parts); the temperature of the mixture must be kept between 5° and 15°, and the operation lasts two to three hours. The product is filtered; the filtrate acidified with hydrochloric acid, concentrated, and the thick liquid boiled with 3 parts of strong hydrochloric acid for 12 hours in a flask provided with a reflux condenser, in order to decompose the carbamide; the well-cooled liquid is then mixed with an excess of sodium hydroxide, and distilled in a current of steam, the distillation being stopped as soon as the distillate ceases to reduce Fehling's solution. The distillate consists of an aqueous solution of methylhydrazine, ammonia, and methylamine. The latter compounds are removed by boiling the solution briskly for eight hours in a flask with a reflux condenser. The methylhydrazine is converted into the acid sulphate, which is deposited on the addition of absolute alcohol to the concentrated solution. The free base is obtained by decomposing a concentrated solution of the sulphate with sodium hydroxide. The last traces of water are removed by treating the base with barium oxide in sealed tubes at 100°. Methylhydrazine, $NHMe\cdot NH_2$, is a colourless, mobile liquid, fuming in damp air. It boils at 87° (745 mm.), and is miscible in all proportions with water, alcohol, and ether. It strongly reduces Fehling's solution at the ordinary temperature, and attacks cork, caoutchouc, and the skin. The *acid sulphate*, N_2H_3Me,H_2SO_4, forms long white needles. It melts at 139·5°, and decomposes at 182°. Unlike the normal sulphate, it is insoluble in alcohol. The *hydrochloride* is precipitated from its alcoholic solution by ether. The oxalate is soluble in warm alcohol. The picrate is deposited from alcohol in yellow, needle-shaped crystals, and melts at 162° with decomposition. *Methylsemicarbazide*, $NH_2\cdot CO\cdot N_2H_2Me$, prepared by the action of potassium cyanate on methylhydrazine sulphate. crystallises in prismatic plates, and melts at 113°. It is freely soluble in water and alcohol. *Methylphenylthiosemicarbazide*, $NHPh\cdot CS\cdot N_2H_2Me$, is formed by the action of phenylthiocarbimide on an aqueous solution of methylhydrazine. This compound is soluble in water and alcohol, and melts at 143°; the aqueous solution is decomposed by mineral acids. *Dibenzoylmethylhydrazine*, N_2HMeBz_2, is freely soluble in alcohol and in dilute alkalis; it melts at 143°, and crystallises in colourless needles. *Methylpicrazide*, $N_2H_2Me\cdot C_6H_2(NO_2)_3$, is formed when an alcoholic solution of picryl chloride is added to a solution of the base. It crystallises in yellow plates, melts at 171° with decomposition, and is freely soluble in alcohol and ether.

Oxalyldimethylhydrazine, $N_2H_2Me\cdot C_2O_2\cdot N_2H_2Me$, melts at 221°, but it begins to sublime about 160°. It is soluble in alcohol, and reduces Fehling's solution when gently warmed. The *nitroso*-derivative crystallises in plates, and melts at 147° with decomposition.

W. C. W.

Action of Methylhydrazine on Dialdehydes and Diketones. By K. KOHLRAUSCH (*Annalen*, **253**, 15—24).—Methylphenylhydrazine reacts with benzile at 100°, yielding *benzilemethylphenylhydrazone*, $COPh\cdot CPh\colon N\cdot NMePh$, a crystalline substance freely soluble in alcohol, ether, and light petroleum. It melts at 55—56°, and is completely decomposed at 200°; it is also decomposed by strong hydrochloric acid at the ordinary temperature. *Benzilemethylphenylosazone*, $C_2Ph_2(N\cdot NMePh)_2$, is formed when a mixture of benzile (1 mol.) and methylphenylhydrazine ($2\frac{1}{2}$ mols.) is heated at 120°; the crude product is treated with hot dilute sulphuric acid to remove the excess of base, and the red, crystalline mass which is deposited when the mixture cools is purified by recrystallisation from alcohol. The pure substance forms yellow needles soluble in ether and acetone, melts at 179—180°, and is decomposed at 220°; it is not readily attacked by strong hydrochloric acid.

Glyoxalmethylphenylosazone, $C_2H_2(N\cdot NMePh)_2$, is deposited as a yellow precipitate, when an aqueous solution of glyoxal is added to an acetic acid solution of methylphenylhydrazine. It melts at 217—218°, and is completely decomposed at 250°. This osazone does not give a characteristic coloration with ferric chloride.

Benzoylacetonemethylphenylhydrazone, $CH_2Ac\cdot CPh\colon N\cdot NMePh$, is freely soluble in ether. It melts at 103—104°, and begins to decompose at 210°. 1′.2′.3′-*Methylphenylacetylindole* is formed when methylphenylhydrazone is fused with zinc chloride. The indole melts at 136°, and dissolves freely in glacial acetic acid. It is decomposed by strong hydrochloric acid at 100°, yielding Degen's 1′.2-methylphenylindole (Abstr., 1887, 149).

Acetylacetonemethylphenylhydrazine, $CH_2Ac\cdot CMe\colon N\cdot MePh$, is a yellow oil which can be distilled in a vacuum without decomposition. The compound formed by the action of methylphenylhydrazine on an excess of acetonylacetone could not be isolated, as it undergoes spontaneous decomposition, losing a molecule of water, and changing into the methylphenylamidodimethylpyrroline described by Knorr (Abstr., 1887, 276).

Acetonylacetonemethylphenyldihydrazone, $C_2H_4(CMe\colon NMePh)_2$, is deposited in the form of an oil, which slowly crystallises when an aqueous solution of acetonylacetone is added to excess of methylphenylhydrazine dissolved in acetic acid. The crystals melt at 143—144°, and dissolve in alcohol, ether, benzene, and light petroleum. The dihydrazone dissolves also in hydrochloric acid; when this solution is heated, the preceding pyrroline-compound appears to be formed.

W. C. W.

Derivatives of Dichloromaleimide. By G. CIAMICIAN and P. SILBER (*Ber.*, **22**, 2490—2497).—Chloranilidomaleimide (m. p. 195—196°) is decomposed when heated above its melting point; it is soluble in ether and hot alcohol, but only sparingly in boiling water.

It dissolves in hot dilute sulphuric acid, yielding a colourless solution, and in alcoholic solutions dimethylaniline produces a reddish-brown coloration.

Chloramidomaleimide, $C_4ClO_2(NH_2)\colon NH$, is obtained in small quantity when dichloromaleimide is heated under pressure with excess of alcoholic ammonia. It crystallises from water in golden needles, melts at 220°, and is soluble in alcohol and ether, but insoluble in benzene. It dissolves in alkalis with a yellow coloration, but the solution becomes colourless on heating.

Dichloromaleamic acid, $COOH\cdot C_2Cl_2\cdot CO\cdot NH_2 + H_2O$, prepared by heating dichloromaleimide (8 grams) with ammonia (80 c.c.) in sealed tubes, separates from water in crystalline aggregates, melts at 175° with decomposition, and is soluble in ether, alcohol, and warm water, but insoluble in benzene. The *silver* salt, $C_4HCl_2NO_3Ag_2$, crystallises in colourless needles, and explodes when heated.

An orange-red compound, $C_{16}H_{13}N_5O_2$ or $C_{16}H_{15}N_5O_2$, separates in crystals when dichloromaleimide is heated with phenylhydrazine in alcoholic solution. This substance crystallises from boiling acetone or glacial acetic acid in orange-red needles, melts at 269—271° with decomposition, and is only sparingly soluble in most ordinary solvents. It dissolves in concentrated sulphuric acid with an intense red coloration, and on adding water an orange-red, flocculent substance is precipitated. F. S. K.

Thioaldehydes. By E. BAUMANN and E. FROMM (*Ber.*, 22, 2600—2609).—β-Trithioaldehyde (Klinger, Abstr., 1879, 720) is formed when hydrogen sulphide is passed through a mixture of aldehyde (1 part) with alcohol previously saturated with hydrogen chloride (3 parts); crystals soon separate, and the whole becomes solid. The product is washed with water and crystallised from alcohol, from which it separates in long needles melting at 125—126°. A small amount of α-trithioaldehyde, melting at 101—102°, is also formed, as well as a few crystals of a substance melting at 76°, possibly Marckwald's γ-derivative (Abstr., 1886, 865).

α-Trithioaldehyde is obtained as the chief product when equal parts of aldehyde, water, and strong hydrochloric acid are used. It crystallises from acetone in splendid prisms an inch long. The β-compound is also formed.

β-Thiobenzaldehyde and γ-thiobenzaldehyde are formed when hydrogen sulphide is passed through a mixture of benzaldehyde and alcoholic hydrogen chloride. The product is boiled with benzene until almost all is dissolved; on cooling, the β-compound separates in crystals having the composition $3C_7H_6S + C_6H_6$ (not $C_7H_6S + C_6H_6$, Klinger); this gives up all the benzene at 160°, and a portion when kept at the ordinary temperature for a long time.

γ-*Thiobenzaldehyde*, C_7H_6S, crystallises from benzene in small, pointed needles melting at 166—167°. The crystals contain no benzene of crystallisation. When the solution in benzene is treated with iodine, the whole solidifies after some time, being converted into the β-derivative.

When α- or β-trithioaldehyde is oxidised with potassium permanganate, they both give as end-product a *trisulphone*, $C_6H_{12}S_3O_6$, together with products containing less oxygen (compare Guareschi, Abstr., 1884, 294). This forms slender needles, softens at 340°, becoming yellow, and sublimes at a higher temperature without melting. It is almost insoluble in water, very sparingly soluble in alcohol, ether, chloroform, and benzene, more soluble in hot acetic acid; it also dissolves readily in strong nitric or sulphuric acid, but is precipitated by water. Alkalis dissolve it readily, and it can be crystallised from ammonia and alkaline carbonates. The constitution of trithioaldehyde sulphone is  $SO_2{<}\begin{matrix}CHMe\cdot SO_2\\CHMe\cdot SO_2\end{matrix}{>}CHMe$. When an alcoholic alkaline solution of the substance is treated with methyl iodide, the compound $C_9H_{18}S_3O_6$, melting at 302°, is formed. In a similar manner, ethyl-, allyl-, and benzyl-groups may be added.

N. H. M.

Thio-derivatives of Ketones. By E. BAUMANN and E. FROMM (*Ber.*, 22, 2592—2599; compare Abstr., 1889, 852).—*Thioacetone* $CSMe_2$, is formed as a readily volatile oil in the preparation of trithioacetone and tetrathioacetone (*loc. cit.*), but was not isolated owing to its instability and the difficulty of separating it from trithioacetone. It is also produced, together with ethyl sulphide and other sulphur-derivatives, when acetone-ethylmercaptole, $CMe_2(SEt)_2$, is heated above 160°. Owing to the very unpleasant odour of the compound, which is stronger than that of any other known substance, the smallest traces of it being sufficient to infect whole districts, the study of the compound was not continued.

Trithioacetone is decomposed by strong nitric acid with explosive violence.

A further examination of the sulphone obtained by oxidising trithioacetone with potassium permanganate (*loc. cit.*), showed that this could be separated by crystallisation from alcohol into two substances. The more sparingly soluble compound, *triacetonetrisulphone*, $C_9H_{18}S_3O_6$, crystallises from glacial acetic acid in slender needles which melt at 302° (uncorr.), and sublime readily. The more readily soluble compound, $C_9H_{18}S_3O_4$, is probably *trithioacetonedisulphone*; it melts at 208°.

Acetonetrisulphone is not changed by acids and alkalis; it dissolves in strong acids, and is precipitated by water unchanged. Boiling fuming nitric acid has no action on it. Its constitution is probably  $CMe_2{<}\begin{matrix}SO_2\cdot CMe_2\\SO_2\cdot CMe_2\end{matrix}{>}SO_2$.

The compound $C_9H_{18}S_3O_4$ dissolves in bromine, yielding an unstable bromine-derivative, which readily decomposes with evolution of hydrogen bromide. When gently heated with fuming nitric acid, the compound is oxidised with formation of much sulphuric acid. Probably the substance has the constitution  $S{<}\begin{matrix}CMe_2\cdot SO_2\\CMe_2\cdot SO_2\end{matrix}{>}CMe_2$.

N. H. M.

The Introduction of Acid Radicles into Ketone Molecules. By L. CLAISEN (*Bull. Soc. Chim.* [3], 1, 496—510; compare Abstr., 1888, 666, 671, 676, and 1889, 584, 619, 850).—A *résumé* of the author's already published work on this subject, concluding with a discussion as to the theory of the reactions. T. G. N.

Substituted Acrylic and Propiolic Acids. By C. F. Mabery and A. W. Smith (*Ber.*, **22**, 2659—2660).—When αβ-dichloracrylic acid is dissolved in carbon bisulphide, and chlorine passed through the solution whilst it is exposed to sunlight, *tetrachloropropionic acid*, $C_2HCl_4{\cdot}COOH$, gradually crystallises out. It forms large, rhombic prisms, is soluble in carbon bisulphide, chloroform, and water, and melts at 76°. Its *barium salt* crystallises in prisms; its *calcium salt* in needles; its *potassium salt* in plates. Its *silver salt* is very unstable.

When αβ-dichloracrylic acid is heated with hydrobromic acid in closed tubes at 110—120°, *bromodichloropropionic acid* is formed. It is soluble in water and boiling carbon bisulphide, crystallises in prisms, and melts at 75—76°.

When an aqueous solution of bromopropiolic acid is mixed with hypochlorous acid and left in the dark, *chlorobromhydroxyacrylic acid*, $C_2(OH)ClBr{\cdot}COOH$, is formed. It is easily soluble in boiling water, is crystalline, and melts at 104—105°. Its *silver salt* is soluble in nitric acid, and is very unstable in aqueous solution. L. T. T.

Action of Phosphorus Pentachloride on Chloralide. Tetrachlorethylidene Trichlorolactate. By R. Anschütz and A. R. Haslam (*Annalen*, **253**, 121—131).—The compound of the composition $C_5HCl_7O_3$, which the authors obtained by the action of phosphorus pentachloride on chloralide (Abstr., 1887, 915), proves to be the tetrachlorethylidene trichlorolactate. It boils at 276° without decomposition. Methyl and ethyl alcohol act on this compound at the ordinary temperature, yielding hydrogen chloride and the ethyl or methyl salts of trichloracetic and trichlorolactic acids. Normal propyl and isobutyl alcohols act less energetically than ethyl alcohol. *Normal propyl trichlorolactate* boils at 115—117° under 12 mm. pressure, and at 248—250° under the ordinary atmospheric pressure. Its sp. gr. at 20°, compared with water at 4°, is 1·51628. *Isobutyl trichlorolactate* boils at 111—112° under 12 mm. pressure, and at 236—238° under the normal atmospheric pressure. Its sp. gr. at 20° is 1·53216. The chloride is slowly decomposed by water, yielding trichloracetic and trichlorolactic acids. These results indicate that the constitution of the chloride is represented by the formula

$$\begin{array}{l} CCl_3{\cdot}C(OH) \\ \quad\;| \\ \quad COO\text{—} \end{array}\!\!>\!CCl{\cdot}CCl_3.$$

W. C. W.

Derivatives of Ethyl Acetoacetate. By R. Schönbrodt (*Annalen*, 253, 168—205).—Ethyl monochloracetoacetate is formed by passing chlorine into ethyl cupracetoacetate suspended in chloroform until the green colour of the compound changes to grey. By the prolonged action of chlorine, a dichloro-substitution-product is obtained. Analogous results are produced when bromine is used instead of chlorine; the ethylic salts of mono- and di-bromacetoacetic acid have been described by Duisberg (*Annalen*, **213**, 152 and 143). *Ethyl iodacetoacetate*, prepared by the action of iodine on ethyl cupracetoacetate, is a yellow oil, miscible with ether and alcohol. The alcoholic solution gives a blood-red coloration with ferric chloride. The compound is unstable. It decomposes at 25° in a vacuum, and its sp. gr. at 14° is 1·7053, compared with water at the same temperature. It is converted into ethyl monochloracetoacetate by the action of silver chloride, but with silver cyanide it yields hydrogen cyanide and ethyl succinosuccinate. The product of the action of silver nitrite on ethyl iodacetoacetate is a yellow oil, probably ethyl nitroacetoacetate. This substance gives an intense blood-red coloration with ferric chloride and strong sulphuric acid It does not yield an amido-compound on reduction with tin and hydrochloric acid, nor does it form a solid compound with hydroxylamine. It combines with phenylhydrazine, yielding phenylmethylisonitrosopyrazolone [1 : 3 : 4 : 5], described by Knorr (Abstr., 1887, 602). The same compound is formed by the action of phenylhydrazine on the ethylic salt of monochlor-, brom-, or iod-acetate. The reaction may be represented as follows: $C_6H_9ClO_3 + 3NHPh{\cdot}NH_2 = C_{10}H_9N_3O_2 + 2NH_2Ph + NH_4Cl + C_2H_5{\cdot}OH$. Bender (Abstr., 1888, 53) has shown that in the ethereal solution, phenylhydrazine and ethyl monochloracetoacetate yield the ethylic salt of β-phenyl azocrotonate. The author confirms the accuracy of this observation.

Ethyl sodacetoacetate reacts with ethyl iodacetoacetate, yielding ethyl diacetosuccinate. Metallic silver eliminates the iodine from ethyl iodacetoacetate, and forms the ethyl diacetofumarate described by Just (Abstr., 1886, 141). Ethyl thiacetoacetate, first prepared by Buchka (Abstr., 1885, 1200), is formed by boiling sulphur in a solution of ethyl cupracetoacetate in benzene. In the presence of alcohol, phosphorus acts on ethyl cupracetoacetate, forming ethyl acetoacetate and triethyl phosphite. Arsenic trichloride is reduced by the copper compound, arsenic being liberated, and ethyl monochloracetoacetate formed. Ethyl cupracetoacetate is not attacked by cyanogen. but nitrogen peroxide acts on it with formation of the nitro-compound which is produced by the action of silver nitrite on ethyl iodoacetoacetate.

Attempts to displace a hydrogen-atom by copper in ethyl methacetoacetate were unsuccessful. W. C. W.

Ethyl Thiacetoacetate. By K. Buchka and C. Sprague (*Ber.*, **22**, 2541—2556; compare Buchka, Abstr., 1885, 1200; Delisle, Abstr., 1887, 915; and Schonbrodt, preceding abstract).—Ethyl thiacetoacetate is best prepared by Delisle's method; 100 grams of ethyl acetoacetate yield 60—70 grams of pure ethyl thiacetoacetate. Molecular weight determinations by Raoult's method in glacial acetic acid solution showed that the molecular formula was $C_{12}H_{18}O_6S$. It melts at about 76°, but the melting point observed depends to a considerable extent on the rapidity of heating and on other conditions. The *sodium*-derivative, $C_{12}H_{16}O_6SNa_2$, is formed when ethyl thiacetoacetate is treated with sodium in ethereal solution.

When ethyl thiacetoacetate is treated with phenylhydrazine, hydrogen sulphide is evolved, and phenylmethylpyrazoloneketophenylhydrazone (phenylmethylpyrazoloneazobenzene), melting at 156°, identical with the compound obtained by Knorr (Abstr., 1887, 601) is formed, together with a yellow substance which is insoluble in all ordinary neutral solvents. The compound obtained by Schönbrodt (*loc. cit.*) by treating ethyl chloro-, bromo-, or iodo-acetoacetate with phenylhydrazine, is not phenylmethylisonitrosopyrazolone, as stated by him, but is identical with the phenylmethylpyrazoloneketophenylhydrazone referred to above.

The yellow compound which is obtained together with phenylmethylpyrazoloneketophenylhydrazone (see above) when ethyl thiacetoacetate is treated with phenylhydrazine is decomposed when heated, but without melting; it dissolves in alkalis, and is reprecipitated on adding acids. It seems to have the composition $C_{10}H_8N_2SO$; when heated with phenylhydrazine, it is converted into phenylmethylpyrazoloneketophenylhydrazone with evolution of hydrogen sulphide, small quantities of di-phenylmethylpyrazolone being also formed.

Paratolylmethylpyrazoloneketoparatolylhydrazone,

$$C_7H_7{\cdot}N_2H{:}C<\begin{matrix}CO{\cdot}N(C_7H_7)\\ CMe=\!=\!=N\end{matrix}>$$

is formed when ethyl thiacetoacetate is treated with paratolylhydrazine; it crystallises from chlorofrom in orange needles, melting at 216—217°. When excess of the hydrazine is employed in the above reaction, a compound, free from sulphur, and probably corresponding with di-phenylmethylpyrazolone is also obtained. If only a small quantity of the hydrazine is used, a sulphur compound, which is only soluble in alkalis, is formed; this substance is converted into tolylmethylpyrazoloneketotolylhydrazone (m. p. 216—217°) when heated with paratolylhydrazine, and when heated with phenylhydrazine it yields a compound. probably tolylmethylpyrazoloneketophenylhydrazone, which crystallises in red needles, melting at 186°.

Ethyl thiacetoacetate combines with α-naphthylhydrazine, yielding similar compounds. F. S. K.

Dithioxamide (Cyanogen Disulphydrate). By J. Formánek (*Ber.*, **22**, 2655—2656). When a saturated solution of cupric sulphate is treated with ammonia until the precipitate first formed is just redissolved, potassium cyanide added in quantity just sufficient to discharge the blue colour, and then a rapid stream of hydrogen chloride passed through the solution, the latter becomes first yellow, and then red; and if it is kept well cooled, small red crystals of the formula $NH_2{\cdot}CS{\cdot}CS{\cdot}NH_2$ gradually separate out. L. T. T.

Hydroxycitraconic Acid and its Derivatives. By P. Melikoff and M. Feldmann (*Annalen*, **253**, 87—95).—In dilute solutions, hypochlorous acid unites with citraconic acid to form chlorocitramalic acid, which has been described by Morawski (this Journ., 1875, 142), and by Gottlieb (*Annalen*, **160**, 101). The acid prepared by Gottlieb's process melts at 139°. It is converted into Morawski's hydroxycitraconic acid by the addition of potassium hydroxide in alcoholic solution.

The precipitate of potassium chloride and hydroxycitraconate is washed with alcohol and ether. It is then dissolved in water, the hydroxy-acid liberated by sulphuric acid, and extracted with ether. The acid melts at 162°, as stated by Scherks (Abstr., 1885, 513). The ethyl salt, $C_3H_4O(COOEt)_2$, has the sp. gr. of 1·1376 at 0° and 1·1167 at 22°, compared with water at the same temperatures.

Hydroxycitraconic acid dissolves in strong hydrochloric acid at 0°; and ether extracts from this solution a monochlorinated hydroxy-acid, $COOH{\cdot}CH(OH){\cdot}CClMe{\cdot}COOH$, crystallising in rhombic plates, which is an isomeride of the acid formed by the union of hypochlorous acid and citraconic acid, $COOH{\cdot}CMe(OH){\cdot}CHCl{\cdot}COOH$. This acid melts at 162°, and forms unstable salts. The compound which is formed by the addition of hydrobromic acid to hydroxycitraconic acid has already been described by Scherks (*loc. cit.*). Hydroxycitraconic acid is a glycidic acid, as it is converted into amidocitramalic acid by the action of alcoholic ammonia at 100°. The amido-acid forms short prisms, which seem to belong to the monoclinic system; it reddens litmus and decomposes carbonates. 100 c.c. of water at 18° dissolve 31 grams of the acid. It is almost insoluble in hot alcohol. The calcium and barium salts are amorphous. The hydrochloride, $OH{\cdot}C_3H_4(NH_2)(COOH)_2,HCl$, forms transparent prisms, soluble in water and alcohol. It melts at 100° with decomposition.

W. C. W.

Acetonediacetic or Hydrochelidonic Acid. By J. Volhard (*Annalen*, **253**, 206—236).—The dilactone of diacetic acid is prepared by maintaining succinic acid in a state of slow ebullition for six hours. When a small quantity of the contents of the retort no longer solidifies on cooling, but remains as a greasy mass, the operation is complete. The crude product is repeatedly extracted with boiling chloroform; on cooling, succinic anhydride is deposited in crystals, and the lactone remains in solution. The chloroform is removed by distillation, the residue dissolved in water, and the lactone is again extracted from this aqueous solution by chloroform. The lactone forms transparent rhombic prisms, $a : b : c = 0{\cdot}3649 : 1 : 0{\cdot}9816$, freely soluble in chloroform, acetone, ether, alcohol, benzene, and ethyl acetate. It melts at 75° and boils between 200 and 205° under 15 mm. pressure. The lactone dissolves in alkalis and in strong hydrochloric or hydrobromic acid yielding acetonediacetic acid, $CO(CH_2{\cdot}CH_2{\cdot}COOH)_2$, which is identical with the hydrochelidonic acid of Lieben and Haitinger (*Monatsh.*, 5, 353), and with Marckwald's propiondicarboxylic acid (Abstr., 1888, 678)

The acid forms rhombic plates soluble in hot water and in alcohol. It melts at 143° and decomposes at a higher temperature. The normal salts of the alkali metals are very soluble in water and do not crystallise well. The acid potassium, sodium, and ammonium salts are anhydrous. The barium salt crystallises with 2 and with 2½ mols. H_2O. The manganese salt $C_7H_8MnO_5 + 2H_2O$ forms pale pink needles. The zinc and cadmium salts crystallise in six-sided plates containing 2 mols. H_2O. The silver salt $C_7H_8Ag_2O_5$ is crystalline and insoluble in water. The dimethyl salt melts at 56° and boils with decomposition at 276—277° (uncorr.). The sp. gr. of the diethyl salt is 1·0862 at 13°. Acetic chloride, acetic anhydride, and phosphoric anhydride convert the acid into the lactone. The phenylhydrazide of acetonediacetic acid melts at 107—108°. The phenylhydrazide of the dimethyl salt melts at 88—90° and dissolves in ether, benzene, and hot alcohol. The corresponding diethyl compound melts at 67°. The oxime of the acid crystallises in prisms and melts with decomposition at 129°. The oximes of the dimethyl and diethyl salts form needles and melt at 52° and 38° respectively. W. C. W.

Alkyl-derivatives of Methyluracil and Nitrouracil. By R. BEHREND (*Annalen*, **253**, 65—68).—Ethyl bromide does not react with free methyluracil, but it acts on potassium methyluracil forming monomethyluracil and dimethyluracil. It is probable that monethylmethyluracil is first formed. A portion of the monethylmethyluracil reacts with potassium methyluracil forming potassium monethylmethyluracil. This is attacked by ethyl bromide, yielding diethylmethyluracil. In a previous communication, the author stated that methyl iodide acts on potassium methyluracil, yielding trimethyluracil, and the dihydride of methyluracil; he now finds that the supposed dihydride is identical with the dimethyluracil described by Hoffmann (next Abstract). W. C. W.

Alkyl-derivatives of Methyluracil. By J. HOFFMANN (*Annalen*, **253**, 68—77).—Ethyl methyluracil and diethylmethyluracil are formed by the action of ethyl bromide or iodide (3 mols.) on potassium methyluracil (1 mol.) in sealed tubes at 150; the excess of ethyl bromide or iodide is removed from the crude product by distillation, the residue is dissolved in water, and the aqueous solution treated with chloroform. The chloroform extract is then dried and distilled, and the residue dissolved in boiling alcohol; on cooling, crystals of ethylmethyluracil are deposited. The mother-liquor contains monethyl- and diethyl-methyluracil. The former is deposited as a crystalline crust, but the diethyl-derivative can only be isolated by dropping a crystal of diethylmethyluracil into the mother-liquor, when crystallisation takes place. *Ethylmethyluracil* is deposited from ethyl bromide in prisms and from alcohol in needles. It is freely soluble in chloroform and in ethyl bromide, and is much more soluble in hot than in cold alcohol. A crystalline silver salt, $C_5H_4EtAgN_2O_2$, is obtained when silver nitrate is added, in sufficient quantity to produce a permanent turbidity, to a solution of ethylmethyluracil in a 10 per cent. solution of potassium hydroxide. *Diethylmethyluracil* crystallises in rhombic plates and melts at 52—53°, dissolves freely in chloroform, alcohol, ether and water, and is decomposed by potassium hydroxide at the ordinary temperature with liberation of ethylamine. Methyl bromide acts on potassium methyluracil at 140°, forming dimethyluracil and trimethyluracil. *Trimethyluracil* melts at 109°, crystallises in rhombic plates, and is freely soluble in chloroform, alcohol, and water, and sparingly soluble in ether. *Dimethyluracil* is insoluble in ether, but can be recrystallised from hot alcohol. *Methyluracil di-iodide*, $C_5H_6N_2O_2I_2$, is formed by the action of iodine dissolved in strong hydriodic acid on methyluracil. It is an unstable compound, dissolving with decomposition in water, alcohol, and chloroform. The di-iodide forms deep violet crystals.

W. C. W.

Nitrouracil-derivatives. By M. Lehmann (*Annalen*, **253**, 77—87).—*Methylnitrouracil*, $C_5H_5N_3O_4 + H_2O$, is formed by the action of methyl iodide on potassium nitrouracil in sealed tubes at 140°. It crystallises in long needles and is soluble in hot water. 100 c.c. of water at 20° dissolve 0·714 gram, and 100 c c. of alcohol at 17° dissolve 0·115 gram of the substance. It is less soluble in ether, chloroform, benzene, and methyl iodide than in water. The potassium, silver and barium salts are crystalline; the silver and barium salts are almost insoluble in cold water. *Methylisobarbituric acid*, $C_5H_6N_2O_3$, is deposited in crystals when methylnitrouracil is reduced by tin and hydrochloric acid; the mother-liquor contains methylamidouracil in small quantity. A neutral solution of methylamidouracil hydrochloride turns red on the addition of potassium cyanate; the colour is destroyed by hydrochloric acid, and *methylhydroxyxanthine*, $C_6H_8N_4O_3$, is deposited as a yellow, crystalline powder. 100 c.c. of water at 16° dissolve 0·16 gram of methylhydroxyxanthine. Methylnitrouracil is decomposed by baryta-water at 160—170°, with liberation of methylamine; dimethylnitrouracil under similar treatment yields dimethylamine. Dimethylnitrouracil melts at 154·5° and is deposited from hot water in needles containing 1 mol. H_2O. It does not unite with bases to form salts. The constitution of methyl- and dimethyl-nitrouracil can be represented by the formulæ,  $CO<\begin{matrix}NH\cdot CH\\NMe\cdot CO\end{matrix}>C\cdot NO_2$ and  $CO<\begin{matrix}NH\cdot CMe\\NMe\cdot CO\end{matrix}>C\cdot NO_2$. Methylnitromethyluracil, prepared by the action of methyl iodide on potassium nitromethyluracil, crystallises in needles and melts at 149°. It unites with bases, forming crystalline salts. *Ethylnitrouracil*, $C_6H_7N_3O_4 + H_2O$, forms silky needles and melts at 194·5; it is deposited from alcohol in anhydrous crystals, and is soluble in hot water, ether, chloroform, benzene, and ethyl bromide. The potassium and silver salts crystallise in needles.

Ethylisobarbituric acid, $C_6H_8N_2O_3$, melts at 250°, but begins to decompose at 230°. It is soluble in hot, but almost insoluble in cold water. *Ethylhdroxyxanthine* crystallises in prisms which turn pink on exposure to the air. *Ethylmethylnitrouracil*,  $CO<\begin{matrix}NEt\cdot CH\\NMe\cdot CO\end{matrix}>C\cdot NO_2$, crystallises from hot water in needles, containing 1 mol. H_2O. The crystals effloresce; it melts at 109°. *Methylethylnitrouracil*,  $CO<\begin{matrix}NMe\cdot CH\\NEt\cdot CO\end{matrix}>C\cdot NO_2$, melts at 73° and crystallises in rhombohedra, containing 1 mol. H_2O. The substance becomes anhydrous at 90°, and remains liquid at the ordinary temperature, but solidifies on the addition of water. It is freely soluble in alcohol and ether.

W. C. W.

Fucusol. By MAQUENNE (*Compt. rend.*, **109**, 571--573).—Dried *Fucus vesiculosus* was heated in an oil-bath at 160° with 4 5 parts of sulphuric acid of 20° B and the product, after neutralisation, was distilled and fractionated. Small quantities of water and acetone were obtained, together with two fractions boiling at 162—163° and 185—187° respectively. The fraction 162—163° consists of pure furfuraldehyde: the fraction 185—187° is *methylfurfuraldehyde*, a liquid of sp. gr. 1·105 at 15°. With ammonia, it yields a crystalline product closely resembling furfuramide; its hydrazone is an oily liquid; with silver oxide, it yields methylpyromucic acid, melting at 108—109°. When treated with hydriodic acid, it resinifies but does not carbonise, and does not become green; the product yields iodoform when mixed with potassium hydroxide. With acetic anhydride in presence of fused sodium acetate, it yields methylfurfuracrylic acid melting at 157° and crystallising from boiling water or alcohol in small, white needles which retain about ⅓ mol. H_2O. If methylfurfuraldehyde is heated with strong hydrochloric acid, it becomes green, a reaction which Stenhouse observed with fucusol. The following reaction serves to detect methylfurfuraldehyde in presence of a large proportion of furfuraldehyde. One drop of the liquid is dissolved in 5—6 c.c. of alcohol of 90° and 1 c.c. of sulphuric acid of 60° is added slowly without agitation; a green coloration appears at the junction of the two liquids. The coloration persists even after agitation if the methylfurfuraldehyde is abundant, but changes to grey if furfuraldehyde is in excess. The reaction is similar to that given by heptine (or its oxidation-products) from perseitol.

This methylfurfuraldehyde is identical with that obtained by Hill from wood tar.

Fucusol is not a distinct compound, as Stenhouse supposed, but is a mixture of furfuraldehyde with about 10 per cent. of methylfurfuraldehyde. C. H. B.

Relation between Sugars and Furfuran-derivatives. By MAQUENNE (*Compt. rend.*, **109**, 603—606).—Methylfurfuraldehyde from *Fucus* (preceding Abstr.) yields acetic acid on oxidation, and hence contains a terminal methyl-group, and is one of the three isomerides which contain the methyl-group in the position 2, 3, or 4 with respect to the aldehyde group. It has the same relation to isodulcitol or rhamnose, $C_6H_{12}O_5$, as furfuraldehyde has to arabinose, $C_5H_{10}O_5$.

Crystallised isodulcitol distilled with four times its weight of sulphuric acid of 15 to 20° B yields a small quantity of acetone, together with pure methylfurfuraldehyde identical with that from *Fucus vesiculosus* or wood tar, but no furfuraldehyde is obtained. Fischer and Tafel have shown that isodulcitol is an aldehyde derived from normal hexane, and according to Herzig it yields acetic acid on oxidation, and hence contains a terminal methyl-group. Its conversion into methylfurfuraldehyde would involve the union of the chains 2 and 5 by means of an atom of oxygen, the methyl-group occupying the position 4, thus:—

$$O\left\langle\begin{array}{l}CMe:CH\\C(CHO)\end{array}\right\rangle CH.$$

Since furfuraldehyde is obtained from arabinose by dehydration, it follows that isodulcitol is ω-methylarabinose, a relation which has often been suggested, but has never previously been established.

The yield of methylfurfuraldehyde from isodulcitol is small, but it suffices to detect the isodulcitol in substances in which its presence is not recognised by the usual methods, and it has been detected in several plants in which it was not known to exist. Since *Fucus vesiculosus* yields methylfurfuraldehyde (*loc. cit.*), it would seem that isodulcitol exists in marine plants. C. H. B.

Selenium and Oxygen-derivatives in the Benzene Series. By C. Chabrié (*Compt. rend.*, **109**, 568—570).—The action of nitric acid on phenyl selenide (Abstr., 1889, 1167), yields nitro-derivatives; potassium permanganate or chromic acid yields indefinite oxidation-products; hydrogen peroxide and hydrochloric acid yield compounds in which oxygen has been introduced into the phenyl-group.

The action of selenious chloride, $SeOCl_2$, on benzene in presence of aluminium chloride yields two compounds according to the proportions of the reacting bodies. *Diphenylselenone*, $SeOPh_2$, is an amber-yellow liquid which boils at 230° under a pressure of 65 mm.; sp. gr. at 19·6 = 1·48. The other product, $PhSeO{\cdot}C_6H_4Cl$, crystallises in white, hexagonal, prismatic lamellæ with a fatty lustre; it melts at 94°, boils at 230° under a pressure of a few millimetres. is insoluble in water, but dissolves in alcohol, and is attacked by cold nitric acid.

Diphenylselenine when treated with bromine water yields the compound, $SeO(C_6H_4Br)_2$, which crystallises from alcohol in modified rhombic prisms melting at 120°. When mixed with hydrogen peroxide and hydrochloric acid and treated with a current of air, diphenylselenine yields the compound, $SeO(C_6H_4Cl)_2$ or $PhSeO{\cdot}C_6H_3Cl_2$, which crystallises from boiling alcohol in small, white prisms, melts at 159°, and is not attacked by cold nitric acid.

The action of the compound $Se(OH)_2Cl_2$ on benzene in presence of aluminium chloride yields diphenylselenine and selenophenol.

C. H. B.

Action of Phosphorus Trichloride on Phenol. By R. Anschütz and W. O. Emery (*Amer. Chem. J.*, **11**, 379—387).—By the action of phosphorus trichloride on phenol, the following three compounds were formed (compare Noack, Abstr., 1883, 735), and were separated by distillation under greatly diminished pressure:—

Phenylphosphoryl dichloride, $PCl_2{\cdot}OPh$; sp. gr. 1·3542 at 20° (water at 4° = 1); boiling at 90° under 11 mm. pressure; *diphenylphosphoryl chloride*, $PCl(OPh)_2$; sp. gr. 1·24378 at 20° (water at 4° = 1); boiling at 172° under 11 mm. pressure; *triphenyl phosphite*, $P(OPh)_3$; sp. gr. 1·18428 at 20° (water at 4° = 1); boiling at 220° under 11 mm. pressure.

The action of phosphorus pentachloride on the preceding compounds was investigated. In the cold, no action takes place; at 100° crystalline compounds are formed, soluble in chloroform and carbon tetrachloride. Chlorine additive-products were almost certainly formed, but they could not be isolated; they were, however, obtained by passing dry chlorine over solutions of the phosphorous compounds in dry ether. *Phenylphosphoryl tetrachloride*, $PCl_4\cdot OPh$, prepared from chlorine and phenylphosphoryl dichloride, forms small plates, soluble in chloroform and carbon tetrachloride, insoluble in ether; it is deliquescent, and is decomposed by water, normal phenyl phosphate being formed. With sulphurous anhydride, it behaves like the corresponding phosphenyl compound, giving thionyl chloride and the oxychloride, $POCl_2\cdot OPh$, boiling at 121—122° under 11 mm. pressure. *Diphenylphosphoryl trichloride*, $PCl_3(OPh)_2$, formed from chlorine and diphenylphosphoryl chloride, is a yellow oil, solidifying to minute crystals, soluble in chloroform, insoluble in ether; it easily decomposes when heated, and also when treated with water, in which case phenyl phosphate is formed. *Triphenylphosphoryl dichloride*, $PCl_2(OPh)_3$, prepared from chlorine and phenyl phosphite, solidifies at a very low temperature; when treated with water, it decomposes into phenyl phosphate and hydrochloric acid.

By the addition of dry bromine to ethereal solutions of the mono- and di-chlorides, the compounds $PCl_2Br_2\cdot OPh$ and $PClBr_2(OPh)_2$ were obtained; these are very unstable substances.

Phenylphosphoryl thiochloride, $PSCl_2\cdot OPh$, was obtained by heating phenylphosphoryl dichloride with sulphur at 190°; it has a sp. gr. of 1·40593 at 20° (water at 4° = 1), boils at 119—120° under 11 mm. pressure, and is a highly refractive liquid, soluble in ether and chloroform. *Diphenylphosphoryl thiochloride*, $PSCl(OPh)_2$, prepared from diphenylphosphoryl chloride and sulphur heated at 190°; melts at 63—64°, and boils at 194° under 11 mm. pressure. Attempts to obtain the preceding two compounds by heating together phenol and phosphorus thiochloride were unsuccessful, hydrogen chloride and normal phenyl phosphate being formed. *Triphenyl thiophosphate*, $PS(OPh)_3$, was obtained by heating phenyl phosphite with sulphur at 190°; it forms crystalline needles melting at 49—50°, and boiling at 245° under 11 mm. pressure; sp. gr. = 1·24411 at 20° (water at 4° = 1). It is found that these thio-compounds have very nearly the same melting points and boiling points as the corresponding oxy-compounds.

The existence of the compound $PCl_4\cdot OPh$ leads to the following view of the action of phosphorus pentachloride on hydroxy-compounds:—

$$R\cdot OH + PCl_5 = HCl + RO\cdot PCl_4 \text{ and } RO\cdot PCl_4 = POCl_3 + RCl.$$

C. F. B.

Apiole. By G. Ciamician and P. Silber (*Ber.*, **22**, 2481—2490; compare Abstr., 1888, 1100).—The authors give the name *apionole* to the tetrahydroxybenzene which forms the basis of apiole; the dimethyl ether of tetrahydroxybenzene is, therefore, dimethylapionole, and "apione" is dimethylmethyleneapionole,

Dimethylapionole, $C_6H_2(OH)_2(OMe)_2$, is obtained when apiolic acid (2·5 grams) is heated at 180° for 4 to 6 hours with potash (8 grams) and alcohol (10 c.c.). It melts at 105—106° and boils at 298°. In aqueous solutions, ferrous sulphate produces, after some time, a blue coloration, lead acetate a gelatinous precipitate, and silver nitrate a crystalline precipitate, which immediately turns black. It dissolves in concentrated sulphuric acid, yielding a yellow solution, which quickly turns red, and on warming becomes violet. The *diacetyl-derivative*, $C_6H_2(OMe)_2(OAc)_2$, crystallises from alcohol, melts at 144°, and is soluble in ether, warm alcohol, and glacial acetic acid, but only sparingly in hot, and insoluble in cold water. It dissolves in warm, concentrated sulphuric acid, yielding a colourless solution, which turns yellow and then brown on heating more strongly.

Tetramethylapionole, $C_6H_2(OMe)_4$, prepared by treating the dimethyl-derivative with methyl iodide in methyl alcoholic potash solution, crystallises from hot water in colourless needles, melts at 81°, and is readily soluble in alcohol, ether, benzene, acetone, and acetic acid, but only sparingly in water. It dissolves in concentrated sulphuric acid, yielding a colourless solution, which turns brownish-red on warming, and in concentrated nitric acid with a yellow coloration. It is not acted on by hydrochloric acid at 100°, but at higher temperatures it is decomposed with evolution of methyl chloride.

Apioneacrylic acid, $CH_2{:}O_2{:}C_6H(OMe)_2{\cdot}CH{:}CH{\cdot}COOH$, prepared by boiling apiolaldehyde with acetic anhydride and sodium acetate, crystallises from hot alcohol in small, yellow needles, melts at 196°, and is readily soluble in hot glacial acetic acid, benzene, and alcohol, but only sparingly in ether and hot water, and almost insoluble in cold water. It dissolves in concentrated sulphuric acid with a yellow coloration, the solution turning brown on warming. The *sodium* salt crystallises in microscopic needles, and is readily soluble in water; in an aqueous solution of the sodium salt, lead acetate, barium chloride, calcium chloride, or zinc sulphate produces a colourless, nickel nitrate or copper sulphate a green, cobalt nitrate a red, silver nitrate a light yellow, and ferric chloride a reddish-brown precipitate.

Apionecrotonic acid, $CH_2{:}O_2{:}C_6H(OMe)_2{\cdot}CH{:}CMe{\cdot}COOH$, prepared from apiolaldehyde in like manner, crystallises from alcohol in light yellow needles, melts at 209°, and is almost insoluble in water, but soluble in ether, hot alcohol, and hot acetic acid. It dissolves in concentrated sulphuric acid with a yellow coloration, the solution turning bluish-green on warming. The *sodium* salt is readily soluble in water. The *calcium* salt, $(C_{13}H_{13}O_6)_2Ca + 5H_2O$, crystallises from hot water in broad, colourless needles, and loses its water at 100°. The *silver* salt, $C_{13}H_{13}O_6Ag$, is colourless, and very sparingly soluble in water. In aqueous solutions of the sodium salt, barium chloride, magnesium sulphate, or zinc sulphate produces a white crystalline precipitate, and solutions of copper, nickel, cobalt, and ferric salts also give a precipitation. When the calcium salt is distilled with lime, a small quantity of a crystalline compound, melting at 83°, is obtained.

When calcium apiolate is distilled with lime, it yields a mixture of substances, some of which are volatile with steam; the non-volatile residue crystallises from alcohol in needles, melts at 71—72°, and seems to have the composition $C_9H_8O_5$.

The nitro-compound (m. p. 117—118°) previously described (*loc. cit.*), and obtained by treating apiolic acid with nitric acid of sp. gr. 1·4 in glacial acetic acid solution, has the composition $C_9H_8N_2O_8$, not $C_9H_8N_2O_7$, as previously given, and is probably dinitrapione.

The nitro-compound (m. p. 116°), prepared from isapiole by Ginsberg (Abstr., 1888, 722), is probably identical with dinitrapione, and the compound (m. p. 137—138°) obtained by the authors from apiolaldehyde is probably a nitro-derivative of apiolaldehyde.

F. S. K.

Chlorination and Bromination of Aniline, Orthotoluidine, and Paratoluidine in presence of Excess of a Mineral Acid. By R. HAFNER (*Ber.*, 22, 2524—2541).—When chlorine is passed into an ice-cold solution of aniline in excess of 97 per cent. sulphuric acid for about 18 hours, almost the whole of the aniline remains unchanged, only small quantities of parachloraniline being formed. Under the same conditions, but employing 65 per cent. sulphuric acid, symmetrical trichloraniline (m. p. 77°), traces of a compound melting at 63—64°, probably trichlorophenol (m. p. 67—68°), and considerable quantities of resinous products are formed, but a large quantity of aniline remains unchanged. Chlorine acts energetically on aniline in 40 per cent. ice-cold sulphuric acid solution; the principal product is trichloraniline, but trichlorophenol, resinous products, and traces of other compounds, probably chloraniline and dichloraniline, are also formed.

When chlorine is passed into an ice-cold solution of aniline in excess of very concentrated (40 per cent.) hydrochloric acid for about 18 hours, most of the base is converted into parachloraniline and trichloraniline, but considerable quantities remain unchanged. Trichloraniline is also formed when chlorine ($\frac{1}{2}$ mol.) is passed into a solution of aniline (1 mol.) in ice-cold, concentrated hydrochloric acid. In 30 per cent. ice-cold hydrochloric acid solution, chlorine acts on aniline much more readily; parachloraniline, dichloraniline, symmetrical trichloraniline, and other compounds, probably chloro-derivatives of phenol, are formed, and none of the base remains unchanged. In 20 per cent. hydrochloric acid solution under the same conditions, trichloraniline, chlorophenols, and large quantities of resinous products are formed.

Bromine, even when added in large excess, has no appreciable action on aniline in 97 per cent. sulphuric acid solution; after four months' time, only small quantities of symmetrical tribromaniline are formed. If a small quantity of iodine is mixed with the bromine, the formation of tribromaniline takes place rather more readily. In 65 per cent. and in 40 per cent. ice-cold sulphuric acid solution, aniline is acted on by excess of bromine, considerable quantities of tribromaniline being formed; in the latter case small quantities of a compound, probably tribromophenol, are also formed. When aniline is treated with excess of bromine in 40 per cent. hydrochloric acid solution, a reaction immediately takes place, and the whole of the base is converted into tribromaniline; in 20 per cent. hydrochloric acid solution, small quantities of tribromophenol are also formed.

Aniline hydrobromide is completely converted into tribromaniline when treated with excess of bromine in a concentrated ice-cold solution of potassium bromide; the yield of the pure product is 90 per cent. of the theoretical quantity.

When chlorine is passed into an ice-cold 97 per cent. sulphuric acid solution of paratoluidine for about 24 hours, metachloroparatoluidine [Me : Cl : NH_2 = 1 : 3 : 4] and larger quantities of orthochloroparatoluidine [Me : Cl : NH_2 = 1 : 2 : 4] are obtained, but a considerable quantity of the base remains unchanged. In 40 per cent. hydrochloric acid solution, the whole of the paratoluidine enters into reaction, yielding metachloroparatoluidine, metadichloroparatoluidine [Me : Cl_2 : NH_2 = 1 : 3 : 5 : 4], a crystalline compound, probably orthochloroparatoluidine, and oily products, probably chlorinated derivatives of cresol.

When paratoluidine is treated with excess of bromine in 39 per cent. ice-cold hydrochloric acid solution, it is almost completely converted into metadibromoparatoluidine, melting at 73—74°, very small quantities of a bromocresol being also produced. In 65 per cent. sulphuric acid solution under the same conditions, large quantities of metadibromoparatoluidine are formed.

When orthotoluidine is treated with excess of chlorine in 98 per cent. ice-cold sulphuric acid solution, it is partially converted into a chlorotoluidine; bromine under the same conditions has no appreciable action, even after eight days' time. F. S. K.

Action of Nascent Nitrous Acid on various Amines and Phenols. By A. Deninger (*J. pr. Chem.* [2], **40**, 296—302).—When sodium nitrite (3 mols.) acts on an aqueous acid solution of aniline, ortho- and para-nitrophenol and some resinous substances are produced, in quantities dependent on the concentration, acidity, and temperature. The quantity of orthonitrophenol produced is greater, the more rapid the reaction, and the higher the temperature above 65°; it varies from 0 to 50 grams, whilst that of paranitrophenol varies from 0 to 33 grams per 100 grams of aniline. Air blown through the liquid diminishes the quantity of phenols produced, as also does the presence of oxidising or reducing substances. The nature of the acid has no apparent effect. To obtain the best yield, 10 grams of aniline, 20 c.c. of sulphuric acid, and 80 c.c. of water are mixed and cooled to 15°; 300 grams of sodium nitrite in 100 c.c. of water are then added, the solution heated in a water-bath and a large quantity of hot dilute sulphuric acid (1 : 1) immediately added. After the reaction, the ortho-compound is distilled over with steam, and the para-compound crystallised from the residue. Nitric oxide alone appears to be evolved during the reaction.

If orthotoluidine (10 grams) be substitued for aniline in the above process, orthonitrocresol [Me : OH : NO_2 = 1 : 2 : 3] (5 to 6 grams), melting at 68—69°, is obtained. By using a more dilute solution and allowing it to stand for 14 days at 15—20° paranitrocresol [Me : OH : NO_2 = 1 : 2 : 5], melting at 96° is obtained. With paratoluidine (100 grams) only one nitrocresol (138 grams), melting at 33—34°, is obtainable.

By acting on diamidoparadiphenyl and diamidoparaditolyl respectively with sodium nitrite (6 mols.) in the way described above, dinitrodiphenol (m. p. 260°) and dinitrodicresol (m. p. 270°) are produced respectively.

The *sulphate* of diamidodicresol (Abstr., 1888, 838), obtained by reducing the dinitrocresol, is sparingly soluble in water; by diazotising it and decomposing with hot sulphuric acid, *tetrahydroxyditolyl* is obtained as a pleasant-smelling oil, which is volatile with steam; its aqueous solution gives a yellowish-white precipitate with ferric chloride.

With naphthylamine, the above treatment yields dinitronaphthol and a little nitronaphthol; when α-naphthylamine is treated with 2 mols. more sodium nitrite than is necessary for diazotising, and distilled at once with steam, β-nitro-α-naphthol (m.p. 128°) is obtained; but if allowed to stand for 14 days at 10—15° α-nitro-α-naphthol is formed. β-naphthylamine yields α-nitro-β-naphthol (m. p. 103°).

Sulphanilic and orthotoluidinesulphonic acids yield by this treatment garnet-red crystals, which lose the sulphonic acid group when treated with super-heated steam and yield nitrophenol and nitrocresol respectively. Naphthionic acid yields nitronaphtholsulphonic acid.

Salicylic acid and its ethereal salts yield nitrosalicylic acid and its ethereal salts.

A new substance is obtained when paraphenolsulphonic acid is treated with sodium nitrite and sulphuric acid; it is still under investigation. A. G. B.

Some Nitrated Diazoamido-compounds. By S. NIEMENTOWSKI (*Ber.*, **22**, 2562—2567).—When metanitraniline is diazotised in the manner described by Sandmeyer for paranitraniline (Abstr., 1885, 981) a resinous precipitate is formed the moment the sodium nitrite solution is added. This can be afterwards separated from the metanitrobenzonitrile by steam distillation. It crystallises from amyl alcohol in lustrous, golden needles, which melt at 191—192° with decomposition. It has the formula $C_{12}H_9N_5O_4$, and is identical with Griess' metadiazoamidonitrobenzene (m. p. 195·5, *Annalen*, **121**, 272) and with Hallmann's dinitroamidoazobenzene (m. p. 175—176°, *Ber.*, **9**, 389). In order to determine the constitution of the compound, a quantity of it was prepared by Hallmann's method; the substance prepared by this method when crystallised from amyl alcohol also gave the m. p. 195°. When the compound is heated with hydrochloric acid (sp. gr. = 1·17) for 10 hours at 185°, metachloronitrobenzene is formed. Amyl alcohol decomposes it at 185° with formation of metanitraniline and nitrobenzene. These reactions and the behaviour of the substance towards aromatic amines and phenols, with which it yields dyes, show that the compound is diazoamidonitrobenzene. Hallmann's method (*loc. cit.*) is a very convenient one for the preparation of nitrated diazoamido-compounds.

Diazoamidonitrotoluene, $C_{14}H_{13}N_5O_4$ (from metanitroparatoluidine), is prepared by treating metanitroparatoluidine (m. p. 114°, 30·4 grams), suspended in alcohol (250 grams) with nitric acid (sp. gr. 1·52, 7·5 grams), and with a saturated solution of potassium nitrite (8·5 grams). It crystallises from amyl alcohol in dark reddish-brown branched needles, melts at 163°, dissolves very sparingly in alcohol, more readily in ether and carbon bisulphide, and very easily in cold benzene, acetone, and chloroform. When heated with alcohol at 170°, it is decomposed into metanitroparatoluidine and metanitrotoluene.

Diazoamidonitrotoluene (from paranitro-orthotoluidine, m. p. 107°) crystallises from alcohol in long, bright yellow needles, melts at 212° with decomposition, and is readily soluble in acetone, benzene, and chloroform. N. H. M.

Trinitrohydrazobenzene. By E. FISCHER (*Annalen*, **253**, 1—5). —The author's process for preparing trinitrohydrazobenzene from picryl chloride and phenylhydrazine has been criticised by Willgerodt and Ferko (Abstr., 1888, 830). In reply, the author maintains that the process yields good results, if the necessary conditions are observed. W. C. W.

Symmetrical Nitrophenylhydrazines of the Aromatic Series. By C. WILLGERODT (*J. pr. Chem.* [2], **40**, 264—270).—Symmetrical picrylhydrazines are obtained by cohabating picryl chloride and the hydrochloride of the aromatic hydrazine (in molecular proportion) in alcohol at the ordinary temperature. Picrylphenylhydrazine, *picrylorthotolylhydrazine*, *picrylparatolylhydrazine*, and *picryl-α-naphthylhydrazine* have been thus obtained.

All these decompose before they melt, at temperatures dependent on their state of division; thus picrylphenylhydrazine in powder decomposes at 177°, whereas its crystals decompose at 181° (compare Abstr., 1888, 829).

The author has studied the action of heat on the nitrophenylhydrazines in presence of various liquids and finds that the decompositions which occur may be classified as follows:—(1.) The liquid does not decompose the nitrohydrazine *per se*; in this case the hydrazine hydrogen reduces the nitro-group to a nitroso-group; such liquids are water, dilute hydrochloric acid, benzene, and glacial acetic acid. (2.) The liquid is an oxidising agent; the nitrohydrazine is oxidised to a nitroazo-compound. (3.) The liquid decomposes the nitrohydrazine altogether. (4.) The liquid acts as a reducing agent, such liquids being ethyl and methyl alcohols, formic acid, and acetone; the first two and acetone convert picrylhydrazine into dinitrosonitroazobenzene, melting at 219—220°; formic acid converts it into a mixture of two substances, melting at 225° and 233°. (5.) The liquid is an organic base; in this case the nitrohydrazine is first converted into nitro-nitroso-azo-compounds, and these into polyazo-compounds.

The paper concludes with a reply to Freund (Abstr., 1889, 977) who criticises the author's and Ferko's former work (Abstr., 1888, 829). A. G. B.

Phenylhydrazone. By E. FISCHER and F. ACH (*Annalen*, **253**, 57—65).—*Acetonedinitrophenylhydrazone*, $C_9H_{10}N_4O_4$, is prepared by slowly adding acetonephenylhydrazone (12 grams) to strong, colourless nitric acid (25 grams) surrounded by a freezing mixture; this solution is allowed to drop into 100 grams of well-cooled fuming nitric acid and the mixture is poured into ice water; the product is extracted with small quantities of ether and the residue purified by recrystallisation from alcohol. It melts at 127° (uncorr.), is soluble in benzene, chloroform. ether, and in hot alcohol, and is quickly decomposed by hot alkaline solutions, but less readily by acids. Phenylhydrazonelevulinic anhydride is converted into the paranitro-derivative,  $NO_2\cdot C_6H_4\cdot N<\genfrac{}{}{0pt}{}{N:CMe}{CO\cdot CH_2}>CH_2$. by fuming nitric acid. This substance crystallises in flat needles of a yellow colour, is soluble in hot alcohol, benzene, and glacial acetic acid, and melts at 118—119°. The alcoholic solution is converted into paraphenylenediamine by reduction with zinc-dust and acetic acid. Warm alcoholic potassium hydroxide or warm concentrated hydrochloric acid converts the anhydride into paranitrophenylhydrazonelevulinic acid, $NO_2\cdot C_6H_4\cdot NH\cdot N:CMe\cdot C_2H_4\cdot COOH$. This acid forms orange-coloured needles soluble in acetone and hot alcohol; it also dissolves in alkalis, forming intense deep-red solutions. It darkens at 190° and melts with decomposition at 200°. The *ethyl* salt melts at 156—157° with slight decomposition. It crystallises in needles and dissolves freely in hot alcohol, benzene, and glacial acetic acid.

The hydrazones of acetone and of acetaldehyde, propaldehyde, and œnanthaldehyde are decomposed by gently warming with pyruvic acid; acetone or aldehyde is liberated and phenylhydrazonepyruvic acid is produced. The ketones and γ-ketonic acids behave in the same way.

Paranitrophenylhydrazonepyruvic acid, $NO_2\cdot C_6H_4\cdot NH\cdot N:CMe\cdot COOH$, is precipitated when pyruvic acid is added to a hot dilute solution of nitrophenylhydrazonelevulinic acid in hydrochloric acid. The acid is soluble in acetone and in warm alcohol, and is decomposed by heat.

W. C. W.

Amidoximes and Azoximes. By F. Tiemann (*Ber.*, **22**, 2391—2395; compare Abst., 1886, 875).—The conversion of nitriles into amidoximes by the action of hydroxylamine may be considered to be a general reaction, as hitherto it has been found to apply to all cases, except that of nitriles such as pentamethylbenzonitrile, which cannot be, or are only with difficulty, converted into the corresponding acid by the usual reagents. As a rule, the formation of the amidoxime takes place much more slowly with nitriles of high molecular weight and rich in carbon, and the acid character of the product is less marked.

The amidoximes combine readily with hydrogen cyanate, phenylcarbimide, and phenylthiocarbimide, yielding uramidoximes, phenyluramidoximes, and phenylthiuramidoximes. The ethyl-derivatives of the amidoximes also combine with phenylthiocarbimide and with phenylcarbimide.

F. S. K.

Phenylallenylamidoxime-derivatives. By H. Wolff (*Ber.*, **22**, 2395—2401; compare Abstr., 1886, 798).—*Phenylallenylethoxime nitrite*, $CHPh:CH\cdot C(N\cdot OEt)\cdot O\cdot NO$, separates in colourless needles when a solution of phenylallenylamidethoxime (1 mol.) in dilute sulphuric acid is treated with sodium nitrite (2 mols.) in the cold.

It turns yellow after a short time and is very unstable, exploding slightly when treated with concentrated sulphuric acid, or when heated quickly. It melts at 61°, is readily soluble in alcohol, chloroform, benzene, and ether, but only sparingly in light petroleum, and almost insoluble in water. It can be crystallised from alcohol at temperatures below 55°, but slight decomposition occurs. It is decomposed by acids or alkalis, yielding cinnamic acid. The *chloride*, $CHPh{:}CH{\cdot}CCl{:}N{\cdot}OEt$, separates as a yellowish oil when the amidethoxime is dissolved in excess of hydrochloric acid, and the solution treated with sodium nitrite. It is soluble in ether, alcohol, benzene, and chloroform, but only sparingly soluble in light petroleum and carbon bisulphide, and almost insoluble in water; it is not decomposed when warmed for a short time with acids or bases.

Phenyldibromopropenylethoxime chloride, $CHBrPh{\cdot}CHBr{\cdot}CCl{:}N{\cdot}OEt$, prepared by warming the chloride with a slight excess of bromine, is a solid compound readily soluble in ether, benzene, and chloroform, but only sparingly in light petroleum, and insoluble in water.

Phenylallenylphenyluramidethoxime,

$$CHPh{:}CH{\cdot}C(NOEt){\cdot}NH{\cdot}CO{\cdot}NHPh,$$

obtained by treating phenylallenylamidethoxime with phenylcarbimide, crystallises from dilute alcohol in colourless needles, melts at 155—156°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in light petroleum, hot water, and hydrochloric acid, and insoluble in potash and cold water.

Phenylallenylphenyluramidoxime,

$$CHPh{:}CH{\cdot}C(NOH){\cdot}NH{\cdot}CO{\cdot}NHPh,$$

prepared in like manner from phenylallenylamidoxime, crystallises from dilute alcohol in colourless needles, melts at 158—159°, and is readily soluble in ether, but only moderately so in benzene and chloroform, sparingly in light petroleum, and insoluble in cold water; it is only very sparingly soluble in acids and alkalis.

Phenylallenyluramidoxime, $CHPh{:}CH{\cdot}C(NOH){\cdot}NH{\cdot}CO{\cdot}NH_2$, separates in colourless needles when an aqueous solution of phenylallenylamidoxime hydrochloride is treated with potassium cyanate; it melts at 158—159°, and is readily soluble in alcohol and ether, but only moderately in benzene and chloroform, and sparingly in light petroleum and cold water. It forms salts with acids, and dissolves unchanged in alkalis, but when treated with concentrated acids or alkalis at the ordinary temperature, it is reconverted into the amidoxime. The *platinochloride*, $(C_{10}H_{11}N_3O_2)_2,H_2PtCl_6$, is crystalline.

Ethyl phenylallenylamidoximecarboxylate,

$$CHPh{:}CH{\cdot}C(NH_2){:}N{\cdot}O{\cdot}COOEt,$$

is obtained, together with the hydrochloride of the amidoxime, when phenylallenylamidoxime (2 mols.) is treated with ethyl chlorocarbonate (1 mol.) in benzene solution. It is a crystalline, unstable compound, melts at 101°, and is readily soluble in ether, alcohol, chloroform, and benzene, but only sparingly in light petroleum, and insoluble in water.

Phenylallenylcarbonylimidoxime, $\mathrm{CHPh{:}CH{\cdot}C}\Big<\begin{matrix}\mathrm{N—O}\\ \mathrm{NH{\cdot}CO}\end{matrix}\Big>$, is formed when the preceding compound is warmed with alkalis, or heated above its melting point. It crystallises from dilute alcohol in slender needles, melts at 199—200°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in light petroleum, and is insoluble in cold water. It has an acid reaction, and in neutral solutions of the ammonium-derivative, silver nitrate produces a white, and copper sulphate a green precipitate. F. S. K.

Substituted Amidoximes. By H. Müller (*Ber.*, **22**, 2401—2412; compare Abstr., 1886, 875).—Benzenylphenylcarbonylimidoxime, melting at 166—167°, is formed, together with benzylanilidoxime hydrochloride, when benzenylanilidoxime is treated with carbonyl chloride in benzene solution.

Benzenylanilidoxime combines with chloral in the cold, forming a colourless, flocculent compound, $\mathrm{NHPh{\cdot}CPh{:}NOH,C_2Cl_3OH}$, which melts at 128—130°, is readily soluble in alcohol, ether, chloroform, and benzene, and is decomposed by concentrated acids and boiling water.

Ethylbenzamide, $\mathrm{COPh{\cdot}NHEt}$, prepared by gradually adding benzoic chloride to an ethereal solution of ethylamine in the cold, separates from ether in large crystals, melts at 69—70°, and is soluble in water, benzene, chloroform, and alcohol, but only sparingly in light petroleum; it is moderately easily soluble in hydrochloric acid, but insoluble in soda.

Benzoparatoluidide, $\mathrm{COPh{\cdot}NH{\cdot}C_6H_4Me}$, prepared from benzoic chloride and toluidine in like manner, crystallises in plates, and melts at 157—158°.

Thiobenzoparatoluidide, $\mathrm{CSPh{\cdot}NH{\cdot}C_6H_4Me}$, is best prepared by warming the preceding compound with phosphorus pentasulphide; it crystallises from dilute alcohol in long yellow needles, melts at 128—129°, and is readily soluble in alcohol, ether, chloroform, benzene, light petroleum, and soda, but insoluble in water.

Benzenylparatoluidoxime, $\mathrm{NOH{:}CPh{\cdot}NH{\cdot}C_6H_4Me}$, prepared by heating thiobenzotoluidine with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution, crystallises from dilute alcohol in long, colourless needles, melts at 176°, and is readily soluble in ether, chloroform, benzene, acids, and alkalis, but only moderately so in hot water. The *hydrochloride*, $\mathrm{C_{14}H_{14}N_2O,HCl}$, crystallises in colourless needles, and is sparingly soluble in water.

Benzenylparatoluylcarbonylimidoxime, $\mathrm{C_6H_4Me}\Big<\begin{matrix}\mathrm{CPh}\\ \mathrm{CO}\end{matrix}\Big>\mathrm{NO}$, prepared by treating benzenyltoluidoxime with ethyl chlorocarbonate in chloroform solution, crystallises from dilute alcohol in yellowish needles, melts at 163°, and is readily soluble in ether, chloroform, benzene, and light petroleum, but insoluble in water, acids, and alkalis.

Ethenylanilidoxime, $\mathrm{NOH{:}CMe{\cdot}NHPh}$ (m.p. 120—121°), is obtained when thiacetanilide is boiled with an alcoholic solution of hydroxylamine hydrochloride and sodium carbonate. The *hydrochloride*,

$C_8H_{10}N_2O,HCl$, crystallises in colourless needles. The *platinochloride*, $(C_8H_{10}N_2O)_2,H_2PtCl_6$, crystallises in slender, yellow needles. The *benzoyl*-derivative, NOBz:CMe·NHPh, crystallises from dilute alcohol in colourless needles, melts at 110°, and is soluble in benzene, chloroform, and ether, but insoluble in water and light petroleum.

Methenylanilidoxime, NOH:CH·NHPh, prepared in like manner, crystallises from a mixture of benzene and light petroleum in colourless needles, melts at 116°, and is moderately easily soluble in water, alcohol, ether, chloroform, and benzene, but almost insoluble in light petroleum. The *hydrochloride*, $C_7H_8N_2O,HCl$, crystallises in needles. The *platinochloride*, $(C_7H_8N_2O)_2,H_2PtCl_6$, crystallises in yellowish needles. The *benzoyl* derivative, NOBz:CH·NHPh, crystallises in colourless needles, melts at 144—145°, and is moderately easily soluble in alcohol, ether, chloroform, and benzene, but almost insoluble in water and light petroleum. F. S. K.

Action of Acetaldehyde and of Ethyl Acetoacetate on Benzenylamidoxime. By F. TIEMANN (*Ber.*, 22, 2412—2417).—

Ethylidenebenzenylamidoxime, $CPh<\substack{NO\\NH}>CHMe$, separates in rhomprisms, when an aqueous solution of acetaldehyde (1 mol.) and benzenylamidoxime (1 mol.) is kept for some time in a warm place. It melts at 82°, and is readily soluble in alcohol, ether, acetone, and benzene, but only sparingly in hot, and insoluble in cold water; it is decomposed when heated with acids. The *hydrochloride*, $C_9H_{10}N_2O,HCl$, prepared by passing hydrogen chloride into an ethereal solution of the base, is crystalline. The *platinochloride*, $(C_9H_{10}N_2O)_2,H_2PtCl_6$, is an orange-yellow compound, soluble in alcohol and decomposed by water. The base is converted into benzenylethenylazoxime by potassium permanganate in cold, dilute sulphuric acid solution.

Benzenylacetoethenylazoxime, $CPh<\substack{NO\\N}>C{\cdot}CH_2Ac$, prepared by heating benzenylamidoxime with ethyl acetoacetate, crystallises from boiling water in short, yellowish prisms, melts at 86°, and is readily soluble in alcohol, ether, benzene, and acetone, but only sparingly in light petroleum and boiling water; it dissolves freely in alkalis, but is insoluble in acids. When boiled with alkalis, it is decomposed into benzenylethenylazoxime and acetic acid. The *oxime*, $C_{11}H_{11}N_3O_2$, crystallises from alcohol in colourless needles, melts at 80°, and is soluble in ether, benzene, and hot water, but almost insoluble in light petroleum and cold water. It is a feeble acid, and reduces Fehling's solution on warming. The *hydrazone*, $C_{17}H_{16}N_4O$, prepared by heating the ketone with phenylhydrazine, crystallises from dilute alcohol in yellowish needles, melts at 126°, and is insoluble in water and light petroleum, but readily soluble in alcohol, ether, benzene, and acetone.

F. S. K.

Paranitrobenzenylamidoxime and Paramethylorthonitrobenzenylamidoxime. By J. WEISE (*Ber.*, 22, 2418—2432).—*Paranitrobenzenylamidoxime*, $NO_2{\cdot}C_6H_4{\cdot}C(NH_2){:}NOH$, is obtained, together with paranitrobenzamide (m.p. 197°), when paranitrobenzonitrile, prepared from paranitraniline by Sandmeyer's method, is digested with hydroxylamine hydrochloride and sodium carbonate in aqueous solution. It crystallises in yellow needles, melts at 169°, distils without decomposition, and gives all the reactions of amidoximes; it is moderately easily soluble in alcohol and hot water, but rather sparingly in benzene, ether, and chloroform, and insoluble in light petroleum. The *hydrochloride*, $C_7H_7N_3O_3,HCl$, crystallises from water in colourless, hygroscopic needles, melts at 185° with decomposition, and is soluble in alcohol, but is reprecipitated on adding ether. The *ethyl*-derivative, $NO_2\cdot C_6H_4\cdot C(NH_2):N\cdot OEt$, is obtained by treating the amidoxime with sodium ethoxide and digesting the resulting deep-red solution with ethyl iodide; it is best obtained in a pure state by decomposing the hydrochloride with dilute soda. It forms large, yellow, prismatic crystals, melts at 59—60°, and is readily soluble in alcohol and ether, but only moderately so in benzene, and sparingly in light petroleum and hot water. The *hydrochloride* separates from alcoholic ether in colourless crystals.

Paranitrobenzenylethenylazoxime,  $NO_2\cdot C_6H_4\cdot C\left\langle\begin{matrix}NO\\ N\end{matrix}\right\rangle CMe$, prepared by dissolving the amidoxime in acetic anhydride, crystallises in colourless plates, melts at 144°, and is readily soluble in alcohol, ether, and benzene, but only very sparingly in hot water. The corresponding *benzenyl*-compound,  $NO_2\cdot C_6H_4\cdot O\left\langle\begin{matrix}NO\\ N\end{matrix}\right\rangle CPh$, prepared by warming the amidoxime with benzoic chloride, crystallises from alcohol in small, colourless needles, melts at 198°, and sublimes without decomposition when heated slowly, but explodes when heated quickly. It is insoluble in light petroleum, and only moderately soluble in alcohol, but readily in ether, benzene, and glacial acetic acid.

Ethyl paranitrobenzenylamidoximecarboxylate,

$$NO_2\cdot C_6H_4\cdot C(NH_2):NO\cdot COOEt,$$

is formed when the amidoxime is treated with ethyl chlorocarbonate in cold chloroform solution. It crystallises from cold, dilute alcohol in small needles, melts at 169°, and is moderately easily soluble in alcohol, ether, benzene, and chloroform, but only very sparingly in water, and insoluble in light petroleum.

Paranitrobenzenylcarbonylimidoxime,  $NO_2\cdot C_6H_4\cdot C\left\langle\begin{matrix}NO\\ NH\end{matrix}\right\rangle CO$, is obtained when the preceding compound is boiled with alkalis or heated alone; it separates from alcohol in small, yellow needles, melts at 286°, and is insoluble in light petroleum, and only very sparingly soluble in hot water, but more readily in alcohol, ether, and benzene. It is a very stable compound, and dissolves freely in alkalis; in a neutral solution, copper sulphate produces a green precipitate.

Carbonyldi-paranitrobenzenylamidoxime,

$$CO[NO:C(NH_2)\cdot C_6H_4\cdot NO_2]_2,$$

prepared by treating the amidoxime with carbonyl chloride in benzene solution at the ordinary temperature, crystallises in small, yellowish needles, melts at 232°, and is very readily soluble in alcohol, and moderately so in hot water, but more sparingly in benzene and ether, and insoluble in light petroleum; it is converted into paranitrobenzenylcarbonylamidoxime when warmed with alkalis.

Ethylideneparanitrobenzenylamidoxime, $\mathrm{NO_2\cdot C_6H_4}{<}\genfrac{}{}{0pt}{}{\mathrm{NO}}{\mathrm{NH}}{>}\mathrm{CHMe}$, separates in dark yellow crystals when an aqueous solution of the amidoxime is treated with a slight excess of acetaldehyde and kept for some days; it crystallises in needles, melts at 153°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in hot water, and insoluble in light petroleum. It is not acted on by dilute acids or alkalis in the cold, but oxidising agents convert it quantitatively into the azoxime. It is decomposed into its constituents when warmed with dilute hydrochloric acid. A yellow, flocculent compound separates from the solution when ethylideneparanitrobenzenylamidoxime is treated with warm dilute soda. This substance melts at 252°, is very stable, and is insoluble, or only very sparingly soluble in most ordinary solvents. It dissolves unchanged in concentrated sulphuric acid, and is not acted on by reducing or oxidising agents, or when heated at 150° with concentrated hydrochloric acid; it is decomposed by fuming nitric acid, yielding a neutral compound which melts at about 180°, and seems to be a dinitroethenylazoxime.

Chlorethylideneparanitrobenzenylamidoxime,

$$\mathrm{NO_2\cdot C_6H_4\cdot C}{<}\genfrac{}{}{0pt}{}{\mathrm{NO}}{\mathrm{NH}}{>}\mathrm{CH\cdot CH_2Cl},$$

is formed when the amidoxime is boiled with dichlorethyl ether in aqueous solutions. It crystallises from dilute alcohol in yellow plates, melts at 176°, and is very readily soluble in alcohol, but only moderately easily in benzene, ether, and water, and insoluble in light petroleum. It resembles the preceding compound in its chemical behaviour, and yields a complex condensation-product when warmed with alkalis.

Ethylparanitrobenzenyloxime nitrite. $\mathrm{NO_2\cdot C_6H_4\cdot C(NOEt)\cdot O\cdot NO}$, prepared by treating the amidoxime with sodium nitrite in cold, dilute sulphuric acid solution, is a yellow, very unstable, flocculent compound melting at 55° with explosive violence; it is soluble in alcohol and ether, but insoluble in water. It decomposes slowly at the ordinary temperature with evolution of oxides of nitrogen, and explodes when heated with water or when treated with concentrated sulphuric acid.

Paranitrobenzenylacetoethenylazoxime,  $\mathrm{NO_2\cdot C_6H_4\cdot C}{<}\genfrac{}{}{0pt}{}{\mathrm{NO}}{\mathrm{N}}{\geqslant}\mathrm{C\cdot CH_2Ac}$, is formed when the amidoxime is digested with ethyl acetoacetate. It crystallises from dilute alcohol in golden plates, melts at 140°, and is readily soluble in alcohol and ether, but only moderately so in benzene, very sparingly in water, and insoluble in light petroleum. When heated with alkalis, it is quickly decomposed into acetic acid and nitrobenzenylethenylazoxime.

Paramidobenzenylamidoxime, $\mathrm{NH_2\cdot C_6H_4\cdot C(NH_2){:}NOH}$, prepared by reducing the nitro-compound with stannous chloride and hydrochloric acid and decomposing the resulting salt with sodium carbonate, crystallises in yellow plates, turns brown at 160°, and melts at 174° with decomposition. It is very readily soluble in alcohol, but only moderately easily in benzene and ether, sparingly in hot water and insoluble in light petroleum; it gives the reactions of amidoximes, and dissolves freely in alkalis.

Paramethylorthonitrobenzonitrile, [CN : NO_2 : Me = 1 : 2 : 4], prepared from metanitroparatoluidine by Sandmeyer's method, crystallises from water in long yellowish needles, melts at 99°, distils without decomposition, and is readily soluble in alcohol. ether, benzene, and chloroform. but only sparingly in hot water, and almost insoluble in light petroleum.

Paramethylorthonitrobenzenylamidoxime, $NO_2 \cdot C_6H_3Me \cdot C(NH_2)\colon NOH$, is obtained by digesting methylnitrobenzonitrile with hydroxylamine in alcoholic solution, and is best prepared in a pure state by decomposing the copper-derivative with hydrogen sulphide. It crystallises in long, yellow needles, melts at 161°, and shows the properties of an amidoxime; it is moderately easily soluble in alcohol and hot water, but only sparingly in benzene, ether, and chloroform, and is insoluble in light petroleum. The *hydrochloride*, $C_8H_9N_3O_3,HCl$, is a colourless, crystalline compound, soluble in alcohol, but reprecipitated on adding ether.

Paramethylorthonitrobenzamide, [$CONH_2$: NO_2 : Me = 1 : 2 : 4], is formed in the preparation of the preceding compound. It crystallises from water in long, yellow needles, melts at 152°, and is readily soluble in alcohol, ether, and benzene, but almost insoluble in light petroleum; it is converted into the corresponding acid when boiled with alkalis.

Paramethylorthamidobenzenylamidoxime,

$$NH_2 \cdot C_6H_3Me \cdot C(NH_2)\colon NOH,$$

is produced in small quantities when methylnitrobenzenylamidoxime is reduced with stannous chloride and hydrochloric acid. It is a brown, flocculent compound, melts at about 166°, and gives the reactions of amidoximes. The *hydrochloride* is a colourless, crystalline, hygroscopic compound soluble in alcohol, but reprecipitated on adding ether. F. S. K.

Para- and Ortho homobenzenylamidoxime and their Derivatives. By L. H. SCHUBART (*Ber.*, 22, 2433—2440; compare Abstr., 1886, 797).—*Parahomobenzenylethenylazoxime*,

$$C_6H_4Me \cdot C \lesssim \begin{matrix} NO \\ N \end{matrix} \gtrsim CMe,$$

prepared by boiling the amidoxime with acetic anhydride, crystallises in colourless prisms, melts at 80°, and is readily soluble in alcohol, ether, chloroform, and benzene, but insoluble in acids and alkalis.

Parahomobenzenylethoxime chloride, $C_6H_4Me \cdot CCl\colon NOEt$, obtained by treating the amidethoxime with hydrochloric acid and sodium nitrite, is a yellow oil, boils at about 200°, and is soluble in alcohol and ether. The corresponding *bromide*, prepared in like manner, is a heavy, brown oil; it decomposes at 155°, and is readily soluble in ether, chloroform, and benzene.

Parahomobenzenylpropenylazoxime-ω-carboxylic acid,

$$C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{NO}{N}C\cdot C_2H_4\cdot COOH,$$

is formed when the benzenylamidoxime is melted with succinic anhydride. It crystallises from boiling water in colourless needles, melts at 138·5°, and is soluble in alcohol, ether, chloroform, and benzene.

Parahomobenzenyluramidoxime, $C_6H_4Me\cdot C(NOH)\cdot NH\cdot CO\cdot NH_2$, prepared by treating the hydrochloride of the amidoxime with potassium cyanate in aqueous solution, crystallises in colourless needles, melts at 170°, and is readily soluble in alcohol, ether, and benzene, but only sparingly in water. The *thiouramidoxime,*

$$C_6H_4Me\cdot C(NOH)\cdot NH\cdot CS\cdot NHPh,$$

prepared by treating the amidoxime with phenylthiocarbimide, crystallises from hot water in colourless needles, melts at 190°, and is readily soluble in alcohol and ether, but more sparingly in chloroform and benzene.

Parahomobenzenylphenyluramidoxime,

$$C_6H_4Me\cdot C(NOH)\cdot NH\cdot CO\cdot NHPh,$$

prepared from phenylcarbimide in like manner, separates from dilute alcohol in colourless crystals, melts at 155°, and is readily soluble in alcohol, ether, and hot water.

Ethyl parahomobenzenylamidoximecarboxylate,

$$C_6H_4Me\cdot C(NH_2)\colon NO\cdot COOEt,$$

is obtained by treating the amidoxime with ethyl chlorocarbonate in chloroform solution; it crystallises from dilute alcohol in colourless needles, melts at 130°, and is readily soluble in alcohol, ether, chloroform, and benzene, but only sparingly in light petroleum and water.

Parahomobenzenylcarbonylimidoxime, $C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{NO}{NH}CO$, crystallises from hot water in colourless needles, melts at 220°, and is soluble in ether, alcohol, and alkalis.

Diparahomobenzenylazoxime,  $C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{NO}{N}C\cdot C_6H_4Me$, is formed when the amidoxime is heated with glacial acetic acid. It crystallises from dilute alcohol in long, colourless needles, melts at 135°, and is insoluble in water, but readily soluble in ether, benzene, chloroform, and light petroleum.

Ethylideneparahomobenzenylamidoxime, $C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{NO}{NH}CHMe$, melts at 127·5°. and is readily soluble in alcohol, ether, and benzene, but only sparingly in hot water.

Parahomobenzenylacetoethenylazoxime, $C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{NO}{N}C\cdot CH_2Ac$, pared by treating the amidoxime with ethyl acetoacetate, crystallises from boiling water in colourless needles, melts at 97°, and is readily soluble in alcohol, ether, and benzene.

Orthohomobenzenylamidoxime, $C_6H_4Me\cdot C(NH_2)\colon NOH$, obtained from homobenzonitrile (b. p. 195°), crystallises from hot water in yellowish needles, melts at 149·5°, is readily soluble in alcohol, ether, and benzene, and shows the characteristic reactions of amidoximes.

The *ethyl*-derivative, $C_{10}H_{14}N_2O$, forms colourless prismatic crystals, melts at 140°, and is readily soluble in ether, alcohol, and benzene. The *benzoyl*-derivative, $C_{15}H_{14}N_2O_2$, crystallises from dilute alcohol in needles melting at 145°.

Orthohomobenzenylbenzenylazoxime,  $C_6H_4Me\cdot C{<}^{NO}_{N}{>}CPh$, prepared by dissolving the benzoyl-derivative (see above) in cold, concentrated sulphuric acid, crystallises in long, colourless needles, melts at 80°, and is insoluble in acids, alkalis, and cold water, but readily soluble in alcohol, ether, benzene, and chloroform. F. S. K.

Action of Carbon Bisulphide on the Potassium Compound of Parahomobenzenylamidoxime. By L. H. SCHUBART (*Ber.*, 22, 2441—2442).—A compound $C_9H_8N_2S_2$ is formed when parahomobenzenylamidoxime (1 mol.) is dissolved in alcoholic potash and the solution boiled for about three hours with carbon bisulphide (1 mol.). It crystallises from alcohol in yellow needles, melts at 165°, and is soluble in ether, chloroform, benzene, and alkalis.

The compound $C_8H_6N_2S_2$ can be obtained from benzenylamidoxime in like manner. It crystallises from alcohol in yellow prisms, and melts at 160°. F. S. K.

Xylenylamidoxime and its Derivatives. By E. OPPENHEIMER (*Ber.*, 22, 2442—2449).—Xylylonitrile [CN : Me_2 = 1 : 2 : 4], prepared from metaxylidine by Sandmeyer's method, separates from cold dilute alcohol in long, colourless crystals, melts at 23—24°, is volatile with steam, and is readily soluble in alcohol and ether (compare Gasiorowski and Merz, Abstr., 1885, 772).

Xylenylamidoxime, $C_6H_3Me_2\cdot C(NH_2)\colon NOH$, is obtained when the preceding compound is heated with hydroxylamine for 5 to 6 hours at 80—85°. It crystallises in colourless needles, melts at 178°, and is readily soluble in alcohol, ether, chloroform, and hot water, but only sparingly in cold water; it gives all the characteristic reactions of amidoximes. The *ethyl*-derivative, $C_{11}H_{16}N_2O$, crystallises in colourless needles, melts at 172°, and is readily soluble in alcohol, ether, chloroform, benzene, and hot water, but only sparingly in cold water. The *benzoyl*-derivative, $C_{16}H_{16}N_2O_2$, separates from dilute alcohol in colourless crystals, melts at 158°, and is only sparingly soluble in water and light petroleum, but readily in alcohol, ether, and chloroform.

Xylenylbenzenylazoxime,  $C_6H_3Me_2\cdot C{<}^{NO}_{N}{>}CPh$, prepared by heating the benzoyl-derivative described above, crystallises in yellowish scales, melts at 98°, sublimes readily, and is volatile with steam; it is readily soluble in alcohol, ether, chloroform, and benzene.

Acetylxylenylamidoxime, $C_6H_3Me_2{\cdot}C(NH_2){:}NOAc$, obtained by treating the amidoxime with acetic chloride in ethereal solution, crystallises from cold alcohol in colourless needles, melts at 189°, and is readily soluble in alcohol and chloroform, but only sparingly in ether. The corresponding *ethenylazoxime*, $C_{11}H_{12}N_2O$, is prepared by heating the amidoxime with acetic anhydride and distilling the product with steam; it separates from alcohol or ether in crystals and melts at 89°.

Xylenylazoximepropenyl-ω-carboxylic acid,

$$C_6H_3Me_2{\cdot}C{<}\overset{NO}{\underset{N}{}}{>}C{\cdot}C_2H_4{\cdot}COOH,$$

prepared by fusing the amidoxime with succinic anhydride, crystallises in long, colourless needles, melts at 112°, and is readily soluble in alcohol, ether, benzene, and chloroform; it forms crystalline salts with bases.

Ethyl xylenylamidoximecarboxylate, $C_6H_3Me{\cdot}C(NH_2){:}NO{\cdot}COOEt$, is obtained by treating the amidoxime with ethyl chlorocarbonate in chloroform solution. It crystallises from dilute alcohol in colourless needles, melts at 142°, and is readily soluble in alcohol, ether, and chloroform, but only sparingly in light petroleum; it has feeble basic properties.

Xylenylcarbonylamidoxime, $C_6H_3Me_2{\cdot}C{<}\overset{NO}{\underset{NH}{}}{>}CO$, prepared by heating the preceding compound, crystallises from hot water in needles, melts at 182°, and is readily soluble in alcohol and ether; it has acid properties.

The *compound* $C_9H_{12}N_2O,CCl_3{\cdot}COH$ is formed by the direct combination of its constituents; it separates from a mixture of benzene and light petroleum in crystals, melts at 112°, and dissolves unchanged in alcohol and ether, but is decomposed by water and by dilute acids.

Xylenyluramidoxime, $C_6H_3Me_2{\cdot}C(NOH){\cdot}NH{\cdot}CO{\cdot}NH_2$, separates in colourless crystals when the hydrochloride of the amidoxime is treated with potassium cyanate in ethereal solution. It melts at 155°, is readily soluble in ether, alcohol, benzene, and light petroleum, but only sparingly in water; it combines with acids and also, but less readily, with bases. The *phenyl*-derivative,

$$C_6H_3Me_2.C(NOH){\cdot}NH{\cdot}CO{\cdot}NHPh,$$

crystallises from alcohol in light yellow scales, melts at 138°, and is soluble in alcohol, ether, benzene, chloroform, hot water, and acids.

Xylenylphenylthiuramidoxime, $C_6H_3Me_2{\cdot}C(NOH){\cdot}NH{\cdot}CS{\cdot}NHPh$, separates from dilute alcohol in light yellow crystals, melts at 150°, and is soluble in alcohol, ether, benzene, acids, and boiling water, but almost insoluble in alkalis. F. S. K.

Action of Sulphuric Acid and Selenic Acid on Aromatic Compounds. By ISTRATI (*Bull. Soc. Chim.* [3], 1, 480—481).—Finding that the prolonged action of sulphuric acid on benzene produced a sulphonic acid, sulphobenzide, and a franceïn, the author heated selenic acid, sp. gr. 1·4 (100 grams), with pure benzene (50 c.c.)

for 32 hours at 80°; neither selenobenzide nor a francein was produced, but after neutralisation of the acid by barium carbonate, a small quantity of a crystalline organic compound, which the author believes to be phenyl selenide (comp. Abstr., 1889, 41), was extracted from the barium salt by hot water. Pentachlorobenzene similarly treated gave a corresponding result. T. G. N.

New Data relating to Franceïns. By ISTRATI (*Bull. Soc. Chim.* [3], 1, 481—487; compare Abstr., 1888, 591).—When sulphuric acid is heated with halogen-derivatives of benzene, it causes the migration of halogen-atoms, and this determines the formation from the initial compound of franceïns whose chlorine values differ. Thus from 1 : 2 : 4-trichlorobenzene, three franceïns resulting from the oxidation of di-, tri-, and tetra-chlorobenzenesulphonic acids are produced, and these are accompanied by a small quantity of 1 : 2 : 4 : 5-tetrachlorobenzene. From 1 : 2 : 4 : 5-tetrachlorobenzene, a franceïn is obtained which is separable into five franceïns of varying solubilities and compositions. Numerous analyses are given. T. G. N.

Franceïn from 1 : 2 : 4 : Trichlorobenzene. By ISTRATI (*Bull. Soc. Chim.* [3], 1, 488—492).—From comparative experiments which he has made as to the formation of franceïns from 1 : 2 : 4-trichlorobenzene, the author finds that the yield of franceïn is dependent on the temperature, and varies inversely as the amount of sulphonic acid remaining in the mixture at the close of the operation. T. G. N.

Action of Heat on a Mixture of Sulphuric Acid and Sulphonic Derivatives. By ISTRATI (*Bull. Soc. Chim.* [3], 1, 492—496).—From experimental observations, the author concludes that when a mixture of excess of sulphuric acid and a sulphonic acid or a sulphonate is heated, regeneration of hydrocarbons with formation of water and of pyrosulphuric acid respectively occur, while sulphobenzide is formed as a condensation-product, and a decomposition of the sulphonic acid into sulphurous anhydride, hydrocarbon, and oxygen determines the formation of a franceïn by the oxidation of unaltered sulphonic acid. T. G. N.

α-Ketoaldehydes. By H. MÜLLER and H. v. PECHMANN (*Ber.*, 22, 2556—2561).—Benzoylformaldehyde (phenylglyoxal), COPh·COH (Abstr., 1888, 146), is prepared by dissolving nitrosoacetophenone (30 grams) in a 35 per cent. solution of sodium hydrogen sulphite (120 grams) contained in a litre flask. When cold, the whole solidifies to a yellowish crystalline mass, and is then stirred with alcohol and glacial acetic acid (1 c.c.), and after some time filtered by suction. The product (30 or 40 grams at a time) is boiled with 11 parts of 17 per cent. sulphuric acid in a flask fitted with an upright condenser until one quarter of the liquid is boiled off. On cooling, crystals of phenylglyoxal hydrate separate and are purified by crystallisation from boiling water. It dissolves in about 35 parts of water at 20°. When heated with nitric acid (sp. gr. 1·4), benzoylformic acid is formed. When an aqueous solution is treated with phenylhydrazine dissolved in dilute acid, the *α-hydrazone*, NHPh·N:CPh·COH, separates as a brown, crystalline precipitate which may be obtained from alcohol in yellow plates, melts at 142—143°, and is readily soluble in most solvents. The osazone, $C_{20}H_{18}N_4$, is obtained by heating phenylglyoxal with phenylhydrazine acetate (2 mols.) or, more conveniently, from nitrosoacetophenone and an excess of phenylhydrazine; it is identical with Laubmann's compound from benzoyl carbinol and phenylhydrazine (Abstr., 1888, 366). When the aldehyde is dissolved in aqueous soda and boiled for a few minutes, sodium mandelate is formed. It is probable that in the formation of mandelic acid from benzoylcarbinol (Breuer and Zincke, Abstr., 1880, 645) and from acetophenone dibromide (Engler and Wöhrle, Abstr., 1887, 948) benzoylformaldehyde is formed as intermediate product (compare Zincke, *Annalen*, **216**, 315).

When phenylglyoxal is treated with ammonia, a compound of the formula $C_{22}H_{19}N_3O$ or $C_{22}H_{17}N_3O$ is obtained. This crystallises from dilute alcohol in yellowish-white, lustrous plates, melting at 192—193°, and can be distilled; it is soluble in alkalis, and is not changed by sulphuric acid.

Phenylglyoxal reacts with hydroxylamine, yielding the compound $C_{16}H_{13}N_3O_3$. The latter melts at 219°, dissolves in alkalis, and is precipitated by acids as a white powder which becomes yellow when exposed to light.

Nitrosomethyl paratolyl ketone, $C_6H_4Me{\cdot}CO{\cdot}CH{:}NOH$, prepared by Claisen's method, crystallises from benzene in colourless needles melting at 100°.

Paratolylglyoxal hydrate, $C_6H_4Me{\cdot}CO{\cdot}CH(OH)_2$, is prepared from the above compound in a manner similar to phenylglyoxal. It crystallises from water in white, matted needles, softens at 95°, melts at 100—102°, and is readily soluble in alcohol, ether, and benzene, but less soluble in water and light petroleum. When shaken with benzene containing thiophen, and sulphuric acid, the latter becomes green. The aldehyde behaves towards alkalis like the phenyl-compound, is oxidised by nitric acid (sp. gr. 1·4) to toluylformic acid and by permanganate to paratoluylic acid (m. p. 180°). The *osazone*, $C_{21}H_{20}N_4$, obtained by heating a solution of the aldehyde with an excess of phenylhydrazine acetate for 30 minutes on a water-bath, crystallises in yellow needles melting at 145°.

Naphthyl methyl ketone, $C_{12}H_{10}O$, melts at 51—52°, boils at 300—301°, and when oxidised yields *β*-naphthoic acid. It is not identical with the compound obtained by Claus and Feiss (Abstr., 1887, 271), but possibly is with Pampel and Schmidt's (Abstr., 1887, 252) compound.

N. H. M.

Isomeric Dinitroparatoluic Acids. By B. Rozański (*Ber.*, 22, 2675—2682).—By nitrating orthonitroparatoluic acid (Abstr., 1888, 1088), two dinitro-derivatives were obtained, and their constitution established from the corresponding dinitrotoluenes.

2 : 5-*Dinitroparatoluic acid* ($COOH : NO_2 : Me : NO_2 = 1 : 2 : 4 : 5$) is very sparingly soluble in cold water, easily in alcohol and acetone, crystallises in needles, and melts at 188°. The *sodium salt* (with $3H_2O$) forms glistening, yellow scales; the *barium salt*

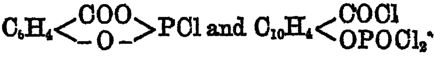
(with $2\frac{1}{2}H_2O$), small, yellowish-white needles; the *calcium salt* (with $2H_2O$), reddish-brown scales; the *ammonium salt*, lemon-yellow scales; the *silver salt*, a white, amorphous powder; the *copper salt*, a light-green powder; the *mercuric*, *lead*, and *iron salts*, white precipitates.

2 : 3-*Dinitroparatoluic acid* [$COOH : NO_2 : NO_2 : Me = 1 : 2 : 3 : 4$] forms yellowish prisms soluble in alcohol, and melts at 249°. It and its salts are less soluble in most solvents than the 1 : 2 : 4 : 5 acid. The *barium salt* (with $4H_2O$) forms pale-yellow needles; the calcium salt (with H_2O), pale-yellow scales. The other salts are similar to those of the isomeric acid. L. T. T.

Acetometanitrobenzoic Anhydride. By W. H. Greene (*Amer., Chem. J.*, **11**, 414—415).—When dry silver metanitrobenzoate is treated with excess of cold acetic chloride and the product poured into water, metanitrobenzoic acid is regenerated; Liebermann's statement (this Journal, 1877, ii, 617) that metanitrobenzoylacetic acid (acetometanitrobenzoic anhydride) is formed is incorrect.

Acetometanitrobenzoic anhydride is, however, obtained by treating sodium or silver metanitrobenzoate with acetic chloride, and extracting the product with ether. It forms colourless needles, which melt at 45°. It is insoluble in water, but the presence of either water or alcohol in the ether used for extraction causes complete decomposition of the anhydride. C. F. B.

Action of Phosphorus Trichloride on Salicylic Acid. By R. Anschütz and W. O. Emery (*Amer. Chem. J.*, **11**, 387—392).—When salicylic acid is heated with excess of phosphorus trichloride at 70—85°, and the product distilled, first at the ordinary pressure, to get rid of the excess of phosphorus trichloride, and then under reduced pressure, *salicylophosphorus chloride*, $C_7H_4O_3PCl$, solidifies in the receiver. This melts at 36—37°, boils at 127° under 11 mm. pressure, decomposes under ordinary pressure at about 245°, and is soluble in ether, chloroform, and benzene. With phosphorus pentachloride, or with chlorine, it gives an additive-compound, $C_7H_4O_3PCl_3$, of sp. gr. = 1·5587 at 20° (water at 4° = 1), boiling at 168° under 11 mm. pressure; this compound can also be obtained by the action of phosphorus pentachloride on salicylic acid. With bromine, a similar compound, $C_7H_4O_3PClBr_2$, is obtained, of sp. gr. 1·8852 at 20° (water at 4° = 1), and boiling at 185—188° under 11 mm. pressure. The following are given as the most probable formulæ for salicylophosphorus monochloride and its chlorine additive-product respectively:—



$$C_6H_4<\begin{matrix}COO\\-O-\end{matrix}>PCl \text{ and } C_{10}H_4<\begin{matrix}COCl\\OPOCl_2\end{matrix}.$$

C. F. B.

Constitution of Isoeuxanthone. By C. Arbenz (*Chem. Centr.*, 1889, ii, 73; from *Archiv. Sci. phys. nat. Genève* [3], 21, 375).—Phenylsalicylic acid is converted by nitric acid into the dinitro-derivative, $NO_2{\cdot}C_6H_4(O{\cdot}C_6H_4{\cdot}NO_2){\cdot}COOH$, which may be split up into paranitrophenol and paranitrosalicylic acid, proving that both nitro-groups are in the para-position. Sulphuric acid converts the dinitro-derivative into dinitrodiphenyleneketone oxide, which may be reduced to the diamido-derivative, isoeuxanthone. J. W. L.

Oxidation of Orthocarboxycinnamic Acid. By E. EHRLICH (*Monatsh.*, **10**, 574—577; compare Abstr., 1888, 842).—The author has previously shown (Abstr., 1888, 1306) that in alkaline solution, β-naphthol, when oxidised with a limited quantity of permanganate, gives rise to orthocarboxycinnamic acid, $COOH{\cdot}CH{:}CH{\cdot}C_6H_4{\cdot}COOH$; whilst the employment of an excess of the oxidising agent leads to the formation of orthocarboxyphenylglyoxylic acid,

$$COOH{\cdot}CO{\cdot}C_6H_4{\cdot}COOH.$$

The former acid, however, is not to be regarded as an intermediate product, for when a 2 per cent. solution of permanganate is slowly run into a solution of orthocarboxycinnamic acid (10 grams) and potash (10 grams) in water (1 litre), decolorisation ceases when about 80 per cent. of the permanganate theoretically required to convert it into orthocarboxyphenylglyoxylic acid has been added, and the solution contains only orthobenzaldehydecarboxylic acid, $COH{\cdot}C_6H_4{\cdot}COOH$ (yield 50 per cent.), which melts at 98—99°, reduces an ammoniacal solution of silver, and furnishes a compound with phenylhydrazine, melting at 107—108°. The author has not succeeded in his endeavour to obtain orthobenzaldehydecarboxylic acid by the direct oxidation of β-naphthol. G. T. M.

Isomeric Derivatives of Ethylbenzene. By L. SEMPOTOWSKI (*Ber.*, **22**, 2662—2674).—When ethylbenzene is heated to boiling, an equal volume of sulphuric acid added, and then, after cooling, the mass is treated with a small quantity of ice-cold water, only *para-ethylbenzenesulphonic acid* is formed; this crystallises in long, colourless, deliquescent needles, is slightly soluble in water, and has a rough, bitter taste. The *barium salt* (with H_2O) forms colourless, silky needles; the *calcium salt*, silvery scales; the *copper salt* (with $4\frac{1}{2}H_2O$), light-blue, glistening scales, decomposing at 170°; the *cadmium salt* (with $7H_2O$), large, transparent, quadratic plates; the potassium salt (with $\frac{1}{2}H_2O$), micaceous scales, decomposing at 150°. All these salts are soluble in water. The *sulphamide*, $C_6H_4Et{\cdot}SO_2NH_2[Et : SO_2NH_2 = 1 : 4]$, crystallises from alcohol in flat, micaceous prisms, easily soluble in ether, sparingly so in water, and melting at 109°. The constitution was proved by the fusion of the potassium salt with potash, when parahydroxybenzoic acid was formed. With a shorter fusion, *para-ethylphenol*, $C_6H_4Et{\cdot}OH$ was obtained; this forms long needles, which melt at 45—46°, boil at 213—214°, and are sparingly soluble in water.* It is very soluble in alcohol and ether, and its aqueous solution gives a violet-grey coloration with ferric chloride, and a yellowish-white precipitate with bromine-water.

The *metasulphonic acid*, $C_6H_3Et(SO_3H){\cdot}OH[Et : SO_3H : OH = 1 : 3 : 4]$, is formed both at high and low temperatures. It is a reddish oil, of phenol-like odour and miscible with water. The *barium salt* forms colourless, hexagonal plates, decomposing at 120°; the *potassium salt*, silky needles; the *calcium salt*, colourless needles. On fusion with potash, the acid yields protocatechuic acid, proving the correctness of the constitution given.

---

* Probably identical with the α-ethylphenol of Beilstein and Kuhlberg, and of Fittig and Kiesow.—*Abstractor.*

Metaparadihydroxyethylbenzene, $C_6H_3Et(OH)_2$ [Et : OH : OH = 1 : 3 : 4], is a liquid boiling at 295° and soluble in water. Its aqueous solution is coloured green by ferric chloride, and this colour passes, on the addition of soda, through blue to claret colour.

Orthobromethylbenzenemetasulphonic acid [Et : Br : SO_3H = 1 : 2 : 3 or 5] was obtained by the sulphonation of bromethylbenzene. Its *barium salt* (with $3H_2O$), forms colourless plates, sparingly soluble in cold water; its *potassium salt* (with $\frac{1}{2}H_2O$), colourless scales; and the *sulphamide*, glistening prisms melting at 104—105°.

Parabromethylbenzeneorthosulphonic acid, similarly formed, yields a crystalline *barium salt* (with $4H_2O$), easily soluble in water. The *potassium salt* forms easily soluble scales, the *sulphonamide* large, micaceous scales, melting at 123—124°.

Barium orthoethylbenzenesulphonate (with H_2O), formed by debrominating the bromine-derivative, forms soluble scales; the *cadmium salt*, long, soluble needles; the potassium salt very soluble, glistening scales.

Barium orthoethylphenolmetasulphonate forms microscopic scales. *Barium meta-ethylbenzenesulphonate* (with $2H_2O$), obtained by debrominating the bromine-derivative, forms crystals easily soluble in water; the *potassium salt*, easily soluble scales; the *sulphonamide*, glistening scales melting at 85—86°. When fused with potash, this acid yields *meta-ethylphenol*, which forms a colourless oil liquid at −20°, and boiling at 202—204°.

Barium meta-ethylphenolsulphonate forms easily soluble crystals.

L. T. T.

Disulphones and Trisulphones. By E. Fromm (*Annalen*, **235**, 135—167).—Baumann and Escales (Abstr., 1887, 123) obtained ethylidenediethylsulphone by oxidising α-dithioethylpropionic acid. It is more conveniently prepared by acting on a mixture of acetaldehyde and ethyl mercaptan with zinc chloride. The resulting ethyl mercaptal of acetaldehyde (b. p. 186°) is oxidised by agitation with a solution of potassium permanganate containing sulphuric acid. Ethylidenediethylsulphone melts at 75°, and boils at 320° with decomposition. The bromide melts at 115°. Attempts to obtain substitution-products by the action of alkalis, sodium ethoxide, mercaptan, or aniline on the bromide were unsuccessful (Abstr., 1888, 357). *Ethylidenediethylsulphone chloride*, $CMeCl(SO_2Et)_2$, and sodium phenylsulphinite are formed by the action of benzenesulphonic chloride on ethylidenediethylsulphone and sodium ethoxide. The chloride can be prepared by exposing to direct sunlight for several days an aqueous solution of ethylidenediethylsulphone saturated with chlorine. It is deposited from an aqueous solution in needles which melt at 102—103°. The iodide is prepared by boiling the disulphone with an excess of iodine, the crude product being treated with a cold solution of sodium hydroxide, then washed with cold water, and finally recrystallised from boiling water. The iodide crystallises in needles and melts at 128—129°; at a higher temperature it gives off iodine.

Diethylsulphonedimethylmethane has been described by Baumann (Abstr., 1887, 123). It can be prepared by the action of methyl iodide on an alkaline aqueous solution of ethylidenediethylsulphone.

Diethylsulphonethylmethylmethane is formed by boiling a mixture of sodium ethoxide, ethyl iodide, and ethylidenediethylsulphone in a flask with a reflux condenser. It forms quadratic crystals, and melts at 76°.

The ethyl mercaptal of propaldehyde is lighter than water, and boils between 196° and 200°. On oxidation with permanganate, it yields propylidenediethylsulphone, $CH_3·CH_2·CH(SO_2Et)_2$; this crystallises in silky needles and melts at 77—78°. The ethyl mercaptal of isobutaldehyde boils between 200 and 210°; it is lighter than water. *Isobutylidenediethylsulphone* melts at 94° and crystallises in needles; it is almost insoluble in cold water. The ethyl mercaptal of benzaldehyde, $PhCH(SEt)_2$, is lighter than water, and boils with decomposition at 250—255°. *Benzylidenediethylsulphone* melts at 133—134°; it is insoluble in cold water, but is soluble in cold solutions of the alkalis. By the action of sodium ethoxide and methyl iodide, it is converted into diethylsulphonemethylmethane.

Diethylsulphonemethane, prepared by the oxidation of the ethyl mercaptal of formaldehyde (from methylene chloride and sodium ethyl mercaptide) is identical with the disulphone Baumann obtained from ethyl orthothioformate (Abstr., 1887, 124). It is converted into diethylsulphonedimethylmethane (sulphonal) by the action of methyl iodide in the presence of an alkali; this melts at 125—126°. *Diethylsulphonediethylmethane* is more difficult to propare. It melts at 86—88°. An aqueous solution of diethylsulphonemethane readily absorbs chlorine, forming the dichloride, $CCl_2(SO_2Et)_2$. It crystallises in needles and melts at 98—99°. The corresponding diethylsulphonedibromomethane has already been described by Baumann (*loc. cit.*).

Diethylsulphonedi-iodomethane melts at 176—177°, but begins to turn brown at 170°. It crystallises in needles, and is sparingly soluble in hot water.

Diphenylsulphonemethane, $CH_2(SO_2Ph)_2$, prepared by oxidising the phenyl mercaptal of formaldehyde, crystallises in needles and melts at 118—119°. It is soluble in benzene and hot alcohol. Diphenylsulphonedimethylmethane melts at 128° and is soluble in hot alcohol. The corresponding diethyl-derivative melts at 130—131°, and is sparingly soluble in hot alcohol.

When diethylsulphonedibromomethane (1 mol.) is boiled with phenyl mercaptan (1 mol.) and an aqueous solution of sodium hydroxide (rather more than 3 mols.), phenyl bisulphide and diethylsulphonethiophenylmethane are formed. The former is deposited from the solution on cooling, whilst the latter separates out on acidifying the filtrate; it is washed with cold water and recrystallised from absolute alcohol.

Diethylsulphonethiophenylmethane, $PhSCH(SO_2Et)_2$, crystallises in plates and melts at 86°. It is sparingly soluble in hot water and more readily soluble in a solution of sodium hydroxide. On oxidation by permanganate, *diethylsulphonephenylsulphonemethane*,

$$PhSO_2 \cdot CH(SO_2Et)_2,$$

is produced. This trisulphone melts at 165°. It is less soluble in alcohol than in water, and is precipitated from its aqueous solution by strong acids. The aqueous solution turns litmus red, and decomposes carbonates. W. C. W.

Phenylated Indoles. By W. H. Ince (*Annalen*, 253, 35—44).—3′-Phenylindole yields a crystalline *picrate* soluble in benzene, ether, acetone, and alcohol, and melts at 105°. The *nitrosamine*, $C_{14}H_{10}N_2O$, forms minute, yellow needles, and melts at 60—61°; it is freely soluble in benzene, acetone, ether, and chloroform, but is insoluble in solutions of caustic alkalis. Phenylacetaldehydemethylphenylhydrazone is formed by the interaction of phenylacetaldehyde and methylphenylhydrazine. The alcoholic solution of this compound is decomposed by an alcoholic solution of hydrogen chloride with deposition of ammonium chloride. The liquid is neutralised with ammonia and evaporated, leaving a residue of impure 1′-3′-*methylphenylindole;* this is purified by solution in ether and distillation in a vacuum. The pure indole dissolves in benzene, alcohol, and ether; its alcoholic solution gives a blue colour to a pine chip moistened with hydrochloric acid. The picrate forms dark brown needles, and melts at 90°. Fischer and Schmidt (Abstr., 1888, 958) pointed out that zinc chloride at 170° converts 3′-phenylindole into 2′-phenylindole. In the same way, zinc chloride at 220° transforms 1′-3′-methylphenylindole into the 1′-2′-methylphenylindole described by Degen (Abstr., 1887, 149).

3′-*Phenyl-β-naphthindole* is obtained by the action of alcoholic hydrogen chloride on the hydrazone produced by the interaction of phenylacetaldehyde and β-naphthylhydrazine; it crystallizes in glistening needles, and melts with decomposition at 211°, is soluble in benzene, alcohol, ether, acetone, and hot light petroleum, and stains a pine chip green. The *picrate* forms reddish-brown needles, melts at 119—120°, and is soluble in benzene, acetone, chloroform, alcohol, and ether. The 3′-phenyl-β-naphthindole is converted into 2′-phenyl-β-naphthindole by treatment with zinc chloride at 130°. 2′-Phenyl-β-naphthindole can be more conveniently prepared by the action of zinc chloride on acetophenone-β-naphthylhydrazone, obtained by the condensation of acetophenone and β-naphthylhydrazine. The hydrazone melts at 150°, but it begins to turn brown at 117°. *β-naphthindole* melts at 129—130°, and is freely soluble in alcohol, ether, and benzene. It forms a crystalline picrate (m. p. 165—166°), which is soluble in benzene and ether.

W. C. W.

Benzidine- and Benzidinesulphone-sulphonic Acids. By P. Griess and C. Duisberg (*Ber.*, 22, 2459—2474).—*Benzidinesulphonic acid*, $NH_2 \cdot C_6H_4 \cdot C_6H_3(NH_2) \cdot SO_3H$, is formed in small quantities in the preparation of the disulphonic acid (compare Griess, Abstr., 1881, 428), and it can also be obtained in larger quantity by heating benzidine sulphate for 1½ to 2 hours at 170° with sulphuric acid monohydrate (about 6 parts). It is best prepared by heating benzidine sulphate at 170° for about 24 hours (D.R.-P., No. 44,779). It forms anhydrous crystals, and is very sparingly soluble in boiling water, and practically insoluble in alcohol and ether; it is decomposed when heated, yielding a small quantity of benzidine. The *hydrochloride*, $C_{12}H_{12}N_2SO_3,HCl$, separates from hot, dilute, hydrochloric acid in greyish, nodular, anhydrous crystals, and is decomposed by boiling water. The *barium* salt, $(C_{12}H_{11}N_2SO_3)_2Ba + 5H_2O$, is moderately easily soluble in hot water, and separates on cooling in small needles or plates. The *tetrazo*-compound is obtained when an excess of hydrochloric acid and a slight excess of sodium nitrite are added to an ice-cold alkaline solution of the sulphonic acid. It is readily soluble in water, and combines with phenols, hydroxysulphonic acids, and aromatic hydroxycarboxylic acids in alkaline solution, and with amines and amidosulphonic acids in sodium acetate solution, forming yellow, red, and purple dyes. The compounds obtained with the hydroxycarboxylic acids, phenols, and amines respectively are sparingly soluble; the other dyes are readily soluble in water. They all dye unmordanted cotton wool in an alkaline bath, and generally the shade produced is more distinctly purple than that obtained with tetrazodiphenyl dyes, but not so much so as that produced with tetrazodiphenyldisulphonic acid colouring matters.

Benzidinemetadisulphonic acid (compare Griess, *loc. cit.*) is best prepared by heating benzidine sulphate (1 part) with sulphuric acid (2 parts) at 210° for 36 to 48 hours; the yield of the pure compound is 90 per cent. The azo-compounds derived from the tetrazo-derivative do not dye vegetable fibres as readily as those obtained from the tetrazomonosulphonic acid, but they have a more decided blue shade.

Benzidine is not acted on by fuming sulphuric acid at temperatures below 100—120°, but the azo-compounds obtained from tetrazodiphenyl and naphthylamines react with fuming sulphuric acid in the cold, the hydrogen in the benzidine being substituted.

Benzidinetrisulphonic acid $C_6H_2(NH_2)(SO_3H)_2 \cdot C_6H_3(NH_2) \cdot SO_3H + 2H_2O$, is obtained, together with the tetrasulphonic acid, when benzidine sulphate is heated for a long time at 180—190° with sulphuric acid monohydrate, or when a solution of benzidine in a little sulphuric acid monohydrate is heated at 160—170°, poured into fuming sulphuric acid, and heated again until a small portion gives only a slight precipitate when treated with water. The product is poured into water, the solution filtered to separate small quantities of the disulphonic acid, and neutralised with barium carbonate. The barium salt of the trisulphonic acid is readily soluble in cold water, and can be easily separated from the salt of the tetrasulphonic acid, which is only sparingly soluble. Benzidinetrisulphonic acid is precipitated in soft, colourless plates on adding concentrated hydrochloric acid to a moderately concentrated solution of the barium salt. It is readily soluble in cold water, but only sparingly in alcohol, and is reprecipitated from the alcoholic solution on adding ether; it is completely decomposed when heated. The *barium* salt,

$$(C_{12}H_9N_2S_3O_9)_2Ba_3 + 12H_2O,$$

crystallises in small, colourless prisms, and is precipitated from its concentrated aqueous solution on adding alcohol.

Benzidinetetrasulphonic acid,

$$C_6H_2(NH_2)(SO_3H)_2{\cdot}C_6H_2(NH_2)(SO_3H)_2,$$

is precipitated in small, colourless needles on adding hydrochloric acid to a concentrated aqueous solution of the barium salt; it is very readily soluble in cold water, and is also soluble in alcohol. The *barium* salt, $C_{12}H_8S_4O_{12}Ba_2 + 8H_2O$, crystallises in colourless needles or prisms, and is very sparingly soluble in hot water and insoluble in alcohol.

Benzidinesulphone,  $\begin{array}{l}C_6H_3(NH_2)\\ | \\ C_6H_3(NH_2)\end{array}\!\!>SO_2$, is best prepared by gradually adding benzidine sulphate (1 part) to a 20 per cent. sulphuric acid solution of sulphuric anhydride and heating the mixture on the water-bath until it is free from unchanged benzidine; the product is poured on to ice, and the benzidinesulphone sulphate is separated by filtration and decomposed with soda. It crystallises in very small, yellow, anhydrous needles, melts above 350°, and is almost insoluble in boiling water, and insoluble in alcohol, ether, and benzene. The salts are decomposed by water. The *hydrochloride*, $C_{12}H_{10}N_2SO_2,2HCl$, crystallises from hot, dilute, hydrochloric acid, in which it is moderately easily soluble, in almost colourless plates. The *sulphate*,

$$C_{12}H_{10}N_2SO_2,H_2SO_4 + 1\tfrac{1}{2}H_2O,$$

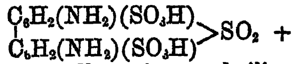
crystallises in grey or colourless needles or plates, and is only sparingly soluble in hot, dilute sulphuric acid. The *platinochloride* crystallises in small, dark, yellow plates, and is insoluble in water.

A *hydroxybenzidine*, $C_{12}H_{11}N_2{\cdot}OH$, is formed when the sulphone is heated at 180° with caustic soda; it is a grey compound, very sparingly soluble in water, but readily in soda. The *sulphate* and *hydrochloride* are sparingly soluble in water.

When benzidinesulphone hydrochloride is treated with sodium nitrite in aqueous solution, and the resulting brown, amorphous, tetrazo-compound reduced with stannous chloride and hydrochloric acid, the hydrazine is obtained in small, yellow needles sparingly soluble in water. The latter is decomposed when boiled with copper sulphate solution, yielding a diphenylenesulphonic acid melting at 228°, and identical with the compound obtained by Stenhouse (*Annalen*, **156**, 332) from diphenylene sulphide.

The azo-dyes obtained from benzidinesulphone differ from those of benzidine and benzidinesulphonic acids in possessing a marked blue shade.

Benzidinesulphonesulphonic acid,  $SO_3H{\cdot}C_6H_2(NH_2)<\begin{array}{l}C_6H_3(NH_2)\\ SO_2\text{———}\end{array}>$, is formed, together with the di-, tri-, and tetra-sulphonic acid, when the sulphone is heated with fuming sulphuric acid at temperatures above 100°. The crude product is poured on to ice, and, after keeping for some time, the solution is filtered; the tri- and tetra-sulphonic acids, being readily soluble in cold water, pass into the filtrate, whilst the mono- and di-sulphonic acid, which are only sparingly soluble, remain on the filter. The residue is dissolved in soda, and the monosulphonic acid is precipitated from the filtered solution by adding acetic acid; the disulphonic acid in the filtrate is then precipitated by adding a large excess of hydrochloric or sulphuric acid. Benzidinesulphonesulphonic acid crystallises from hot water, in which it is only sparingly soluble, in small, light-yellow needles, and is almost insoluble in alcohol. The *tetrazo*-derivative is a reddish-brown, amorphous compound; it combines with amines, phenols, and with their carboxylic and sulphonic acids, forming dyes which are of a redder shade, and are much more sparingly soluble than those derived from benzidinesulphonedisulphonic acid (see below). The *calcium* salt, $(C_{12}H_9N_2S_2O_5)_2Ca + 8\frac{1}{2}H_2O$, crystallises in small, yellow needles, and is readily soluble in hot water, but only moderately so in boiling alcohol, and sparingly in cold water. The *barium* salt (with $3\frac{1}{2}H_2O$) crystallises in small, golden needles, and is more sparingly soluble in water than the calcium salt.



Benzidinesulphonedisulphonic acid, $\begin{matrix}C_6H_2(NH_2)(SO_3H)\\ | \\ C_6H_2(NH_2)(SO_3H)\end{matrix}\!\!>SO_2 + 1\frac{1}{2}H_2O$, separates in small, light-yellow needles when a boiling aqueous solution is evaporated. It is moderately easily soluble in hot water, but only sparingly in alcohol, and almost insoluble in cold hydrochloric or sulphuric acid. The *tetrazo*-compound is a light-yellow, voluminous substance; it combines with naphthols and naphtholsulphonic acids, yielding purple to violet dyes, and with naphthylamines and naphthylaminesulphonic acid, forming red or bluish-violet colouring matters. It yields beautiful reddish-violet or indigo-blue azo-dyes (sulphoneazurines) with alkyl- and phenyl-naphthylamines. The *calcium* salt, $C_{12}H_8N_2S_3O_8Ca + 7H_2O$, crystallises in yellow needles or plates, and is readily soluble in hot, but only sparingly in cold water, and insoluble in alcohol. The *barium* salt (with $4\frac{1}{2}H_2O$) crystallises in needles or very small prisms, and is insoluble in alcohol, and only very sparingly soluble in boiling water. The *sodium* salt crystallises from hot, concentrated, aqueous solutions in long, yellow needles, and is only sparingly soluble in cold water.

Orthotolidine yields analogous compounds to those obtained from benzidine under the same conditions. *Orthotolidinesulphonic acid* is very sparingly soluble in water, and does not crystallise readily. The *tetrazo*-derivative is readily soluble in water. The *barium* salt loses 4 mols. H_2O when dried at 150°. The *disulphonic acid* crystallises from hot, concentrated, aqueous solutions in small, colourless, needles, and is readily soluble in hot water. The *tetrazo*-derivative is insoluble in water. The salts are moderately easily soluble in water; the *sodium* salt crystallises in cubes (with $4H_2O$), the *calcium* salt in plates (with $5H_2O$), and the *barium* salt in needles (with $3H_2O$).

Tolidinesulphone is a greenish-yellow, amorphous compound, the salts of which are very similar to those of benzidinesulphone (D.R.-P., No. 44,784).

F. S. K.

β-Naphthylhydrazine. By F. HAUFF (*Annalen*, **253**, 24—35).—The derivatives of β-naphthylhydrazine bear a close resemblance to the corresponding phenylhydrazine-derivatives. The acetyl-derivative, $C_{10}H_7\cdot N_2H_2Ac$, prepared by boiling β-naphthylhydrazine with glacial acetic acid for several hours in a reflux apparatus, forms colourless needles soluble in alcohol, chloroform, and benzene, and melts at 164—165°. *Benzoylnaphthylhydrazine*, $C_{10}H_7\cdot N_2H_2Bz$, is obtained on adding benzoic chloride to an ethereal solution of naphthylhydrazine (2 mols.); naphthylhydrazine hydrochloride is precipitated, and the filtrate on being evaporated, and the residue treated with a hot dilute solution of sodium hydroxide to remove unaltered benzoic chloride leaves the hydrazine. When pure it crystallises in needles, melts at 154—155°, and is soluble in hot alcohol, ether, benzene, and chloroform. In order to introduce a second benzoyl-group into the preceding compound, it is necessary to act on it with benzoic chloride at a high temperature. The *dibenzoyl*-derivative, $C_{10}H_7\cdot N_2HBz_2$, melts at 162—163°.

β-Naphthylsemicarbazide, $C_{10}H_7\cdot N_2H_2\cdot CO\cdot NH_2$, prepared by the action of potassium cyanate on naphthylhydrazine hydrochloride, is soluble in hot alcohol and acetic acid; it melts at 220° (uncorr.), and resembles the corresponding phenyl-derivative in its chemical properties. It is decomposed by the action of hydrochloric acid in sealed tubes at 140°, yielding naphthazine, which has previously been described by Witt (Abstr., 1887, 153).

β-Naphthylthiosemicarbazide, $C_{10}H_7\cdot N_2H_2\cdot CS\cdot NH_2$, is obtained by boiling an alcoholic solution containing equal parts by weight of naphthylhydrazine hydrochloride and ammonium thiocyanate. This substance melts at 201—202° (uncorr.), and is soluble in hot aniline and alcohol. It is decomposed by hydrochloric acid in sealed tubes at 130—140°, yielding *naphthylthiocarbizine*,  $C_{10}H_7N{<}\begin{array}{l}NH\\ |\\ CS\end{array}$. The carbizine melts at 253—254°, and crystallises in plates. It is soluble in warm alcohol, and forms a crystalline hydrochloride and platinochloride. A violet precipitate is formed when bleaching powder is added to the alcoholic solution of the base.

Naphthylhydrazine naphthylthiocarbazinate,

$$C_{10}H_7\cdot N_2H_2\cdot CS\cdot SH,N_2H_3\cdot C_{10}H_7,$$

crystallises in plates and melts with decomposition at 145°. It is soluble in warm alcohol.

Ethyl-β-naphthylhydrazine is prepared by the action of ethyl iodide (2 mols.) on naphthylhydrazine in alcoholic solution. It is a pale-yellow oil, freely soluble in alcohol, ether, benzene, and chloroform. It reduces warm Fehling's solution. The solution in chloroform is slowly decomposed by mercuric oxide, yielding naphthylethylamine.

W. C. W.

Derivatives of β-Naphthylhydrazine. By A. HILLRINGHAUS (*Ber.*, **22**, 2656—2657).—In reference to Hauff's work on this subject (preceding Abstract), the author states that he has also recently obtained the acetyl-derivative, the semicarbazide, and the thiosemicarbazide. L. T. T.

Derivatives of the Two Isomeric Naphthenylamidoximes

By E. Richter (*Ber.*, 22, 2419—2459; compare Abstr., 1887, 374, also Ekstrand, *ibid.*, 373).—β-Napthenylamidoxime (m. p. 150) is readily soluble in alcohol and ether, but only moderately easily in benzene and chloroform and insoluble in light petroleum. The corresponding α-compound (m. p 148—149) resembles the β-derivative in its behaviour with solvents.

Benzoyl-β-naphthenylamidoxime, $C_{10}H_7\cdot C(NH_2):NOBz$, prepared by heating the amidoxime with benzoic chloride, crystallises from hot alcohol in colourless needles, melts at 179°, and is only sparingly soluble in cold alcohol, ether, benzene, chloroform, and light petroleum, insoluble in water.

Naphthenylbenzenylazoxime, $C_{10}H_7\cdot C{<}\genfrac{}{}{0pt}{}{NO}{N}{>}CPh$, is formed when the preceding compound is boiled with water, dilute acids, or dilute alkalis, or when it is treated with concentrated sulphuric acid. It crystallises from dilute alcohol in colourless plates, melts at 116°, and is readily soluble in alcohol, ether, benzene, chloroform, and light petroleum, but almost insoluble in water.

Acetyl-β-naphthenylamidoxime, $C_{1}H_{12}N_2O_2$, crystallises from alcohol or benzene in yellowish needles, melts at 154°, and is only sparingly soluble in ether, chloroform, and light petroleum, and insoluble in water; when boiled with water, or when treated with concentrated sulphuric acid, it is converted into the azoxime melting at 85° (compare Ekstrand, *loc. cit.*).

Ethyl-β-naphthenylamidoximecarboxylate, $C_{10}H_7\cdot C(NH_2):NO\cdot COOEt$, separates from alcohol in colourless needles, melts at 121°, and is readily soluble in alcohol, ether, benzene, chloroform, and acids, but very sparingly in light petroleum, and insoluble in water and alkalis.

β-Naphthenylcarbonylimidoxime, $C_{10}H_7\cdot C{<}\genfrac{}{}{0pt}{}{NO}{NH}{>}CO$, crystallises from hot benzene in colourless needles, melts at 216°, and is moderately soluble in alcohol, ether, and chloroform, but sparingly in benzene and hot water. The *sodium*-derivative is crystalline. In an aqueous solution of the ammonium-derivative, lead acetate produces a white, and copper sulphate an apple-green precipitate.

β-Naphthenylamidethoxime, $C_{10}H_7\cdot C(NH_2):NOEt$, crystallises from dilute alcohol in colourless needles, melts at 74—75°, and is readily soluble in alcohol, ether, benzene, chloroform, light petroleum, and hydrochloric acid, but very sparingly in water, and insoluble in alkalis.

Ethylidene-β-naphthenylamidoxime, $C_{10}H_7\cdot C{<}\genfrac{}{}{0pt}{}{NO}{NH}{>}CHMe$, prepared by dissolving the amidoxime in acetaldehyde, crystallises from hot water in colourless needles, melting at 121—122°. It is readily soluble in alcohol, ether, benzene and light petroleum, very sparingly soluble in cold water, and insoluble in acids and alkalis.

Acetoethenyl-β-naphthenylazoxime, $C_{10}H_7\cdot C{<}\genfrac{}{}{0pt}{}{NO}{N}{>}C\cdot CH_2Ac$, is formed by boiling the amidoxime with ethyl acetoacetate; it crystallises from hot water in nacreous plates, melts at 108—109° and is soluble in alcohol, ether, benzene, and chloroform but insoluble in light petroleum.

Acetyl-α-naphthenylamidoxime crystallises from dilute alcohol in colourless needles, melts at 129°, and is insoluble in water, but readily soluble in alcohol, ether, benzene, and chloroform; when treated with concentrated sulphuric acid, or when boiled with water, it is converted into the azoxime (compare Ekstrand, *loc. cit.*).

Ethyl-α-naphthenylamidoximecarboxylate crystallises in colourless needles, melts at 111°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in light petroleum, and insoluble in water.

α-Naphthenylcarbonylimidoxime, prepared by boiling the preceding compound with water or alkalis, crystallises from dilute alcohol in colourless needles, melts at 189°, and is readily soluble in alcohol but only sparingly in ether, benzene, and chloroform and insoluble in light petroleum and water. In aqueous solutions of the ammonium-derivative, lead acetate produces a white, and copper sulphate a green precipitate. F. S. K.

Acetyl- and Ethyl-derivatives of Camphonitrophenol. By P. Cazeneuve (*Bull. Soc. Chim.* [3], 1, 467—469; compare Abstr., 1889, 618).—The acetyl-derivative of camphonitrophenol, $C_8H_{14}{<}\begin{matrix}C\cdot NO_2\\ \|\\ C\cdot OAc\end{matrix}$, after saponification and subsequent saturation with slight excess of hydrogen chloride, gives with ferric chloride a violet-red coloration, which indicates the formation of the compound $C_8H_{14}{<}\begin{matrix}CH\cdot NO_2\\ |\\ C(OH)_2\end{matrix}$. The ethyl-derivative, $C_8H_{14}{<}\begin{matrix}C\cdot NO_2\\ \|\\ C\cdot OEt\end{matrix}$, is made by heating sodium camphonitrophenoxide with excess of ethyl iodide in sealed tubes at 120° for three hours; after separation of sodium iodide, the liquid is evaporated to dryness and the residue crystallised from benzene. The compound forms large, colourless, flat crystals, which melt at 54° and decompose on distillation. T. G. N.

Camphonitrophenol Phosphate. By P. Cazeneuve (*Bull. Soc. Chim.* [3], 1, 469—471).—The normal phosphate, $(C_{10}H_{14}NO_2)_3PO_4$, is prepared by boiling camphonitrophenol with phosphorus trichloride for several hours. It exists as an amorphous, yellowish, insoluble substance, which, when heated, decomposes without melting. Nitrophenol forms an analogous compound, $(C_6H_4NO_2)_3PO_4$, with phosphorus pentachloride, only traces of metachloronitrobenzene being simultaneously produced. This reaction confirms the constitution previously given to camphonitrophenol. T. G. N.

Camphonitrophenol Benzoate and Phthalate. By P. Cazeneuve (*Bull. Soc. Chim.* [3], 1, 471—472).—The benzoate,  $C_8H_{14}<\begin{matrix}C\cdot NO_2\\ \|\\ C\cdot OBz\end{matrix}$ is prepared by the reaction of equal parts of camphonitrophenol and benzoic chloride at 100°; it forms small crystals which are insoluble in water, but soluble in hot alcohol, ether, and benzene; these melt at 131°; and partially volatilise at 150° without decomposing. On saponification with alcoholic potash, it yields potassium benzoate and the compound  $C_8N_{14}<\begin{matrix}C\cdot NO_2\\ |\\ C(OH)_2\end{matrix}$.

Phthalic chloride by a similar reaction forms a compound,

$$(NO_2\cdot C_{10}H_{14}O)_2C_8H_4O_2,$$

which melts at 275° with slight decomposition. T. G. N.

Quercetin-derivatives. By J. Herzig (*Monatsh.*, 10, 561—567; compare Abstr., 1888, 1309).—In a previous communication the author has called attention to the fact that pure xanthorhamnin is not the sole product obtained from Persian-berries by the method of Liebermann and Hormann (Abstr., 1879, 271). It is now shown that besides xanthorhamnin, the berries contain a glucoside of rhamnetin or some unstable molecular compound of the glucosides of rhamnetin and quercetin. This result is in accordance with the fact that Schützenberger obtained two glucosides (α- and β-rhamnin) from Persian-berries. His α-rhamnetin (from α-rhamnin) is evidently identical with rhamnetin, his β-rhamnetin (from β-rhamnin) with quercetin. G. T. M.

Scutellarin, one of the Constituents of Scutellaria lanceolaria. By D. Takahashi (*Chem. Centr.*, 1889, ii, 100.)—The root of *Scutellaria lanceolaria*, one of the labiatæ, is used medicinally in China and Japan. By extracting the root with ether, agitating the ether extract with sodium hydroxide, and acidifying the alkaline solution, a yellow, flocculent substance, *scutellarin*, is obtained. It forms odourless and tasteless, shining, flat, yellow needles, melts at 199—199 5°, is insoluble in cold, little soluble in hot water, very readily soluble in alcohol, ether, chloroform, light petroleum, and carbon bisulphide; soluble in sodium hydroxide and carbonate solutions, but carbonic anhydride is not expelled from the latter. It dissolves in concentrated sulphuric acid with a yellow coloration and water reprecipitates the substance unchanged. It dissolves in nitric acid with red coloration, and in like manner in a solution of sulphuric acid and potassium nitrite. Fehling's solution is not reduced by it, even after boiling with hydrochloric acid. It does not combine with phenylhydrazine; neither silver nitrate nor lead acetate precipitates it from its alcoholic solution, but solutions of lead and copper acetates produce a yellow-red precipitate with the alcoholic solution. When treated with bromine in carbon bisulphide solution, a substance crystallising in yellowish needles is formed; the determination of bromine in it, however, gave unsatisfactory results. The elementary analysis of scutellarin gave figures which corresponded with the formula $C_{10}H_8O_3$; it contains neither nitrogen nor water of combination. 5 grams of scutellarin produced no effect when administered to a dog in an emulsion of milk and gum arabic. The author believes it to be a phenol, and possibly an isomeride of juglone. J. W. L.

Crystallised Digitalin. By ARNAUD (*Compt. rend.*, **109**, 679—682).—Digitalin prepared by Nativelle's method from the *digitalis* of the Vosges formed very thin, brilliant, white, rectangular lamellæ, which melt at 243°, dissolve in absolute alcohol to the extent of 0·650 part in 100 at 14°, and also, contrary to the statement of Schmiedeberg, dissolve in boiling benzene. When subjected to fractional solution, the melting points of the different fractions varied only between 242° and 245°.

A second quantity prepared by Adrian melted at 245—246°, and when dissolved fractionally in alcohol and benzene the melting points varied only between 243 and 245°, as with the first sample.

Digitalin is a distinct chemical individual, and it is not necessary to denote it by any name such as digitoxin. It seems to be the type of a large group of compounds. C. H. B.

Dihydropyrroline. By F. ANDERLINI (*Ber.*, **22**, 2512—2515).—Dihydropyrroline hydrochloride is decomposed when heated, giving off vapours which colour pine-wood red; it is partially decomposed by concentrated hydrochloric acid at 130—140°. The *aurochloride*, $C_4NH_7,HAuCl_4$, crystallises from cold water in small prisms, melts at 152°, and is slowly decomposed when boiled with water. The *picrate*, $C_4NH_7,C_6H_3N_3O_7$, separates from water in yellow crystals, melts at 156°, and is readily soluble in alcohol and water.

Benzoyldihydropyrroline, C_4NH_6Bz, prepared by heating dihydropyrroline hydrochloride with benzoic chloride at 110°, is an oily liquid, boils at 160—161° (2 mm.), and is miscible with alcohol and ether, but is insoluble in water. It dissolves freely in concentrated hydrochloric acid, yielding a salt which does not crystallise readily.

Benzyldihydropyrroline, $C_4NH_6{\cdot}CH_2Ph$, prepared by treating dihydropyrroline with benzyl chloride, boils at 150°. The *aurochloride*, $C_{11}H_{13}N,HAuCl_4$, crystallises from water in yellow needles melting at 111°. F. S. K.

Derivatives of Alkylpyrrolines. By C. U. ZANETTI (*Ber.*, **22**, 2515—2519; compare Ciamician and Zanetti, Abstr., 1889, 727).—1-Ethylpyrroline boils at 129—130° (762 mm., corr.). The tetrabromide melts at 83° and is converted into ethyl dibromomaleïmide (m. p. 93—94°) by cold nitric acid of sp. gr. 1·49. The *diacetyl-derivative*, $C_4NH_2EtAc_2$, is a crystalline compound, melts at 58—59°, boils at about 183° (29 mm.), and is readily soluble in alcohol, ether, benzene, light petroleum, and warm water.

When the mixture of *c*-ethylpyrrolines, boiling at 150° (compare Ciamician and Zanetti, *loc. cit.*), is treated with acetic anhydride and sodium acetate, an oil is obtained which can be separated by fractional distillation into a portion boiling at 210—235° and a portion boiling at 240—255°. The former is volatile with steam and has the composition and properties of an 1-acetyl-*c*-ethylpyrroline, C_4NH_3EtAc. The latter, after having been boiled with potash and repeatedly distilled in order to free it from 1-acetyl derivatives, solidifies partially when exposed to long continued cold, and can thus be separated into its constituents; the crystalline substance is an acetyl-derivative melting at 42—44°, probably identical with the compound (m. p. 47°) obtained by Dennstedt and Zimmermann from *c*-ethylpyrroline (compare Abstr., 1886, 1043). Both the liquid and the solid compound give a silver-derivative which has the composition $C_8H_{10}NOAg$.

1-*Propylpyrroline*, C_4NH_4Pr, is obtained in small quantities when potassium pyrroline is treated with propyl iodide, but isomerides and other compounds are also formed; it is a colourless oil boiling at 145·5—146·5° (755·8 mm.). F. S. K.

Nitropyrroline-α-carboxylic Acids. By F. ANDERLINI (*Ber.*, 22, 2503—2506).—*Methyl nitropyrroline-α-carboxylate*,

$$NO_2{\cdot}C_4NH_3{\cdot}COOMe,$$

(m. p. 197°) is formed, together with an isomeride (m.p. 179°) and other nitro-compounds, when finely divided methyl pyrroline-α-carboxylate is gradually added to ice-cold nitric acid of sp. gr. 1·5 and the solution poured into cold water; after neutralising with soda and adding a little sodium carbonate, the solution is extracted with ether. It crystallises from boiling water in colourless needles melting at 197°. The corresponding *acid*, $NO_2{\cdot}C_4NH_3{\cdot}COOH$, obtained by hydrolysing the ethereal salt with potash, crystallises from water with 1 mol. H_2O in light-yellow needles, and is readily soluble in alcohol, ether, and hot water, but only sparingly in benzene and cold water. It loses its water when kept over sulphuric acid under reduced pressure, and the anhydrous crystals melt at 217°.

Methyl nitropyrroline-α-carboxylate (m. p. 179°) is obtained, together with other nitro-compounds, when the alkaline solution from which the isomeride (m. p. 197°) has been extracted is acidified and then extracted with ether. It can be isolated by fractionally crystallising the crude product from water. It separates from dilute alcohol in yellow needles melting at 179°. The corresponding *acid* crystallises from hot water, with 1 mol. H_2O, in light-yellow needles, and is readily soluble in alcohol, ether, and hot water and moderately so in benzene, but only sparingly in cold water. It loses its water when kept over sulphuric acid under reduced pressure, the anhydrous compound melting at 161°.

The mother-liquors from the preceding compound (m. p. 179°) probably contain the third isomeride, which has previously been prepared by Ciamician and Danesi (Abstr., 1882, 875) from dinitropyrocoll, but this compound could not be obtained in a pure condition. They also contain the methyl salt of a dinitropyrrolinecarboxylic acid, $C_4NH_2(NO_2)_2{\cdot}COOMe$; this compound crystallises from water, dilute alcohol, and benzene in light-yellow plates melting at about 115°. F. S. K.

Molecular Weights of the Imidoanhydrides of Pyrrolinecarboxylic and Indolecarboxylic Acids. By G. MAGNANINI (*Ber.*, 22, 2501—2503). Molecular weight determinations by Raoult's method in naphthalene solution show that the molecular formula of pyrocoll is $C_{10}H_6N_2O_2$, that of tetramethylpyrocoll, $C_{14}H_{14}N_2O_2$, that of diacetylpyrocoll, $C_{14}H_{10}N_2O_4$, and that of the imidoanhydride of *a*-indolecarboxylic acid, $C_{18}H_{10}N_2O_2$. The depression constant of naphthalene was taken as 82, according to Raoult. F. S. K.

Action of Methyl Iodide on Tetramethyldihydropyridine. By F. ANDERLINI (*Ber.*, 22, 2506—2511).—Pentamethyldihydropyridine hydriodide is obtained when tetramethyldihydropyridine (b. p. 158°) is treated with methyl iodide (compare Ciamician and Anderlini, Abstr., 1889, 728) The free base boils at 188—190° (45—46°; 7 mm.).

A *base*, $C_{12}H_{21}N$, is formed when pentamethyldihydropyridine is treated with methyl iodide in the cold and the resulting oily hydriodide distilled with potash; the base was not isolated. The *aurochloride*, $C_{12}H_{21}N,HAuCl_4$, crystallises in thin, golden needles melting at 99—99·5°. F. S. K.

Synthesis of Oxypyridine and Piperidine Bases. By A. LADENBURG (*Ber.*, 22, 2583—2590).—*a-Picolylalkine*,

$$C_5NH_4\cdot CH_2\cdot CH_2\cdot OH,$$

is obtained as a thick brown syrup by the action of formaldehyde on *a*-picoline and is purified by distillation under 20—30 mm. pressure. It is a colourless syrup, boils at 179° under 25 mm. pressure, dissolves readily in water and alcohol, sparingly in ether; it is rather hygroscopic and can only be dried over fused potassium carbonate; sp. gr. 1·111 at 0°. The *platinochloride*, $(C_7H_9NO)_2,H_2PtCl_6$, crystallises well in prisms very readily soluble in hot water and melts at 170° with effervescence. The *aurochloride* crystallises in well-formed crystals rather sparingly soluble in water.

Vinylpyridine, $C_5NH_4\cdot C_2H_3$, prepared by distilling the above compound under higher pressure or in presence of potash, is a colourless, mobile liquid, very readily soluble in alcohol, ether, and chloroform, &c., but only sparingly in water. It boils with decomposition at 158—159° at the ordinary pressure, but distils without decomposition at 79—82° under 29 mm. pressure; sp. gr. = 0·9985 at 0°. The *platinochloride*, $(C_7H_7N)_2,H_2PtCl_6$, crystallises in needles or large plates, melts at 174° with decomposition, and is rather readily soluble in water. The *aurochloride*, *cadmioiodide*, *bismuth iodide*, and *mercurochloride* crystallise well.

a-Piperolylalkine, $C_5NH_{10}\cdot CH_2\cdot CH_2\cdot OH$, obtained by the action of sodium and alcohol on picolylalkine, is a colourless crystalline base which melts at 31—32° and boils at 225—228°. It is very hygroscopic and is readily soluble water, alcohol, and ether. It is a strong base and turns red litmus blue. The *platinochloride*, $(C_7H_{15}NO)_2,H_2PtCl_6$, crystallises in splendid, large, transparent crystals, like gypsum, and melts at 158°.

α-Methylpipecolinealkine, $C_5NH_9Me{\cdot}CH_2{\cdot}CH_2{\cdot}OH$, is formed when α-pipecolylalkine dissolved in methyl iodide is treated with methyl iodide and sodium at the ordinary temperature. When the methyl iodide has disappeared, the alcohol is evaporated, the residue repeatedly extracted with ether, the base converted into the hydrochloride, and warmed slightly with sodium nitrite The nitrosamine which separates is removed by ether. The hydrochloride is then treated with potash and the tertiary base is extracted with ether, and dried with potash. The *aurochloride* is crystalline; the *platinochloride*, *cadmioiodide*, and *periodide* were also prepared.

Vinylpiperidine, $C_5NH_{10}{\cdot}C_2H_3$ (?), is obtained from pipecolylalkin by the method previously employed for the preparation of tropidine from tropine (*Annalen*, **217**, 118). It is a colourless liquid, boils at 146—148°, is readily soluble in water, and has an odour of tropidine and coniine. The *aurochloride* and *picrate* crystallise well and are rather soluble in water.

α-Picolylmethylalkine, $C_5NH_4{\cdot}CH_2{\cdot}CHMe{\cdot}OH$, is formed in a manner similar to α-picolylalkine from α-picoline and acetaldehyde, and is purified by means of the platinochloride. It is yellowish, boils at 176—181° under 18 mm. pressure, and is readily soluble in water, alcohol, and chloroform, sparingly in ether. The *platinochloride*, $(C_8H_{11}NO)_2,H_2PtCl_6$, crystallises from hot water in small plates which melt at 189° with decomposition; the *aurochloride* crystallises well.

α-Pipecolylmethylalkine, $C_5NH_{10}{\cdot}CH_2{\cdot}CHMe{\cdot}OH$, melts at 47°, boils at 224—226°, and is readily soluble in water, alcohol, and ether, The *platinochloride* melts at 149°. In its properties, the base resembles conydrine, with which it is isomeric. N. H. M.

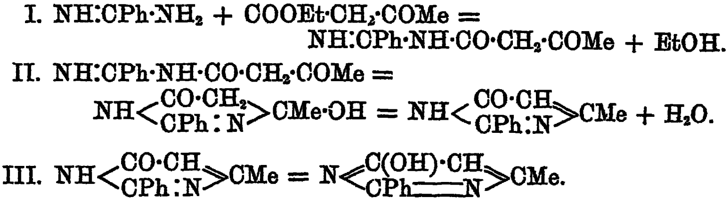
Hydroxymetadiazines (Hydroxypyrimidines). By E. v. MEYER (*J. pr. Chem.* [2], **40**, 303—304).—Amidomethyldiphenylmetadiazine (Abstr., 1889, 578) melts at 168°, not 172°; it can also be obtained by acting on a mixture of ethyl cyanide and phenyl cyanide with sodium or sodium ethoxide.

Hydroxymethyldiphenylmetadiazine (*loc. cit.*) melts at 250°, not 256°; it can also be obtained by the condensation of benzamidine and ethyl methylbenzoylacetate. By heating it with alkaline potassium permanganate, adding dilute hydrochloric acid to the colourless solution, dissolving the precipitate in weak ammonia, filtering, and again precipitating with hydrochloric acid, a *hydroxydiphenylmetadiazinecarboxylic acid*,  $CPh\genfrac{<}{>}{0pt}{}{N=CPh}{N{\cdot}C(OH)}C{\cdot}COOH$, is obtained; this crystallises from alcohol in beautiful, pale-yellow prisms melting at 236° with evolution of carbonic anhydride. When heated in a diphenylamine bath at 250° until evolution of carbonic anhydride ceases, it leaves a yellow, crystalline residue, mostly soluble in potash; if the precipitate obtained by adding hydrochloric acid to this potash solution is digested with weak ammonia and crystallised from alcohol, yellowish slender needles, $C_{16}H_{12}N_2O$, which melt at 280·5° (uncorr.), are obtained. These appear to be identical with Pinner's diphenylhydroxypyrimidine (Abstr. 1889, 1008), which melts at 284°.

Hydroxymethylethylmethylmetadiazine,  $\mathrm{CMe}{<}\begin{matrix}\mathrm{N{=}CEt}\\ \mathrm{N{\cdot}C(OH)}\end{matrix}{>}\mathrm{CMe}$, is obtained from acetamidine and ethyl propionylpropionate; it melts at 167·5°, and is isomeric with the hydroxy-base of cyanmethethine melting at 150° (Abstr. 1885, 646).

A. G. B.

Pyrimidines. By A. PINNER (*Ber.*, 22, 2609—2626; compare Abstr., 1889, 1006).—The formation of the pyrimidines appears to take place in three stages. Employing benzamidine and ethyl acetoacetate as examples, these stages are as follows:—



$$\text{I. } \mathrm{NH{:}CPh{\cdot}NH_2 + COOEt{\cdot}CH_2{\cdot}COMe = NH{:}CPh{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}COMe + EtOH.}$$

$$\text{II. } \mathrm{NH{:}CPh{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}COMe} = \mathrm{NH}{<}\begin{matrix}\mathrm{CO{\cdot}CH_2}\\ \mathrm{CPh:N}\end{matrix}{>}\mathrm{CMe{\cdot}OH} = \mathrm{NH}{<}\begin{matrix}\mathrm{CO{\cdot}CH}\\ \mathrm{CPh{:}N}\end{matrix}{>}\mathrm{CMe} + \mathrm{H_2O}.$$

$$\text{III. } \mathrm{NH}{<}\begin{matrix}\mathrm{CO{\cdot}CH}\\ \mathrm{CPh{:}N}\end{matrix}{>}\mathrm{CMe} = \mathrm{N}{<}\begin{matrix}\mathrm{C(OH){\cdot}CH}\\ \mathrm{CPh{=}N}\end{matrix}{>}\mathrm{CMe}.$$

The ethyloxalylacetylbenzamidine already described (Abstr., 1889, 1009) is the first-stage product in the formation of phenylhydroxypyrimidinecarboxylic acid, and may be easily converted into the latter by the action of soda. The compound obtained at the same time and melting at 263° is *phenylhydroxypyrimidinecarboxylbenzamidine*,  $\mathrm{N}{<}\begin{matrix}\mathrm{CPh{=}N}\\ \mathrm{C(OH){\cdot}CH}\end{matrix}{>}\mathrm{C{\cdot}CO{\cdot}NH{\cdot}CPh{:}NH}$, the benzamidine having reacted with the second carboxyl-group of the acetoxalate. It is converted into the above carboxylic acid by the action of soda. As already noted (*loc. cit.*) the free acid melts with decomposition at 247°; carbonic anhydride being evolved and phenylhydroxypyrimidine is formed.

When benzamidine and ethyl acetomalonate react on one another, one carboxyl-group is separated and the same pyrimidine formed as is obtained from ethyl acetoacetate.

When ethyl acetosuccinate, benzamidine hydrochloride, and sodium hydroxide or potassium carbonate are mixed together, two compounds are obtained melting respectively at 178° and 212°. The former (m. p. 178°) is *ethyl phenylmethylhydroxypyrimidineacetate*,

$$\mathrm{CPh}{<}\begin{matrix}\mathrm{N{-}CMe}\\ \mathrm{N{:}C(OH)}\end{matrix}{>}\mathrm{C{\cdot}CH_2{\cdot}COOEt.}$$

It is easily soluble in alcohol, ether, and acetone, sparingly in water, and crystallises in needles. When saponified with soda, it yields *phenylmethylhydroxypyrimidineacetic acid*, which crystallises in needles, melts at 259°, and is soluble in alcohol. The needles crystallising at 212° have the formula $C_{11}H_{10}N_2O_2$ and are probably *succinylbenzimide*,  $\begin{matrix}\mathrm{CH_2{\cdot}CO}\\ |\\ \mathrm{CH_2.CO}\end{matrix}{>}\mathrm{N{\cdot}CPh{:}NH}$. This compound forms the principal product if caustic soda is used for liberating the benzamidine from its hydrochloride in the reaction, whilst, if potassium carbonate is employed, the pyrimidine is the chief product.

With ethyl acetylglutarate, benzamidine yields *ethylphenylmethylhydroxypyrimidinepropionate*,  $\mathrm{CPh}\left<\begin{matrix}\mathrm{N-CMe}\\ \mathrm{N{:}C(OH)}\end{matrix}\right>\mathrm{C{\cdot}CH_2{\cdot}CH_2{\cdot}COOEt}$, which crystallises in needles, is soluble in alcohol, ether, and acetone, and melts at 145°. The *free acid* forms a white powder almost insoluble in water and alcohol and melting at 215°.

When ethyl diacetosuccinate is mixed with benzamidine, ethyl phenylmethylhydroxypyrimidineacetate (m. p. 178°) and *phenylmethylacetonylhydroxypyrimidine*,  $\mathrm{CPh}\left<\begin{matrix}\mathrm{N-CMe}\\ \mathrm{N{:}C(OH)}\end{matrix}\right>\mathrm{C{\cdot}CH_2{\cdot}COMe}$, are formed. The latter is insoluble in acetone, soluble in alcohol; it crystallises in needles and melts at 215°. The author was unable to obtain the dipyrimidine,  $\mathrm{CPh}\left<\begin{matrix}\mathrm{N-CMe}\\ \mathrm{N{:}C(OH)}\end{matrix}\right>\mathrm{C-C}\left<\begin{matrix}\mathrm{CMe-N}\\ \mathrm{C(OH){:}N}\end{matrix}\right>\mathrm{CPh}$, which he had anticipated, the second acetyl-group appearing always to be separated before the pyrimidine formation set in.

A mixture of ethyl succinylsuccinate and benzamidine yields a substance easily soluble in alcohol and melting at 272° and another almost insoluble in the usual solvents. The former, *tetrahydrophenylhydroxyketoquinazoline*,  $\begin{array}{l}\mathrm{N{:}C(OH){\cdot}C{\cdot}CH_2{\cdot}CH_2}\\ \mathrm{CPh = N{\cdot}C{\cdot}CH_2{\cdot}CO}\end{array}$, crystallises in needles. The latter, owing to its insolubility, could not be thoroughly purified, but appears to have the formula $C_{22}H_{16}N_4O_2$ and to be *dihydrodiphenyldihydroxyantetrazine*,  $\begin{array}{l}\mathrm{N{:}C(OH){\cdot}C{\cdot}CH_2{\cdot}C{\cdot}N = CPh}\\ \mathrm{CPh = N{\cdot}C{\cdot}CH_2{\cdot}C{\cdot}C(OH){:}N}\end{array}$. It dissolves in boiling caustic soda yielding a crystalline *sodium-derivative*, $C_{22}H_{14}Na_2N_4O_3 + 4H_2O$.

The amidine of acetonecyanhydrin, $\mathrm{OH{\cdot}CMe_2{\cdot}C(NH_2){:}NH}$, yields with ethyl acetoacetate, *hydroxyisopropylmethylhydroxypyrimidine*,  $\mathrm{OH{\cdot}CMe_2{\cdot}C}\left<\begin{matrix}\mathrm{N-CMe}\\ \mathrm{N{:}C(OH)}\end{matrix}\right>\mathrm{CH}$, crystallising in easily soluble needles and melting at 98°. If ethyl benzoylacetate is employed instead of the acetoacetate, *hydroxyisopropylphenylhydroxypyrimidine*,

$$\mathrm{OH{\cdot}CMe_2{\cdot}C}\left<\begin{matrix}\mathrm{N-CPh}\\ \mathrm{N{:}C(OH)}\end{matrix}\right>\mathrm{CH},$$

is formed. This crystallises in small, glistening prisms, sparingly soluble in water, easily so in the usual organic solvents, and melts at 198°. L. T. T.

Phenylhydrazonelevulinic Anhydride. By F. ACH (*Annalen*, 253, 44—57). Two compounds are formed by the action of phosphorus pentachloride on phenylhydrazonelevulinic anhydride at 150. One contains 2 atoms of hydrogen less than the anhydride and the second compound is a monochloro-substitution-product of the first. The crude product of the reaction is poured into water containing ice. In the course of 24 hours, phenylmethylchloropyridazone is deposited in crystals. The mother-liquor is rendered alkaline and treated with ether to extract the phenylmethylpyridazone. The residue is redissolved in 100 parts of boiling water, to which a small quantity of hydrochloric acid is added. On cooling, the chloro-substitution-product crystallises out and the base is extracted from the mother-liquor as before. It is finally purified by precipitation as the hydrochloride by passing dry hydrogen chloride through its solution in benzene. *Phenylmethylpyridazone*,  $\mathrm{CO}<\begin{matrix}\mathrm{NPh\cdot N}\\ \mathrm{CH{:}CH}\end{matrix}>\mathrm{CMe}$, is freely soluble in alcohol, ether, chloroform, benzene, and acetone, melts at 81—82°, and has feeble basic properties; its salts are decomposed by water. By the action of sodium on the hot alcoholic solution, a crystalline base is produced which appears to have the composition $C_{22}H_{24}N_4$; this melts at 200° and yields a sparingly soluble platinochloride. The solution in dilute sulphuric acid acquires a violet-blue colour on the addition of chromic or nitrous acid.

Phenylmethylchloropyridazone,  $\mathrm{CO}<\begin{matrix}\mathrm{NPh—N}\\ \mathrm{CCl:CH}\end{matrix}>\mathrm{CMe}$, crystallises in flat prisms and melts at 136—137°. It is freely soluble in hot alcohol, chloroform, benzene, and acetone, and also dissolves in mineral acids, but is reprecipitated unaltered from the acid solutions by water. The nitro-derivative melts at 210—213°. The chlorine is displaced by ethoxyl by the action of alcoholic potassium hydroxide.

Phenylmethylethoxypyridazone melts at 146°, crystallises in flat prisms or plates, and dissolves freely in hot alcohol, benzene, chloroform, acetone, and in hot water, and is also soluble in strong acids. It is decomposed by heating at 125° in sealed tubes with hydrochloric acid, yielding *phenylmethylhydroxypyridazone*. The hydroxy-derivative crystallises in needles and melts at 196°. It is soluble in hot acetone, benzene, and chloroform, in strong mineral acids, and in alkalis. The addition of ferric chloride to the hydrochloric acid solution produces a red-brown coloration, which turns to carmine on dilution. At 170°, hydrochloric acid converts the hydroxy-compound into *phenymethylpyrazolecarboxylic acid*,  $\begin{matrix}\mathrm{CMe\cdot CH}\\ \|\\ \mathrm{N—NPh}\end{matrix}>\mathrm{C\cdot COOH}$. The acid is soluble in hot alcohol, chloroform, benzene, ether, and in strong mineral acids, melts at 165—166°, and decomposes at 200°, yielding phenylmethylpyrazole,  $\begin{matrix}\mathrm{CMe\cdot CH}\\ \|\\ \mathrm{N—NPh}\end{matrix}>\mathrm{CH}$, probably identical with the phenylmethylpyrazole described by Knorr (Abstr., 1887, 601).

Phenylmethylpyrazole melts at 34—36° and boils at 254—255° under 753 mm. pressure. It dissolves freely in ether, alcohol, chloroform, acetone, benzene, and light petroleum. The platinochloride forms orange-coloured, needle-shaped crystals, sparingly soluble in water. The pyrazole is converted into the pyrazoline by the action of sodium on its alcoholic solution. The pyrazoline melts at 73—75° and distils without decomposition. It is soluble in ether, alcohol, and benzene, and gives the characteristic pyrazoline-colour reaction with ferric chloride or chromic acid. W. C. W.

Synthesis of Quinazoline-derivatives. By C. Paal and M. Busch (*Ber.*, 22, 2683—2702).—The authors have studied the action of orthonitrobenzyl chloride on the sodium-derivatives of formanilide and of acetanilide and of some of their homologues. The acetanilides did not give satisfactory results, but with the formanilides the following reactions (where R is an aromatic radicle) take place:—

$$NO_2\cdot C_6H_4\cdot CH_2Cl + R\cdot NNa\cdot COH = NO_2\cdot C_6H_4\cdot CH_2\cdot NR\cdot COH.$$

On reduction, the product yields quinazoline-derivatives,

$$NO_2\cdot C_6H_4\cdot CH_2\cdot NR.COH + 3H_2 = C_6H_4<\begin{matrix}N=CH\\ \quad |\\ CH_2\cdot NR\end{matrix} + 3H_2O\cdot$$

Action of Orthonitrobenzyl Chloride on Sodium Formanilide.—Sodium formanilide is prepared by adding sodium to a benzene solution of formanilide, and then a proportional quantity of orthonitrobenzyl chloride is added. *Orthonitrobenzylformanilide*, $NO_2\cdot C_6H_4\cdot CH_2\cdot NPh\cdot COH$, is soluble in the usual organic solvents, insoluble in water. It melts at 77°, and forms yellow, monosymmetric plates giving the measurements $a : b : c = 0\cdot5477 : 1 : 1\cdot085$ and $\beta = 69° 7'$. This formanilide was also obtained by boiling orthonitrobenzylaniline (Lellmann and Stickel, Abstr., 1886, 793) with formic acid. When reduced with zinc and acetic or hydrochloric acid, *phenyldihydroquinazoline*,  $C_6H_4<\begin{matrix}N=CH\\ \quad |\\ CH_2\cdot NPh\end{matrix}$, is formed; this crystallises in hexagonal plates, is almost insoluble in water and alkalis, easily soluble in mineral acids, alcohol, ether, &c. It melts at 95° and distils at a very high temperature with partial decomposition. When distilled with zinc-dust, it yields equal quantities of aniline and benzonitrile. Its *sulphate*, $(C_{14}H_{12}N_2)_2,H_2SO_4 + 2H_2O$, crystallises from water in needles, loses water at 70° and melts at 79°; when free from water it melts at 140—143°; the *hydrochloride*, $+ 2H_2O$, forms glistening needles melting at 80°; the anhydrous salt melts at 221°, and is easily soluble in alcohol and ether. The *platinochloride* forms yellow crystals melting at 208°; the *aurochloride* orange scales; the *stannochloride*, $C_{14}H_{12}N_2,HSnCl_3$, flat, white needles or scales melting at 130—134°. When heated with methyl iodide in closed tubes at 100°, the quinazoline yields three derivatives: the *methiodide periodide*, $C_{14}H_{12}N_2MeI,I$, forming glistening, golden-yellow scales melting at 157°; the *methiodide*, $C_{14}H_{12}N_2,MeI$, crystallising in white needles melting at 170°; and a third substance, crystallising in prisms melting at 180°, which appears to be a second isomeric *methiodide*. When oxidised with potassium permanganate, the quinazoline yields *phenylketodihydroquinazoline*,  $C_6H_4<\begin{matrix}N:CH\\ \quad |\\ CO\cdot NPh\end{matrix}$, which crystallises in almost colourless, glistening scales or well-formed rhombic crystals giving the measurements $a : b : c = 2\cdot4228 : 1 : 3\cdot2742$. It melts at 139° and sublimes without decomposition. No hydroxylamine-derivative or phenylhydrazide could be obtained, but with hydrazine (amidogen) it yields *phenylketohydrazodihydroquinazoline*,  $\begin{matrix}CH\cdot NPh\\ \|\\ N—C_6H_4\end{matrix}>C<\begin{matrix}NH\\ |\\ NH\end{matrix}$; this forms white, glistening needles which melt at 204° and, in small quantities, sublime without decomposition. The *hydrochloride*, $C_{14}H_{10}N_2O,HCl$, crystallises in glistening scales and melts at 213—214°; it loses its hydrogen chloride at a moderate heat. The *platinochloride* crystallises in yellow needles melting above 300°. When the keto-base is treated in alcoholic solution with sodium, *phenyltetrahydroquinazoline*,  $C_6H_4<\begin{array}{l}NH\cdot CH_2\\ \quad\;|\\ CH_2\cdot NPh\end{array}$, is formed which is soluble in organic solvents, crystallises in white needles, melts at 117°, and distils at a high temperature without decomposition. It is only feebly basic, its salts decomposing on the addition of water. It yields a *hydrochloride*, a crystalline *aceto-derivative*, and a *nitrosamine*. An unstable intermediate product containing the ($CH\cdot OH$) group appears to be formed along with the tetrahydro-compound, but it could not be isolated. When oxidised with permanganate, the tetrahydro-derivative is reconverted into the keto-compound, but both here and in the original formation of the keto-derivative small quantities of a sparingly soluble nitrogenous, crystalline compound melting at 219° are formed.

Action of Orthonitrobenzyl Chloride on Sodium Formoparatoluide.—The reactions here are similar to those with formanilide. *Orthonitrobenzylformoparatoluide*, $NO_2\cdot C_6H_4\cdot CH_2\cdot N(C_6H_4Me)\cdot COH$, crystallises in pale yellow needles melting at 79°, and is easily soluble in the usual organic solvents. It may also be easily prepared from orthonitrobenzylparatoluidine (Lellmann and Stickel, *loc. cit.*). *Paratolyldihydroquinazoline*,  $C_6H_4<\begin{array}{l}N{=}CH\\ \quad\;\;|\\ CH_2\cdot N\cdot C_6H_4Me\end{array}$, is easily soluble in alcohol, ether, benzene, and chloroform, sparingly so in light petroleum. It crystallises in glistening, white scales, melts at 120°, and distils with partial decomposition. Distilled with zinc-dust, it yields the amine and nitrile like the phenyl-derivative. The *hydrochloride*, with 2 mols. H_2O, forms flat, white needles and melts at 85°, the anhydrous salt at 251°; the *platinochloride* forms glistening, yellow needles melting at 216°; the *stannochloride*, sparingly soluble needles melting at 165°. Methyl iodide forms two derivatives, namely, the *methiodide*, crystallising in white needles melting at 186°, and green, metallic needles which appear to be the *methiodide periodide*. On oxidation, the base yields *paratolylketodihydroquinazoline*,  $C_6H_4<\begin{array}{l}N{=}CH\\ \quad\;\;|\\ CO\cdot N\cdot C_6H_4Me\end{array}$, which crystallises in micaceous needles sparingly soluble in boiling water, easily in organic solvents, and melting at 146°. The *hydrochloride* forms white needles melting at 213—214°, and is dissociated by slight rise in temperature; the *platinochloride* forms golden yellow scales melting above 300°. By oxidation, *paraketodihydroquinazolylbenzoic acid*,  $C_6H_4<\begin{array}{l}N{=}CH\\ \quad\;\;|\\ CO\cdot N\cdot C_6N_4\cdot COOH\end{array}$, is produced as well as the above quinazoline; the acid forms white crystals sparingly soluble in organic solvents, and melting at 320°. The *silver salt* forms a white, flocculent precipitate. *Paratoyltetrahydroquinazoline* crystallises in white needles, melts at 127°, and is easily soluble in chloroform and benzene, sparingly in ether and alcohol. It forms a red *nitrosamine*, a white, unstable *hydrochloride*, and a yellow, unstable platinochloride.

Action of Orthonitrobenzyl Chloride on Sodiumformo-orthotoluide.—The reactions are similar to those with the isomeric para-compound.

Orthonitrobenzylformo-orthotoluide forms a yellow oil which melts at 76° and decomposes on distillation. *Orthotolyldihydroquinazoline* forms a yellow, amorphous mass, its *platinochloride* orange-yellow needles melting at 210°, and its *stannochloride* and *hydrochloride* could not be obtained in a crystalline form. When reduced in alcoholic solution with sodium, the base appears to yield the *tetrahydro*-derivative but this was not obtained in a pure state. L. T. T.

Hydrastine. By W. KERSTEIN (*Chem. Centr.*, 1889, ii, 91, from *Zeit. Naturwiss. Halle*, 61, 425—429).—According to the author's experiments, hydrastine, obtained from the root of *Hydrastis canadensis*, has the formula $C_{21}H_{21}NO_6$, and forms colourless needles melting at 132°. The *hydrochloride*, $C_{21}H_{21}NO_6,HCl$, and *hydrobromide*, $C_{21}H_{21}NO_6,HBr$, are white, micro-crystalline salts; the *hydriodide* is brownish-yellow.

In addition to those reactions already described, showing the relation which exists between hydrastine and narcotine, the author finds that by oxidation with potassium permanganate in acid solution, opianic acid and probably also cotarnine are formed. When distilled in a current of steam, meconine and trimethylamine are formed in the case of both these alkaloïds. On the other hand, they do not show any similarity in their behaviour towards acetic anhydride, acetic chloride, water under pressure, or dilute sulphuric acid.

From hydrastine ethiodide, by the action of potassium hydroxide solution, *ethylhydrastine* is obtained; it forms lemon-yellow crystals which melt at 127°. By the action of iodine, hydrastine is split up into opianic acid and hydrastonine; the latter is distinguished from tarconine methiodide in that no formaldehyde is formed on boiling its iodide or hydroxide with barium hydroxide.

In addition, from the root of *Hydrastis canadensis*, the author has separated *phytosterin*, $C_{26}H_{44}O + H_2O$; this forms plates, melting at 133°, the solution of which in acetic anhydride gives a red coloration, passing into intense blue with concentrated sulphuric acid.

J. W. L.

Formation of Optically Active Tropic Acids and Optically Active Atropines. By A. LADENBURG and C. HUNDT (*Ber.*, 22, 2590—2592).—A dilute aqueous alcoholic solution of quinine (1 mol.) was added to a hot aqueous solution of tropic acid (m. p. 116—118°, 1 mol.), and the whole evaporated down on a water-bath until crystallisation commenced. On cooling, a quantity of dull, white crystals separated (quinine dextrotropate), and on further evaporation of the mother-liquor an oil separated, which gradually solidified to hard crystals of a glassy lustre (quinine lævotropate).

Quinine dextrotropate melts at 186—187°. The *free acid* crystallises from ether in hard, clear prisms, and from water in clear plates, melts at 127—128°, and showed a rotatory power of 71·4°.

Quinine lævotropate was not obtained quite pure; it melts at 178°. The *free acid*, which was also not obtained pure, melted at 123°, and showed a rotatory power of 65·15°.

When treated with tropine and tropic acid (*Annalen*, **206**, 274), both acids yield the corresponding atropines.

Dextro-atropine crystallises from alcohol in white, lustrous needles, melts at 110—111°, and has a rotatory power of + 10°. The *aurochloride* forms dull, deep-yellow crystals melting at 146—147°.

Lœvo-atropine is a crystalline powder melting at 111°. The *aurochloride* crystallises in lustrous needles and melts at 146°. The base resembles hyoscyamine, but the two are not identical, which is due to the fact that the latter base has two active asymmetrical carbon-atoms, whilst the former has only one. N. H. M.

Bases contained in the young Shoots of Solanum Tuberosum. By R. FIRBAS (*Monatsh.*, **10**, 541—560).—The two products, the one crystalline and the other amorphous, obtained in the preparation of solanine from the young shoots of the potato, are now shown, contrary to earlier views, not to be chemically identical. The author names the crystalline compound *solanine*. It has the formula $C_{52}H_{93}NO_{18},4\frac{1}{2}H_2O$, and when dried at 100° appears to be anhydrous, or to contain only half a molecule of water of crystallisation. From a solution in 85 per cent. alcohol, it crystallises in colourless needles, which melt at 244°, are almost insoluble in ether and alcohol, and are readily dissolved by dilute hydrochloric acid. *Solanidine hydrochloride*, $3(C_{40}H_{61}NO_2,HCl)HCl + H_2O$ or $1\frac{1}{3}H_2O$, is obtained by boiling solanine with a 2 per cent. solution of hydrochloric acid. It is a slightly yellow powder which is only very sparingly soluble in water, and carbonises without melting when heated to 287°. Simultaneously with solanidine hydrochloride, a sugar is formed in accordance with the equation $C_{52}H_{93}NO_{18} = C_{40}H_{61}NO_2 + 2C_6H_{12}O_6 + 4H_2O$.

The amorphous substance obtained simultaneously with solanine, and which the author names *solaneïne*, has, when dried at 100°, the formula $C_{53}H_{87}NO_{13}$, or $C_{52}H_{83}NO_{13}$. The loss of weight on heating the air-dried compound at 100° corresponds with the formula $C_{52}H_{83}NO_{13} + 3\frac{3}{4}$ or $4H_2O$. It is a yellow, horny, perfectly amorphous substance, melting at 208°, is more soluble in an 85 per cent. solution of alcohol than is solanine, and on treatment with hydrochloric acid yields solanidine and a sugar in accordance with the equation $C_{52}H_{83}NO_{13} + H_2O = C_{40}H_{61}NO_2 + 2C_6H_{12}O_6$.

The sugar obtained by the hydrolysis of solanine and solaneïne forms a yellow, amorphous mass with a caramel-like odour, dissolves readily in water and wood-spirit, and has a specific rotatory power of $[\alpha]_D = +28{\cdot}623$. With phenylhydrazine hydrochloride and sodium acetate in aqueous solution, it forms a glucosazone melting at 199°, and resembling the compounds obtained similarly from dextrose, levulose, and several other sugars. With nitric acid it gives no recognisable trace of mucic or saccharic acids. The general behaviour of the sugar points to the conclusion that it is some other sugar than dextrose, or a mixture of sugars.

Solanidine has the formula $C_{40}H_{61}NO_2$ or $C_{41}H_{63}NO_2$, and is obtained from alcoholic solution in amorphous masses interspersed with needles melting at 191°. It dissolves readily in hot alcohol, with difficulty in ether, and on treatment with excess of dilute sulphuric acid forms a sulphate, $3(C_{40}H_{61}NO_2,H_2SO_4),H_2SO_4 + 8H_2O$; this crystallises in scaly plates melting at 247°, and is readily soluble in water. Its diacetyl-derivative, $C_{40}H_{59}O_2NAc_2$, crystallises in needles melting at 203°. G. T. M.

Cinnamylcocaïne from Coca Leaves. By C. LIEBERMANN (*Ber.*. **22**, 2661—2662).—Measurements of crystals and quantitative decomposition determinations are given to show that the cinnamylcocaine which the author prepared synthetically from ecgonine is identical with that obtained by Giesel from the coca leaf.

L. T. T.

Hæmatoporphyrin and Bilirubin. By M. v. NENCKI and A. ROTSCHY (*Monatsh.*, **10**, 568—573; compare Abstr., 1888, 304 and 971).—The authors suggest that Raoult's method may be employed with advantage to determine the molecular weights of unstable substances of organic origin, and have investigated the practicability of the method in two cases. Making use of acetic acid and phenol as solvents, hæmatoporphyrin gave numbers varying between 226 and 331, which correspond with the simple formula $C_{16}H_{18}N_2O_3$ (mol. wt. = 286). In the case of bilirubin, ethylene dibromide and phenol were used as solvents. This compound has the same molecular formula, and is consequently isomeric with hæmatoporphyrin. The range in the numbers obtained in both cases is due to the compounds being only slightly dissolved by the solvents employed. The isomerism of hæmatoporphyrin and bilirubrin is confirmed by the fact that on reduction with tin and hydrochloric acid two different urobilins are obtained. G. T. M.

Chemistry of Vegetable Physiology and Agriculture.

Reduction of Nitrates by the Cholera Bacteria. By R. J. PETRI (*Chem. Centr.*, 1889, ii, 45, from *Centr. Backteriologie u. Parisitenkunde*, 5, No. 17).—The cholera bacteria are found to reduce nitrates to nitrites, and the author remarks that an oxidation of ammonia by these bacteria would therefore appear highly improbable. J. W. L.

Mucous Fermentation. By E. KRAMER (*Monatsh.*, **10**, 467—505).—Mucous fermentation is the process by which certain solutions of sugars or carbohydrates, such as saccharose, glucose, lactose, mannitol, starch, and mucilage, containing the necessary quantity of albuminoids and mineral salts, are converted into a ropy condition. In the process a mucous substance of the formula $C_6H_{10}O_5$ is generally formed simultaneously with variable quantities of mannitol and carbonic anhydride, although in the fermentation of milk the production of all these compounds has not been determined with certainty. The formation of free hydrogen and of lactic and butyric acids in ropy fermention is due to the use of impure cultures, and is not the result of the mucous ferment, which is a micro-organism belonging to the bacteria. Previously the mucous fermentation was considered to be due to Pasteur's so named *Micrococcus viscosus* (which, however, does not exist as described by him), but is now shown, in the case of ths different solutions investigated, to be the result of the action of at least three totally different micro-organisms. It also appears that no true mucous fermentation is brought about by Prazmowsky's *Leuconostoc mesenterioïdes* and *Bacillus polymyxa* or by Cohn's *Ascococcus Billrothii.*

The solutions of carbohydrates which have been investigated can be classed into three divisions according to the nature of the ferment capable of producing change in them. The first division consists of neutral or slightly alkaline solutions containing saccharose, albuminoïds, and mineral salts, such as decoctions of barley, of rice, and of maize, to which saccharose has been added; and the juice of the carrot, beet-root, and onion. The fermentation is produced by Kramer's *Bacillus viscosus sacchari*, and affects the saccharose. To the second division belong acid solutions (for example, wine) containing the albuminoïds and mineral salts and glucose. In these the fermentation is caused by Kramer's *Bacillus viscosus vini.* The third division consists of nearly neutral—acid or alkaline—solutions containing lactose, albuminoids, and mineral salts, such as milk. This class is said by Schmidt-Mülheim to be fermented by a coccus 1 μ in diameter, and capable also of fermenting mannitol.

Kramer's *Bacillus viscosus sacchari* occurs in the form of short rods slightly rounded at the ends, and having a thickness of 1 μ and a length of from 2 5 to 4 μ. They are often joined together, forming strings of as many as 50, and show no individual movement, but only Brown's so-called "molecular motion." When placed on slices of carrot, a blackish mucus is formed, but on isinglass or gelatin made up with saccharose, it produces spreading white colonies; it liquifies the gelatin, and is very active at 22°. The coccus thrives only in neutral or slightly alkaline fluids, producing no change whatever when free acids are present. Kramer's *Bacillus viscosus vini* forms rods 0·6 to 0·8 μ in thickness, and from 2 to 6 μ in length, often occurring in chains 14 μ in length; and belongs to the anaërobic bacteria, whilst the previously described ferment is aërobic. It can only exist in wines or in acid solutions of glucose.

The mucous substance of the formula $C_6H_{10}O_5$ may be regarded as "metamorphosed" cellulose. It is precipitated from the fermented liquid by alcohol, by basic lead acetate, and by baryta-water, in the form of a white, insoluble, amorphous, stringy mass, which has a specific rotatory power of $[\alpha]_D = +195$; is not coloured by iodine, and is dissolved by solutions of the caustic alkalies, forming a yellow liquid, from which alcohol precipitates a compound as a white, scaly mass. The mucous substance is not to be regarded as being directly produced from the nourishing fluid, but as a secondary product of assimilation of the ferment. Similarly the formation of mannitol is to be attributed to the action of the nascent hydrogen and carbonic anhydride, the primary products of the action of the living organism on the dissolved glucose. G. T. M.

Decomposition of Albumin by Anaërobic Ferments. By M. v. Nencki (*Monatsh.*, **10**, 506—525).—The author has investigated the decomposition of serum albumin by three anaërobic bacilli, namely, *Bacillus liquefaciens magnus*, *Bacillus spinosus*, and the *Rauschbrand bacillus.* The fermentations were conducted in a specially arranged flask, and in an atmosphere of nitrogen, hydrogen, or carbonic anhydride. On distillation, after saturation with oxalic acid, the fermented liquid gave gaseous products and liquid fatty acids. On exhaustion with ether, the evaporated residue furnished, besides a small quantity of fatty acids, only phenylpropionic acid, parahydroxyphenylpropionic acid, and scatolacetic acid. The relative quantity in which these three acids are formed depends on the bacillus used and on the length of the fermentation.

Scatolacetic acid,  $C_6H_4<\substack{CMe\\NH}>C\cdot CH_2\cdot COOH$, crystallises from hot water in prisms or six-sided plates, dissolves readily in alcohol and ether, melts at 134° (uncor.). and on treatment with potassium nitrite and acetic acid forms a yellow, crystalline magma of the characteristic nitroso-compound, $C_9H_7N(NO)\cdot C_2H_3O_2$, which melts with decomposition at 135°. Taking these results into consideration, the author shares Salkowski's opinion that there are at least three aromatic groups in albumin, and that these are represented by (1) tyrosine, $OH\cdot C_6H_4\cdot CH_2\cdot CH(NH_2)\cdot COOH$, (2) phenylamidopropionic acid, and (3) scatolamidoacetic acid. When the anaërobic fermentation takes place in the absence of hydrogen, tyrosine is reduced to ammonia, and parahydroxyphenylpropionic acid; phenylamidopropionic acid to phenylpropionic acid, and scatolamidoacetic acid to scatolacetic acid. In the presence of air, these three acids furnish oxidation-products, which may be regarded as being produced as follows:—Phenylacetic acid, benzoic acid, and phenylethylamine from phenylpropionic acid; parahydroxyphenylacetic acid, paracresol, parahydroxybenzoic acid, and phenol from parahydroxyphenylacetic acid, and scatolecarboxylic acid, scatole and indole from scatolacetic acid. G. T. M.

Gases Evolved during the Putrefaction of Serum Albumin. By M. v. Nencki and N. Sieber (*Monatsh.*, **10**, 526—531).—The bad smelling gas evolved during the putrefaction of albumin by *Bacillus liquefaciens magnus* (compare preceding abstr.) contains 97·1 per cent. of carbonic anhydride, hydrogen sulphide, and other gases absorbable by potash, and 2·63 per cent. of free hydrogen. The putrid smell is due in all probability to the presence of methyl mercaptan, for the author has proved that that compound is evolved during the putrefaction of flesh by the *Emphysem bacteria.*

G. T. M.

Formation of Paralactic Acid during the Fermentation of Sugar. By M. v. Nencki and N. Sieber (*Monatsh.*, **10**, 532—540.)—In the preparation of a pure culture of the *Rauschbrand bacillus*, the authors observed that the fluid taken from the swelling on an inoculated guinea-pig contained not merely the organism which until now was the sole recognised bacillus producing the symptoms, but also an anaërobic micrococcus. The coccus has on the average a diameter of 0·6 μ, but possesses no very characteristic form; appearing usually in a shape resembling that of *diplococcus*, more seldom in strings of 3, 4, or 5, and at times in groups resembling *staphylococcus*. The authors name the new ferment *micrococcus acidi paralactici*, because during its growth, it converts grape sugar into sarco- or para-lactic acid. The *Rauschbrand bacillus*, on the other hand, converts sugar into the ordinary lactic acid of fermentation, out of which butyric acid is then formed, with evolution of carbonic anhydride and hydrogen. If in fermenting sugar a culture containing both the bacillus and the micrococcus is employed, lactic and paralactic acids are simultaneously formed. G. T. M.

Function of Ammonium Salts in the Nutrition of Higher Plants. By A. Müntz (*Compt. rend.*, **109**, 646—648).—Soil free from nitrates was mixed with ammonium sulphate, and the mixture carefully sterilised. It was then sown with various plants, every precaution being taken to prevent the introduction of the nitric ferment either at this stage or subsequently. A corresponding set of experiments was made in which the nitric ferment was present. In the latter case a considerable quantity of the ammonium sulphate was nitrified. In the first case no nitrates were present at the close of the experiments, and yet the plants flourished vigorously. The quantities of nitrogen in the seeds and the plants were as follows:—

	In the seed.	In the plant.	Derived from the ammonium sulphate.
Broad-bean..	37 mgr.	956 mgr.	915 mgr.
Horse-bean..	16 „	105 „	89 „
Maize......	3 „	211 „	208 „
Barley......	0·7 „	50 „	49·3 „
Hemp......	0·5 „	115 „	114·5 „

It is evident that the higher plants have the power of directly utilising the nitrogen of ammonium salts, and that preliminary nitrification is not essential. C. H. B.

Fixation of Nitrogen by Leguminosæ. By E. Bréal (*Compt. rend.*, **109**, 670—573; compare Abstr., 1888, 1330).—Spanish beans were grown in a mixture of river gravel, fine sand, and flints, which contained very little nitrogen. They were freely exposed to air, and from time to time were watered with very dilute solutions of potassium chloride and calcium phosphate. In March, the roots were inoculated with bacteria from tubercles on the roots of *Cystisa*. At first the growth was vigorous, then the plants languished, but in June they recovered, flourished, and reached maturity. The total gain of nitrogen was 1·4872 gram for a total weight of dried plants of 64·3 grams. At the same time the 10 kilos of gravel, &c., gained

0·481 gram, corresponding with a gain of 98·31 kilos. per hectare of surface exposed.

Lucerne growing in a pot in sandy soil was inoculated with a fragment of tuberculous root of lucerne, freely exposed to air, and watered with effluent water. The total nitrogen in the water used did not exceed 0·1 gram, and the net gain of nitrogen was 3·258 gram for a total weight of dried crop, including roots, of 97·8 gram. At the same time the soil gained 2·460 grams.

This behaviour of the leguminosæ when growing on soils very poor in nitrogen explains their well-known utility as "improving crops."

C. H. B.

Investigations on Lactarius Piperatus. By R. CHODAT and P. CHUIT (*Chem. Centr.*, 1889, ii, 144, 145, from *Arch. sci. phys. nat.*, *Genève*, 5, 385—403).—After expressing the juices of *Lactarius piperatus*, and extracting the residue with alcohol, it was found that mannitol, a white, crystalline acid, lactaric acid, and a pitchy substance had dissolved. The latter has been named *piperon*. It is solid at ordinary temperatures, but melts on the hand, and has the pepper-like smell of the fungus. Heated with water in the presence of either a little alkali or acid, it remains unchanged. It contains no nitrogen, and is present in the milk of *L piperatus*.

Lactaric acid, $C_{15}H_{30}O_2$, the next lower homologue to palmitic acid (which has been found by Thoerner in other fungi), melts at 69·5—70°, is little soluble in cold alcohol, readily soluble in hot. It exists in the free state in this fungus to the extent of 7·5 per cent. of the dry substance. The authors could not find any poisonous substance in this fungus either by chemical or physiological means.

J. W. L.

Pectic Compounds in Plants. By L. MANGIN (*Compt. rend.*, **109**, 579—582).—Pectic compounds, both neutral and acid, are essential constituents of plant structures. Their presence is recognised by means of certain dyes, such as phenosafranin, methylene blue, Bismark brown, Paris violet, &c., which stain the pectic compounds but do not stain the cellulose, provided that they are used in neutral solutions or in solutions feebly acidified with acetic acid. Nitrogenous compounds, lignin, and cutin are stained by the same dyes, but on treatment with acid the pectic compounds are decolorised, whilst the others remain stained. Other dyes, such as acid green, acid brown, nigrosin, indulin, crocein, ponceaux, in neutral solution stain the nitrogenous substances, lignin, cutin, &c, but not the pectic compounds, and mixtures of these dyes with those of the first group make excellent double stains, which readily distinguish pectic compounds from lignin, cutin, and the nitrogenous compounds. The author has extracted pectic acid from plant structures which take the stain, and has found that after its removal they remain colourless if treated with the same dyes.

If a section of any plant, except a mushroom, is treated for 24 hours with Schweizer's reagent, the cells are filled with a gelatinous mass enclosed in the cell walls left intact by the section-cutter. It would seem that the cellulose does not diffuse across the membranes, and after the sections are washed with water and acetic acid, they have their original structure, although somewhat deformed, and the membranes retain their thickness except in those rare cases where the cell walls consist exclusively of cellulose. After this treatment, the cell walls, which consist of insoluble pectic acid, give no coloration with the ordinary iodine reagents, whilst the contents of the cells become deep blue. On the other hand, the cell walls are deeply stained by methylene blue, whilst the contents remain colourless. The cell walls dissolve readily in ammonium oxalate solution.

Pectic compounds are constant constituents of the cell membranes, and are found, though less frequently, in the cell contents, and even in some cases (*Allium porrum*, *Glyceria aquatilis*) in the nucleus.

C. H. B.

The Atmosphere in Soils. By T. Schloesing, Junr. (*Compt. rend.*, **109**, 618—620, 673—676).—The large volume of air withdrawn from the soil in Boussingault's method introduces several errors. The author withdraws about 15 c.c. through a steel tube of very narrow diameter, and analyses it volumetrically. The air was drawn from the soil, as a rule, at two depths, 25 to 30 cm., representing the true soil, and 50 to 60 cm., representing the subsoil. It consisted of nitrogen, oxygen, and carbonic anhydride, without any measurable quantity of any combustible gas. The proportion of carbonic anhydride in the soil varied from 0·45 to 11·39 per cent., and in the subsoil from 0·0 to 8·80 per cent.; the proportion of oxygen varied from 13·52 to 20·09 per cent. in the soil, and from 13·21 to 20·98 in the subsoil. As a rule, a low proportion of carbonic anhydride is accompanied by a high proportion of oxygen and *vice versâ*. The greater the depth, the greater, as a rule, the proportion of carbonic anhydride, but in one set of samples taken in June, when the air was calm and the temperature high, this law did not hold good. The atmosphere of the same soil shows great variations, owing doubtless, to the varying frequency with which it is renewed in consequence of changes in the atmospheric pressure. Other conditions being constant, the composition of the atmosphere in the soil will show considerable variations in different parts of the same field. It is essential to remember that the gases in the soil are quite as capable of translatory motion as the water. C. H. B.

Influence of the Composition of the Soil on the Physical Properties of Plants. By G. Ville (*Compt. rend*, **109**, 628—631).—The height of plants is in direct relation to the fertility of the soil. In the case of plants in which nitrogen-derivatives are the dominant constituents, a deficiency of nitrogen in the soil has a greater effect than a deficiency of any other constituent. In one and the same year, the same plant will attain to different heights in different soils, but variations due to a deficiency of fertilising agents are always in the same direction. The height at a given period of growth is practically the same in different years. The weight of similar crops varies from year to year, but the variations are always in the same direction for any given variations in the composition of the soil.

The proportion of carrotene in plants depends on the fertility of the soil, and increases with it. Variations in the proportion of chlorophyll follow the same order as variations in the proportion of carrotene. C. H. B.

Production of so-called Sweet Fodder. By E. Mach (*Bied. Centr.*, **18**, 622—624, from *Tiroler landwirtsch. Blätter*, **8**, 137—139).—The object of the experiments was to determine whether the loss of food-substance in the preservation of green fodder by Fry's process is essentially smaller than in the preparation of sour fodder by the older methods. Two samples from a five months' old green maize silo were examined: the one was taken from the middle and was well preserved, the other from the edge, and badly preserved. They contained respectively 80·84 and 82·26 per cent. of water and volatile matter. The following table shows the percentage composition of the two samples (calculated on the dry substance), as well as the constituents of a sample of sweet maize, and the average composition of fresh, green maize (also on the dry substance):—

	Ensilage.		Sweet maize.	Average composition of fresh green maize
	Good.	Bad		
Nitrogenous substance	8·56	9·81	5·60	9·37
Crude fat	3·26	3·19	3·19	3·12
Non-nitrogenous extract	60·13	56·13	52·27	52·50
Crude fibre	33·31	30·65	28·34	30·00
Crude ash	15·00	12·48	7·76	—
Pure ash	10·00	8·71	4·91	6·25
Total free acid (as lactic acid)	—	—	2·00	—
Volatile acids (as acetic acid)	—	—	0·65	—
Dry substance	—	—	—	16·00

The fresh ensilage of good quality contained 0·320 per cent. (in fresh substance) of alcohol, 0·531 per cent. of free acid (calculated as lactic acid), 0 657 per cent. of volatile acids (as acetic acid), and 0·986 per cent. of total volatile acids (as acetic acid). The corresponding numbers for the bad sample are 0·280, 0·316, 0·356, and 0·535.

The sweet maize prepared by Fry's method does not differ essentially from the average composition of fresh maize. The sugar of the fresh maize has disappeared completely, whilst alcohol and free acids have been formed. The fact that a larger amount of volatile acid was found than total free acid is due to the liberation of volatile acids (originally present as salts) in the distillation of the substance in presence of tannic acid.

Analyses of the ensilage at a later period are also given. The whole of the free acid was found to consist of acetic and butyric acids; lactic acid was not present. N. H. M.

Analytical Chemistry.

Estimation of Phosphorus in Phosphor-tin. By W. Hempel (*Ber.*, **22**, 2478).—Phosphor-tin is best analysed by Wohler's chlorine method as employed in the analysis of Fahl-ore. The stannic chloride and phosphoric chloride which are formed are collected in concentrated nitric acid (about 10 c.c.); the vessel is washed out with dilute nitric acid (1 : 2), and the phosphoric acid is precipitated with ammonium molybdate and estimated directly.

F. S. K.

Recognition of Phosphoric Acid of Mineral Origin. By J. Stoklasa (*Chem. Centr.*, 1889, ii, 57, from *Listy. Chem.*, **13**, 153—154).—The author contends that the percentage of fluorine in bones as given by different authors is decidedly too high. Raw bones do not show any fluorine by the Lorenz reaction, whilst incinerated bones give only a slight indication of the presence of this element when tested in the same way. On the other hand, the author found the fossil bones of *Elephas primigenius* to contain 3·54 and 4·36 per cent. of ferric oxide and 2·08 and 2·98 per cent. of fluorine respectively in two different specimens. Bones found in the older alluvials on the island of Festigos contained 2·42 per cent. of ferric oxide, 1·58 of fluorine, 80·04 of tricalcium phosphate. Superphosphates prepared from this phosphate and also from bones were tested by the Lorenz reaction, with the result that fluorine was only found in the former, whilst of the several samples of the latter class of superphosphates only that from bone-ash gave any indication of fluorine, and then but slightly. On the other hand, remarks the author, Lorenz seems to have overlooked the fact that a series of mineral phosphates exist which contain but very little fluorine.

J. W. L.

Rapid Method of Estimating Arsenic. By E. Polenske (*Chem. Centr.*, 1889, ii, 58—59, from *Pharm. Zeit.*, **34**, 299—300).—The method consists in evolving the arsenic as hydrogen arsenide in a Marsh apparatus, deposition of the arsenic in a tube having three bulbs blown on it, and weighing first that part of the tube containing the "mirror," and secondly the tube after dissolving off the arsenic. The evolution flask is recommended to be of a capacity of 250 c.c., and to contain 80—100 grams of zinc. The apparatus includes an acid funnel 30 cm. long, having a U-formed bend, and the evolution flask is also connected with a washing flask containing lead nitrate solution, to which is attached a tube containing calcium chloride, and at the farther end, potash. The decomposing tube is attached to this. All air is expelled from the apparatus, first by adding 5 c.c. of concentrated sulphuric acid and 20 c.c. of water, and the reagents are at the same time tested for arsenic by heating the tube. The solution should not contain more than 4—5 milligrams of arsenic, and is allowed to drop into the acid funnel from a burette at the rate of 0·5—1·0 c.c. per minute. The gas escaping from the end of the tube is passed through a solution of silver nitrate, and the evolution should not be too rapid for the bubbles to be counted. During the evolution of the hydrogen arsenide, two bunsen lamps are placed under the second and third bulbs: in order to test whether all the arsenic is evolved from the flask, the first is heated, and if a "mirror" forms it must be driven onwards into the second bulb, and after a time the same test may be applied again. When it is thus proved that arsenic no longer escapes from the flask, the tube is disconnected and reversed, and any arsenic which may have been deposited in the third bulb is driven into the narrow tube between the second and third bulbs. All the arsenic having been thus collected in this part of the tube, it is cut off and weighed, and after dissolving off the arsenic with nitric acid, it is weighed again, the difference giving the weight of arsenic. Metallic salts and organic substances interfere with the accuracy of the method. J. W. L.

Behaviour of Silicates when Fused with Phosphates. By K. HAUSHOFER (*Chem. Centr*, 1889, ii, 53, from *Sitzungsber. der math.-naturw. Abt. bayr. Akad. Wiss.*, 1889, 8—11).—Many silicates, when fused to a bead with an alkaline phosphate in the blowpipe, swell up, evolve gases, and finally insoluble silica, either in the form of a skeleton or as flakes, is deposited. The evolution of gases is referred by the author to the presence of chlorine, sulphates, or water, and he draws attention to this part of the reaction as an aid in the recognition of the silicate under examination. For instance, hauyn and sodalite, owing to the evolution of the chlorine and sulphuric anhydride, may be distinguished from nepheline, which is but slowly attacked. In like manner, humite is distinguished from olivine by the evolution of hydrofluoric acid, and tourmaline and axinite from beryl. The micas of the scapolite group, epidote and vesuvian, lose their water of constitution, whereas the felspars, amphibole, and granites are but slowly attacked. Similar distinctions may be drawn between crystallised käumerite and the dense rhodochrome, and between pyrophyllite and agalmatolite. J. W. L.

Technical Analysis of Commercial Sodium Sulphide. By B. SHETLIK (*Chem Centr.*, 1889, ii, 211, from *Listy Chem.*, 12, 205—206).—10 grams of the sulphide is dissolved in water, the solution diluted to ½ litre. and 50 c.c. titrated with normal sulphuric acid, phenolphthaleïn being used as an indicator. If the titration is made in the cold, the quantity of acid required must be doubled, whereas if it is carried out at a boiling heat and the acid added until the red colour does not reappear on further boiling the solution, the acid used is equivalent to the sulphide. Insoluble sulphides which are decomposed by dilute acid may be titrated in this way. J. W. L.

Qualitative Analysis of the Ammonium Sulphide Precipitate. By F. MAYER (*Ber.*, 22, 2627—2630).—The presence of chromium in this precipitate renders impracticable the separation by solution in hydrochloric acid and precipitation of the iron and aluminium by boiling with sodium acetate, since the chromium is sometimes wholly and sometimes partially precipitated, whilst if no iron is present, it all remains in the filtrate. The author has found that the presence of excess of iron (at least 5 atoms to every atom of chromium) ensures the total precipitation of the chromium. He, therefore, recommends that where chromium is suspected and iron is not present in large quantities, ferric chloride should be added in excess before boiling with sodium acetate. L. T. T.

Analysis of Aluminium Sulphate. By F. Beilstein and T. Grosset (*Chem. Centr.*, 1889, ii, 60; from *Melanges, Phys. Chim. Bull., St. Pétersbourg*, **13**, 42—47).—The authors recommend the following method. 1—2 grams of substance is dissolved in 5 c.c. of water, 5 c.c. of a cold saturated solution of ammonium sulphate added, and the mixture well stirred during a quarter of an hour. 50 c.c. of 95 per cent. alcohol is added, and the precipitated ammonia alum filtered off and washed with 50 c.c. of alcohol. The filtrate contains all the free acid, which is determined by concentrating and titrating with decinormal alkali. The whole of the aluminium sulphate is precipitated as ammonia alum. J. W. L.

Estimation of Chromium and Copper in Iron and Steel. By C. Reinhardt (*Chem. Centr.*, 1889, ii, 60—61, from *Stahl u. Eisen* **9**, 404—405).—For the determination of chromium, 10 grams of borings or filings are dissolved with 100 c.c. hydrochloric acid in a covered beaker of 500 c.c. capacity, first without heat, then at a boiling heat, oxidised with potassium chlorate, concentrated to one half the volume, filtered into a ¾-litre Erlenmeyer flask, and the insoluble residue washed several times with dilute hydrochloric acid on the filter, and finally with water. The solution is now reduced at a boiling heat by the addition of 10—20 c.c. of sodium hypophosphite solution (200 grams in 400 c.c. of water), and afterwards the chromium is precipitated by the addition of zinc oxide in excess. The precipitate is dissolved in hydrochloric acid, a little more hypophosphite added, and the precipitation repeated. The chromium is separated from the zinc by precipitation with ammonia, which precipitation must be repeated. The chromic oxide, after ignition, is fused, together with the insoluble portion of the material, with 8 grams of a mixture of 4 parts of sodium chloride, 1 part of sodium carbonate, and 1 part of potassium chlorate. From the dissolved flux, the manganese is precipitated with alcohol, the silicic acid with hydrochloric acid and a little sulphurous acid, and the chromium finally precipated as oxide with ammonia. The copper is determined in 10 grams of the material: the hydrochloric acid solution is reduced with sodium hypophosphite, and the copper precipitated with hydrogen sulphide. J. W. L.

Volumetric Estimation of Chromium in Iron and Steel. By E. Wahlberg (*Chem. Centr.*, 1889, ii, 194, from *Berg. u. Hüttenm. Zeit.*, **48**, 180—181).—0·5 gram of the metal is dissolved in boiling nitric acid, sp. gr. 1·20, evaporated to dryness, ground up, transferred to a platinum crucible, mixed with a mixture of 2 grams of magnesia, 1 gram of potassium chlorate, and 1 gram of sodium carbonate, and the whole heated, at first gently, then in the blast flame for one hour.

The mass is dissolved out with 50—100 c.c. of water, any small quantity of manganic acid reduced by a drop or two of alcohol, acidified with sulphuric acid, and the chromic acid estimated by adding a known quantity of ferrous sulphate and determining the amount unoxidised by titrating with potassium permanganate.

J. W. L.

Microscopical Test for Tantalum and Niobium. By K. HAUSHOFER (*Chem. Centr.*, 1889, ii, 62—63, from *Sitzungsber. der math.-naturw. Abt. bayr. Akad. Wiss.*, 1889. 3—8).—The substance to be tested is fused with a very small bead of sodium carbonate in the hottest part of the bunsen flame for 30—40 seconds. It is then treated on the object glass with one drop of water, and the form of the crystals left as the water evaporates is noted; if tantalic acid is present in excess, these are hexagonal plates, whereas an excess of niobic acid causes the formation of hexagonal prisms. If the residue is treated with hydrochloric acid, the columbite acids crystallise out. Addition of sodium hydroxide, slightly warm, causes the formation of hexagonal plates, consisting partly of stars and prisms. A simple test for the columbite acids consists in boiling 20 millgrams of the mineral with 0·8 c.c. of concentrated sulphuric acid, the solution being poured off from the insoluble part, diluted to 2—3 c.c., and a little zinc-dust added; the solution becomes sapphire-blue in a few minutes.

J. W. L.

Hardness of Water. By E. WALLER (*Analyst*, **14**, 108—112).—Attention is directed to the fact that in cases where, either from excessive hardness or from the presence of magnesium salts, it is necessary to dilute a water before applying the soap test, the results may vary widely according to the degree of dilution employed, especially if no deduction is made for the soap required to give a lather with pure water. The hardness of a mixture of calcium and magnesium solutions appears to be less than that of either of the individual solutions apart.

M. J. S.

Estimation of Chlorine in Water. By A. HAZEN (*Amer. Chem. J.*, **11**, 409—414).—An investigation of the ordinary method of estimating chlorine in water by titration with a silver solution, using potassium chromate as an indicator. It is found that an excess of silver is always required to make the colour reaction apparent; this excess is smaller the greater the amount of chromate used, provided that this does not colour the liquid so much as to obscure the end-point; it is also smaller when the volume of the liquid titrated is small. The amount of silver chloride precipitated also influences the result, and, other things being equal, the excess of silver solution used is nearly proportional to the amount of silver precipitated. To correct for this, the use of a silver solution 1 per cent. stronger than its normal value is recommended. It is still better to standardise the silver solution against a solution of sodium chloride; with such a solution, and making a correction for the volume of liquid titrated, accurate results were obtained. If the amount of chlorine is small, the water must be concentrated, a very little sodium carbonate being added to prevent loss of hydrochloric acid on boiling.

C. F. B.

Dynamical Theory of Albuminoïd Ammonia. By R. B. Warder (*Amer. Chem. J.*, **11**, 365—378).—The integral calculus is applied to obtain formulæ representing the distillation of an aqueous solution of ammonia, and the conversion of albuminoid matter into ammonia by alkaline permanganate. It is assumed that the "coefficient of volatility"—that is, the ratio of the concentration in any small portion of the distillate to that of the liquid in the retort—is constant. In the case of the formation of albuminoid ammonia, the law of mass action is applied, and the particular formula is investigated which represents the reaction between one molecule each of three different substances (permanganate, potash, and a nitrogenous substance). Curves are given representing the formulæ obtained. It is found that the rate of formation of albuminoïd ammonia varies with the amounts of permanganate and of potash present, and also with the rate of distillation, and with the concentration of the original solution. The calculated ratios of the amounts of ammonia in successive portions of the distillate do not agree with those obtained by experiment; this discrepancy is attributed to the fact that there is not one simple reaction taking place, but several; and hence the curve actually obtained is the resultant of a number of curves.

It is also found that the amount of ammonia left in the retort when the distillation is stopped, as calculated from the formula, is much less than that actually left. This is attributed to the formation of intermediate compounds which only yield ammonia with great difficulty. The author finally concludes that Wanklyn's ammonia process gives valuable but purely comparative results, and is useless for the absolute estimation of organic nitrogen. C. F. B.

Estimation of Ferrocyanide in Gas-lime. By O. Knoblauch (*Chem. Centr.*, 1889, ii, 211—212, from *J. Gasbeleucht. u. Wasserversorg*, **32**, 450—459).—10 grams of the well mixed and finely ground-up gas-lime is digested, with frequent agitation, for 15—16 hours with 50 c.c. of 10 per cent. potassium hydroxide in a flask graduated on the neck at 250 c.c. and at 255 c.c. The volume is then made up to 255 c.c., the whole well mixed, and filtered; 100 c.c. of the filtrate is added to a hot solution of ferric chloride (containing 60 grams of ferric chloride and 200 c.c. of hydrochloric acid in the litre), the precipitate collected and washed with hot water, the funnel being covered meanwhile. The filter-paper with the precipitate is again transferred to the beaker in which the precipitation took place, the precipitate treated with 20 c.c. of 10 per cent. potassium hydroxide, and the whole then transferred to a 250 c.c. flask and made up to that volume. 50 to 100 c.c. of the solution is filtered from the insoluble ferric hydrate and paper, 3—5 c.c. dilute sulphuric acid added, and the solution titrated with standard solution of cupric sulphate, which has been standardised with a solution of potassium ferrocyanide (4 grams in 1 litre). If hydrogen sulphide is present, it must be removed before the titration by adding 1—2 grams of lead carbonate. In applying this volumetric method for determining hydroferrocyanic acid with cupric sulphate, the indicator used is a drop of ferric chloride on a piece of filter-paper to which is applied a drop of the solution under experiment; so long as an excess of potassium ferrocyanide is present, the formation of prussian-blue will at once take place. Towards the end of the titration it is necessary to filter very small quantities of the solution into a dilute solution of ferric chloride, when the last traces of soluble ferrocyanide can be observed.

J. W. L.

Absorption of Bromine by Fatty Acids. By G. HALPHEN (*J. Pharm.* [5], **20**, 247—249).—The process may be applied either to fats or to the fatty acids obtained from them; the results differ in the two cases, but are comparable amongst themselves. A saturated aqueous solution of bromine and one of sodium hydroxide coloured with eosin are required. 20 c.c. of soda-lye at 36° B. is added to 980 c.c. of water and 2 grams of eosin. 20 c.c. of carbon bisulphide and 10 c.c. of bromine solution of known strength are placed in a flask provided with a cork. The soda solution is run in gradually from a burette. After each addition, the flask is closed and shaken four or five times, and the addition repeated until the brown colour passes to a salmon tint. The bromine solution is titrated by means of the sodium solution before each estimation, as its strength varies constantly. 20 c.c. of carbon bisulphide is placed in a 250 c.c. flask, 1 gram of fatty acid is added, and an excess of bromine to the amount of about 0·5 gram. The flask is shaken up and allowed to remain for five hours; at the end of this time the absorption is complete. The excess of bromine is titrated by means of the soda solution; the brown mass formed gradually passes to a white, soapy solution which becomes rosy on the addition of a few drops of the soda solution in excess.

The vegetable oils absorb much more bromine than does lard, so that their presence in lard can thus be easily detected.—J. T.

Note.—The standard solutions could not be originated by the method given.

J. T.

Estimation of Citric Acid in Lemon Juice. By R. WILLIAMS (*Analyst*, **14**, 25—29).—The object of this paper is to recommend the use of sodium hydroxide with phenolphthaleïn as indicator for determining the acidity of lemon juice, instead of sodium carbonate with litmus-paper. Normal sodium citrate blues litmus-paper, but has no effect on phenolphthaleïn; accordingly titrations of pure citric acid made with sodium hydroxide and the latter indicator give numbers agreeing closely with theory, whilst those with the carbonate and litmus are low. Nevertheless, for some unexplained reason, the carbonate gives higher results than the hydroxide when applied to lemon juice, and estimations by precipitation as calcium salt agree better with the latter than with the former, being in fact generally lower than either.

M. J. S.

Impurities in Commercial Salicylic Acid. By B. FISCHER (*J. Pharm.* [5], **20**, 258—261; from *Pharm. Zeit.*, 1889, 329, after *Pharm. Zeit. Russ.*, 1889, **28**, 378).—Salicylic acid contains cresotic acid when manufactured from impure phenol containing cresol. The presence of potash in the sodium hydrate employed occasions the formation of parahydroxybenzoic acid; this acid is also produced if the temperature is too low at the time when the current of carbonic anhydride is passed, whilst too high a temperature at this stage results in the production of hydroxyisophthalic acid, due to the action of the gas on the sodium salicylate already formed. Lastly, particularly in presence of iron salts, brown or yellow compounds are formed by oxidation, which are insoluble in water, and give a yellow colour to the salicylic acid. In a well-conducted process, parahydroxybenzoic and hydroxyisophthalic acids are usually not formed in quantities exceeding 0·4 per cent., and the first is easily removed by washing, as it is readily soluble in water. The second acid is less soluble in water, and may amount to 1 per cent. in certain cases. Cresotic acid is the most important impurity, as apart from its obscure physiological action, its presence is very objectionable. The amount of cresotic acid present may be estimated by titrating with decinormal baryta solution, using phenolphthaleïn as indicator. Owing to the difference in their molecular weights, less solution is required to saturate cresotic acid than is required by salicylic acid, but great care is needed to obtain satisfactory results, and certain accidental impurities should be previously sought for, namely, water, colouring matters, and sodium chloride. With this view, dissolve in ether; if the solution is not clear, filter, evaporate, and dry first at 60°, then in a vacuum over sulphuric acid. In the absence of these impurities, it is necessary to dry the sample. The baryta solution is standardised by the use of pure salicylic acid obtained by converting the commercial acid into the calcium salt, recrystallising, and then decomposing the salt by means of hydrochloric acid. For the detection of cresotic acid, 15 c.c. of water and 1 to 2 grams of calcium carbonate are boiled in a 200 c.c. flask; 3 grams of the salicylic acid is added, and the flask is agitated over a flame until the volume is reduced to about 5 c.c. By this time some crystals have formed. After cooling, the mother-liquor is transferred to a test tube and evaporated to 1 c.c. On rubbing this with a glass rod, crystallisation sets in. 1 c.c. of water is added, and the liquid filtered through a small plug of cotton. The filtrate is made up to 1 c.c. and hydrochloric acid is added; if the original acid contained 3 to 5 per cent. of cresotic acid, there separates out a mixture of acids which fuses in boiling water and collects at the bottom of the test tube in the form of thick, oily drops. The test does not succeed with less than 1 per cent. Hydroxyisophthalic acid may be separated from salicylic acid by distillation in a current of steam. The first acid remains in the still as a light-grey powder or as small lumps. By dissolving it in sufficient hydrochloric acid and filtering through charcoal, it can be obtained in the form of slender, white needles, which fuse with decomposition about 300—305°. The author has found in one sample of commercial salicylic acid 0·5 per cent. hydroxyisophthalic acid, and in another 5·5 per cent. of cresotic acid.

J. T.

Oil Testing. By F. JEAN (*J. Pharm.* [5], **20**, 337—341).—The author's method comprises the determination of the density, melting point of the fatty acids, the elevation of temperature under the influence of sulphuric acid, and the refractive power. To determine the density, Wesphal's balance is employed. To determine the melting point, a special apparatus is employed consisting of a thin U-shaped tube, in the two limbs of which are platinum wires nearly touching the bottom of the tube. A layer of solid acid comes between the ends of the wire, but this is displaced by mercury which has been charged in one side of the tube, when the temperature of a surrounding beaker of water has reached the melting point of the enclosed acid. The mercury causes electrical contact between the wires, and the transmitted current rings a bell when the temperature is read off, as given by a thermometer immersed in the bath. To determine the rise in temperature when mixed with sulphuric acid, a small beaker 4 cm. diameter and 6 cm. high is marked to contain 15 c.c., and in this is placed an acid tube provided with a stopper having a small tube through which air can be blown into the interior, and a small glass tube reaching from the bottom of the acid tube, and just passing through its side towards the upper end, so that on blowing into the acid tube its contents are expelled and mixed with oil in the beaker. 15 c.c. of the oil to be tested is placed in the beaker and heated to 40°, the acid tube is charged with 5 c.c. of sulphuric acid at 65° B. and placed within the beaker; the whole is allowed to cool down to 30°, and is then placed in a felt-lined box, when the acid is transferred to the oil by blowing and well mixed with it, the temperature is carefully observed, and the maximum reached is noted. In general, when this temperature and the density of the oil are satisfactory, the sample may be regarded as pure. Oils which have been oxidised or otherwise changed require treatment with alcohol, or, better still, saponification, before determining the rise in temperature. Sometimes when the rise of temperature is nearly the same for two oils, that of their two fatty acids may differ much more. One or two results may be given of oils and their acids:—Olive oil 41·5°, acid 45°; linseed oil 61°, acid 109°; colza (Pas-de-Calais) 37°, acid 44°; ditto (India) 37°, acid 46°. To determine the refractive power of the oil, a special oleorefractometer is employed which is not described. The index of refraction only varies within narrow limits for the same species if care be taken to remove excess of acid by treatment with alcohol. The purity of a sample may be safely affirmed when the index of refraction, the rise in temperature, and the density agree with a standard oil of known purity.

J. T.

Oil of Sesame. By W. Bishop (*J. Pharm.* [5], **20**, 244—247).—If this oil is shaken for a short time with pure hydrochloric acid of 21—22° B. in the proportion of 8 of oil to 12 of acid, no special effect is produced, but if the oil is exposed to air and solar light for some days, and the same test is applied, the mixture becomes green and, after a time, the colour is found to be confined to the acid layer. If the action of air and light be much prolonged, the green colour is intensified, and after a still longer period, a bluish-violet, flocculent precipitate is produced. The green acid solution gives an absorption-spectrum almost exactly coinciding with that of chlorophyll. The application of this reaction will serve to indicate, when the results are positive, that a sample of sesame oil has been exposed to light and air for some time, and is not probably of recent production. Such an oil added to olive oil in the proportion of 5 to 10 per cent. can be easily detected by this method, whilst 10 to 20 per cent. of oil of sesame may be detected in the same way after some days' exposure. J. T.

Optical Examination of Oils and Fats. By E. H. AMAGAT and F. JEAN (*Compt. rend.*, **109**, 616—617).—Determination of the refractive index in a refractometer of special construction is a delicate and trustworthy means of detecting adulterations in oils and fats. The variations in the refractive indices of samples of the same oil from different sources are very slight, and distinctive differences are observed between vegetable oils, animal oils, and mineral oils. As little as 10 per cent. of oleomargarin can be detected in butter. C. H. B.

Analysis of Fats and Oils. By J. MUTER and L. DE KONINGH (*Analyst*, **14**, 61—65).—The authors' object has been to re-determine the iodine absorption (Hübl's) of the liquid fatty acids from various oils and fats under conditions which should be as uniform as possible, and should exclude any alteration of the acids either by exposure to air or by drying at a high temperature.

A weighed portion of the fat is saponified with alcoholic potash, and the solution accurately neutralised with acetic acid. It is then poured into an excess of a boiling solution of lead acetate. The precipitate is washed, then transferred to a stoppered bottle and treated with ether. The ether solution is filtered from lead stearate, &c., into a Muter's "olein tube," in which it is decomposed by dilute hydrochloric acid. The volume of the ethereal solution of the fatty acids having been read, an aliquot part is run into a flask and most of the ether distilled off. The ether vapour protects the fatty acids from the air. Alcohol is then added, and the solution is titrated with soda; this gives the total amount of the liquid fatty acids, calculating them as oleic acid. Another portion of the ethereal solution containing 0·5 gram of the fatty acid is then evaporated in a bottle through which a stream of carbonic anhydride is being passed. When the last traces of ether are removed, 50 c.c. of Hübl's reagent is instantly added, and the bottle, having been stoppered, is placed in the dark for 12 hours, side by side with a blank, after which the excess of iodine is titrated by thiosulphate. The authors anticipate that the "iodine absorbing power" thus ascertained will permit the amount of any admixture of fats to be calculated with more precision than has hitherto been possible. M. J. S.

Extraction of Fat from Milk Solids. By H. D. RICHMOND (*Analyst*, **14**, 121—130).—Of the 15 or more methods which have been proposed for the extraction of the fat from the dry residue of milk, those of Adams (paper coil), Soxhlet (plaster of Paris), and Storch (pumice) give the highest and most concordant, but yet not identical results. The author has reinvestigated these three methods, using kieselguhr in place of pumice. In Adams' method, some analysts extract the paper coils with ether for a short time before using them; others apply a correction based on blank experiments with the same batch of paper. The author finds that the complete extraction of the paper with ether requires a very prolonged treatment; the total extract in 7½ hours being more than three times as much as that obtained in the first 1½ hour. The matter extracted consists chiefly of the calcium salt of a resinous acid. The most complete and rapid extraction is obtained by the use of alcohol containing 10 per cent. of acetic acid. After 3 or 4 hours' treatment with this reagent in a Soxhlet's apparatus, nothing soluble in ether remains. With the plaster and kieselguhr methods, the chief requisite is to grind the dried residue to a very fine powder, and to extract it with ether for at least 3 hours. Working in this way, the three methods agree closely. From the results of numerous determinations by the three methods, the author has developed a new formula for deducing the percentage of fat from that of total solids and the specific gravity: $T = 1{\cdot}17\ F - 0\,263\,\frac{G}{D}$ (apparently a misprint for $+\ 0{\cdot}263\,\frac{G}{D}$), where T is the percentage of total solids, F that of fat, D is the specific gravity of the milk, and $G = 1000\,(D - 1)$. This formula gives results which do not differ materially from those of Hehner and Richmond's older formula (*Analyst*, **13**, 32). The most satisfactory method of estimating the total solids appears to be the evaporation of not more than 2 grams of milk in a flat-bottomed basin and drying for 1 or 1½ hour. M. J. S.

Volumetric Method for the Estimation of Fat in Milk, &c. By C. L. Parsons (*Analyst*, **14**, 181—187).—This method is proposed as one which can be carried out at the dairy by unskilled persons. 100 c.c. of the milk is placed in a bottle 11 inches high and 1½ in diameter. 10 c.c. of soda solution (made by dissolving 1 part of commercial caustic soda in 2 parts of water) is added, then 5 c.c. of alcoholic soap solution (1 ounce of Castile soap to the gallon). 50 c.c. of gasoline (free from residue) is next added; the bottle is corked and shaken hard five or six times during half-an-hour. The petroleum solution of the fat is then allowed to rise to the surface. Should it fail to do so, 5 c.c. or more of the alcoholic soap solution may be added and gently mixed in. When the upper layer is perfectly clear, 25 c.c. of it is withdrawn and evaporated in a small flask, which has its neck cut off obliquely. Two drops of strong acetic acid is added to the fat, which is then dried at 120° for 1½ hours and drained from the flask into a measuring tube graduated in twentieths of a cubic centimeter. A table given in the paper converts the readings of the volume of the fat into percentages. The necessary precautions are fully described.
M. J. S.

Condensed Milk and the Estimation of Caseïn and Lactalbumen. By H. Faber (*Analyst*, **14**, 141—147).—The author proposes to employ the estimation of the relative proportions of casein and lactalbumen as a means of distinguishing between fresh milk and that which has been condensed and afterwards diluted with water.

Fresh milk contains from 0·35 to 0·45, or perhaps more, of lactalbumen. By boiling the milk about two-thirds of this is coagulated, or so modified that it is precipitated together with the caseïn. The heating to about 75°, to which condensed milk must be subjected in order to sterilise it, has a similar effect. The two albuminoids can be separated by Sebelien's method. The casein is first precipitated by magnesium sulphate, 2 vols. of the saturated solution of that salt being first added, and then as much of the powdered crystals as the mixture is able to dissolve; the precipitate is washed with a saturated solution of magnesium sulphate; and the lactalbumen is precipitated from the filtrate by either tannic acid or phosphotungstic acid. In these precipitates, the nitrogen is estimated by Kjeldahl's method. Test analyses show that the separation is very exact.

M. J. S.

Estimation of Soluble and Insoluble Fatty Acids in Butter. By W. JOHNSTONE (*Analyst*, **14**, 113—114) and H. D. RICHMOND (*ibid.*, 153—155).—Instead of estimating the volatile fatty acids by the Reichert process, the author prefers the following method. The butter is saponified with a known quantity of alcoholic potash and the excess found by titration. The alcohol having been removed by boiling, an excess of acid is added, and the insoluble fatty acids are filtered off and washed. After air-drying they are dissolved by ether and weighed after evaporation. They are now again saponified by standard potash, and the amount they neutralise is ascertained. The difference between these two titrations gives the amount of fatty acid soluble in water, which thus estimated is considerably higher than is shown by Reichert's process. The author hints that the results of the latter may be vitiated by the production of propionic, acetic, and formic acids by the action of potash on the glycerol. Richmond, commenting on the above process, shows that the results given cannot possibly be correct, the total fatty acids, together with the glycerol residue corresponding to the potash neutralised, adding up to more than the weight of the butter taken, and that this is due to the titration of the insoluble acids being performed in aqueous solution. The results by Reichert's process, when corrected for the recognised average deficiency of $\frac{1}{10}$, add up almost exactly to 100 per cent. He points out that at the temperature of the water-bath potash has no action on glycerol. M. J. S.

Examination of Lard for Adulteration. By T. S. GLADDING (*Analyst*, **14**, 32—34).—The following tests should all be applied to a suspected sample:—(1) specific gravity at 100°; (2) Hübl's iodine test; (3) Bechi-Millian test (Abstr., 1889, 319); (4) Dalican's "Titre" test; (5) Belden's microscopic test for beef fat (*Analyst*, **13**, 70). Dalican's "titre" is the temperature of crystallisation of the fatty acids. These are to be prepared from the sample by saponification, washed well with hot water, and filtered through dry paper into a test-tube. The crystallising point is then taken with a thermometer graduated to tenths of a degree. The titre of lard may range from 36·4° to 41·4°; iodine absorption from 57 to 68·4 per cent., a high titre being associated with a low iodine absorption, and *vice versâ.*

The titre of beef fat is about 41·6 to 44; iodine absorption, 43·8 to 40; that of cotton-seed oil, 33·3, iodine absorption, 108. The one adulterant will therefore to some extent mask the other; they are, however, respectively revealed by Bechi's and Belden's tests. The high specific gravity of cotton-seed oil affords the only means of estimating the amount of it present. (See also Abstr., 1889, 319, 659.)

M. J. S.

Action of Acids on Benzoic Sulphinide and Analysis of "Saccharin." By I. Remsen and W. M. Burton (*Amer. Chem. J.*, 11, 403—408).—When benzoic sulphinide, $C_6H_4{<}\begin{matrix}CO\\SO_2\end{matrix}{>}NH$ [= 1 : 2], is boiled with dilute acids, hydrogen ammonium orthosulphobenzoate. $COOH{\cdot}C_6H_4{\cdot}SO_3NH_4$ [= 1 : 2] is formed, together with a little orthosulphaminebenzoic acid, $COOH{\cdot}C_6H_4{\cdot}SO_2NH_2$. The best strength of acid is that obtained by diluting strong hydrochloric acid of sp. gr. 1·17 with 8 to 10 times its volume of water.

Commercial "saccharin" is found to be a mixture of parasulphaminebenzoic acid, benzoic sulphinide, and hydrogen potassium orthosulphobenzoate, the amount of sulphinide present being somewhat less than 50 per cent.

To analyse it, 2 grams are boiled for one hour with 100 c.c. of dilute hydrochloric acid (1—8) in a flask of 250 c.c. capacity, provided with a reflux condenser. The clear solution is then evaporated to about 15 c.c., when the parasulphaminebenzoic acid separates out; it is dried at 80° and weighed. The filtrate, containing hydrogen ammonium orthosulphobenzoate (from the decomposition of the sulphinide) and the hydrogen potassium salt of the same acid, is evaporated; the residue is weighed, and the amount of potassium in it is estimated by heating a portion with sulphuric acid, and weighing the potassium sulphate formed. Two samples of saccharin were analysed, each five times; the mean percentage composition of each is given below.

	$COOH{\cdot}C_6H_4{\cdot}SO_2NH_2$.	Benzoic sulphinide.	$COOH{\cdot}C_6H_4{\cdot}SO_3K$.

II	44·49	48·33	7·99

C. F. B.

Estimation of Morphine in Opium. By F. A. Flückiger (*Arch. Pharm.* [3], 27, 721—732, 769—772).—The author discusses various points which arise in the estimation of morphine, and arrives at the following fairly good, although not quite perfect, method. 8 grams of opium powder is placed in a folded filter of 12 cm. diameter with a little tapping, and is dried at 100°. After half an hour 10 c.c. of ether mixed with 10 c.c. of chloroform is poured over it, the covered funnel being frequently struck, and finally 10 c.c. more of chloroform is poured on. After all possible liquid has run through, the filter with its contents is opened out and dried at a gentle heat. Next the powder is vigorously and repeatedly shaken in a flask with 80 c.c. of water and filtered after two hours. 42·5 grams of the filtrate is well and often shaken in a weighed flask with 7·5 c.c.

of alcohol (0·83 sp. gr.), 15 c.c. of ether, and 1 c.c. of ammonia (0·96). After six hours, the contents of the flask are poured on to a double-folded filter of 10 cm. diameter, and the morphine is washed on to the filter with about 10 c.c. of water. This is dried, returned to the dried flask, and dried at 100° until its weight becomes constant. This process with a particular sample gave 12·90, 13·12, 13·35 per cent. of morphine, which was not pure white, but which dissolved completely in lime-water with very little colour. As an appendix the author criticises in some detail an article by E. R. Squibb in the "Ephemeris" for July, on morphine estimation, and, although he sees many defects in the process given, he remarks that the comprehensive paper deserves the fullest consideration. J. T.

Analysis of Pepper and the occurrence of Piperidine in the same. By W. Johnstone (*Analyst*, **14**, 41—49).—Moisture and ash.—A weighed portion is dried at 100° and then incinerated in a muffle. The ash is treated successively with water and hydrochloric acid, and the amount of insoluble matter noted.

Oil.—20 grams is distilled with water; the distillate is shaken with ether, the ethereal solution is evaporated at a very low temperature, and the residue is dried over sulphuric acid.

Piperidine.—20 grams is distilled as for the oil determination, and the distillate is titrated with N/10 sulphuric acid (compare Abstr., 1889, 298). That the piperidine is not derived from the hydrolysis of piperine is shown by the fact that pure piperine yields no piperidine when distilled with water, also that in distilling pepper with water, piperidine soon ceases to come over, although the amount obtained is very small in comparison with the piperine present.

Piperine.—10 grams is digested at 100° in a closed bottle with 3 grams of potash dissolved in 25 c.c. of water and 25 c.c. of alcohol. The bottle (4 oz.) should have the neck ground flat and be closed by a plate of caoutchouc pressed tightly upon it by a screw-frame. After 4—6 hours' digestion, the bottle is cooled, the contents are washed into a large flask and distilled as long as the distillate is alkaline. The theoretical yield of piperidine is obtained.

Crude Fibre.—A small quantity is boiled for half an hour in a flask with inverted condenser with 200 c.c. of dilute sulphuric acid (12·5 grams per litre). The residue is twice boiled with water, then with 200 c.c. of potash (12·5 grams per litre), and again twice with water. It is collected on a tared filter, dried and weighed, and any ash it contains deducted.

Nitrogen.—Determined by soda-lime, as usual.

Alcoholic Extract.—10 grams is extracted with 95 per cent. alcohol in a Soxhlet's apparatus for 24 hours. The alcohol is distilled off and the extractive matters dried at 100°.

Starch.—The exhausted residue from the preceding is, without drying, washed into a flask with 200 c.c. of water and 20 c.c. of hydrochloric acid (1·121) and heated in boiling water for three hours. After cooling, the liquid is filtered, neutralised with soda, made up to 500 c.c., and titrated with Fehling's solution.

In 13 genuine samples from various localities, the moisture ranged from 12 to 15 per cent., ash 1·07 to 4·46 (long pepper 7·57), oil 0·53 to 1·87, piperidine 0·21 to 0·77, piperine 5·21 to 13·03, fibre 4·2 to 15·05, starch 29·6 to 53·5, ash insoluble in acid 0·06 to 0·62 (long pepper 1·47). Any larger amount of insoluble ash would probably be the best indication of a fraudulent addition. M. J. S.

Detection of Cocaïne Hydrochloride. By M. GOELDNER (*Arch. Pharm.* [3], **27**, 799; from *Pharm. Zeit*, **34**, 471).—The author believes that the following is a characteristic test for cocaïne. 6 or 7 drops of pure, strong sulphuric acid are added to some crystals of resorcinol in a porcelain basin, and the latter is moved to and fro a little, then a little cocaïne hydrochloride is added to the yellow liquid. A somewhat strong reaction follows, and a splendid, blue coloration is immediately obtained; a drop of sodium hydroxide changes this to a light-rose colour. The reaction goes more quickly with powdered resorcinol in place of crystals. Very small quantities of the reagent give no colour reaction. Other alkaloïds give nothing approaching to this reaction. J. T.

Estimation of Indigotin for Commercial Purposes. By F. A. OWEN (*Chem. Centr.*, 1889, ii, 217—218; from *J. Amer. Chem. Soc.*, **10**, 178).—1 gram of the substance is weighed on a watch-glass, dried at 100°, finely powdered, rubbed with water to a thin paste, and washed into a 250 c.c. flask. 3 grams of zinc-dust and 6 grams of sodium hydroxide are added, the solution diluted to a little above the mark, shaken up now and then, and after the reaction is complete (during which the solution must remain green, red or brownish streaks indicate that the reduction has been carried too far; a froth indicates the presence of too much zinc), 50 c.c. of the clear liquid is exposed to the air for half an hour, acidified with hydrochloric acid, and filtered through a well-washed filter, dried at 100°, and weighed. J. W. L.

General and Physical Chemistry.

Emission Spectrum of Ammonia. By G. MAGNANINI (*Zeit. physikal. Chem.*, 4, 435—440).—The author has determined the positions of a large number of the lines of the ammonia spectrum. These are compared with the lines of Hasselberg's second hydrogen spectrum, with which they show a remarkable coincidence. H. C.

Absorption Spectrum of Nitrosyl Chloride. By G. MAGNANINI (*Zeit. physikal. Chem.*, 4, 427—428).—The absorption spectrum of nitrosyl chloride vapour consists of six absorption bands in the orange and green parts of the spectrum. The wave-lengths corresponding with these bands and their relative intensities are given. H. C.

Electromotive Force of Selenium. By S. KALISCHER (*Ann. Phys. Chem.* [2], **37**, 528).—The author observes that Righi (Abstr., 1889, 555) appears to have misunderstood a remark made by him in a former note (*ibid.*, 3). He had pointed out that selenium cells often give an E.M.F. before exposure to light, and that, therefore, before experimenting on the influence of light on them, they should be tested in the dark to see if they already give any E.M.F. He had no intention of asserting the necessity of actually manufacturing the cells in darkness, and preventing their even being exposed to light before experimenting with them. G. W. T.

Electrical Conductivity of Hydrogen Chloride in Different Solvents. By I. KABLUKOFF (*Zeit. physikal. Chem.*, 4, 429—434).—The conductivity of solutions of hydrogen chloride in benzene, xylene, hexane, and ether is excessively small, that in ether being greatest and that in benzene the least. The molecular conductivity of the solution in ether is found to decrease with rising dilution. Solutions of hydrogen chloride in methyl, ethyl, isobutyl, and isoamyl alcohols have a somewhat greater conductivity. The methyl alcohol solutions have the highest conductivity, being about four times greater than the ethyl and 30 times greater than the isobutyl alcohol solutions. Amyl alcohol, like ether, gives a decreasing molecular conductivity with rising dilution. Hydrogen chloride was also examined in aqueous solutions of ethyl alcohol. The presence of ethyl alcohol is found to greatly decrease the conductivity of hydrogen chloride in water, an addition of 6 per cent. of alcohol causing a decrease of 20 per cent. in the conductivity.

If a solution of benzene saturated with hydrogen chloride is allowed to remain for two or three days, crystals separate out which melt without decomposition, and can be sublimed at high temperature. They are probably of the composition $C_6H_6,3HCl$. H. C.

Electrical Conductivity of Solid Mercury. By L. Grunmach (*Ann. Phys. Chem.* [2], **37**, 508—515).—As the result of a further experimental investigation of this subject, the author finds that the apparent resistance of mercury when just melted is 2·5 times its value just before liquefaction begins.

The value 1·5 formerly obtained by the author (Abstr., 1889, 201) is, therefore, too small. The value now obtained by him is smaller than that given by Cailletet and Bouty, namely 0·4, and the author attributes the difference between his present and former results, and between both of them and that obtained by Cailletet and Bouty, in great part to the change in volume which mercury undergoes in passing from the solid to the liquid state, and the effects of this change of volume on the resistance, depending as they do on the dimensions of the tubes and their regularity of bore. The degree to which the result is affected in this manner cannot be determined until these changes of volume have been measured, and the author states that an investigation of this point has been commenced.

The results of the investigation described in this paper confirm the conclusion formerly arrived at by the author, that the temperature-coefficient of decrease of resistance for solid mercury decreases from the solidifying point down to —80°, the lowest temperature at which observations were made.

The values obtained for this coefficient in the former and present series of observations respectively are given below :—

Range of temperature.	Temperature-coefficient. First series.	Temperature-coefficient. Second series.
—80° to —70°	0·0010	0·0008
—70 „ —60	0·0010	0·0011
—60 „ —50	0·0012	0·0013
—50 „ —40	0·0017	0·0023

The results of the present investigation therefore confirm the conclusion formerly arrived at by the author, that assuming the truth of Clausius's law expressing the relation between the electrical resistances of simple metals and their absolute temperatures, then mercury must be considered as an exception. G. W. T.

Thermoelectric Currents between Amalgamated Zinc and Zinc Sulphate. By K. A. Brander (*Ann. Phys. Chem.* [2], **37**, 457—462).—The primary object of the investigation was to determine the relation between the E.M.F. developed and the difference of temperature between the electrodes.

The electrodes, of amalgamated zinc, were placed in two vessels communicating by means of a siphon, and filled with a solution of zinc sulphate. One of these vessels was kept at the temperature of the place of observation, while the temperature of the other was gradually raised.

The author found that, within the limits of errors of observation, the E.M.F. was proportional to the difference of temperature, until this difference exceeded 20·45°, after which the E.M.F. appeared to increase rather more rapidly than the temperature difference. A few experiments were also made to determine the effect of varying the concentration of the zinc sulphate solution, and their results showed that the E.M.F. increased with the concentration. G. W. T.

Electrochemistry and Thermochemistry of some Organic Acids. By H. Jahn (*Ann. Phys. Chem.* [2], **37**, 408—443).

Formic Acid.—When a solution of sodium formate in water was acidified with formic acid and subjected to electrolysis, it yielded hydrogen and carbonic anhydride. The sodium salt must first be resolved into sodium and the group HCO_2, the former forming sodium hydroxide with the water of solution, whilst the latter must either break up into carbonic anhydride and hydrogen or form formic acid again with the water of solution, according to the equation $2H + CO_2 + H_2O = 2H_2CO_2 + O$, the free oxygen then combining with a portion of the formic acid to form carbonic anhydride and water. Now Bunge has shown that in the electrolysis of formic acid no hydrogen is given off at the anode, which excludes the first explanation, and shows that a simple combustion of the acid takes place at the anode. The results were confirmed by determinations of the amount of gas liberated by the passage of a measured quantity of electricity.

The author made a series of determinations of the heat of combustion of formic acid which agreed very well together, and their mean gave 62·87 cal. as the heat of combustion of a milligram molecule of formic acid. Thomsen obtained the value 60·2 cal., and the author observes that this may be considered as a very close agreement, considering that, as Ostwald has shown, the heat of combustion varies considerably with the temperature.

Acetic Acid.—A solution of sodium acetate in water was electrolysed at the temperature 0°. A considerable quantity of carbonic anhydride was formed, and after the gas given off had been freed from this, the residue was found to consist of hydrogen and ethane, about 65 per cent. of the former and 35 per cent. of the latter. Very slight traces of iodoform were obtained from the liquid residue in the electrolytic cell. From this it follows that the action consisted in the setting free of acetic acid at the anode, and its combination with the oxygen simultaneously liberated; but if this took place entirely in the manner usually assumed, $2C_2H_4O_2 = C_2H_6 + 2CO_2 + H_2O$, the volumes of hydrogen and of ethane would have been equal. The excess of hydrogen present, combined with the absence of free oxygen, shows that part of the acetic acid must have been burnt to form carbonic anhydride and water, according to the equation $C_2H_4O_2 + O_4 = 2CO_2 + 2H_2O$. In some quantitative experiments made with stronger currents, the proportion of hydrogen was found to be somewhat smaller. The proportion of hydrogen present in the evolved gases was also found to diminish as the strength of the solution was increased. These results show that the complete combustion of the acetic acid to carbonic anhydride and water is favoured by increasing the strength of the decomposing current, and by diminishing the strength of the solution.

Assuming Thomsen's values for the heats of solution required for the calculation, the author determined the heat of combustion of the milligram molecule of liquid acetic acid to water and gaseous carbonic anhydride to be 208 81 cal., which is in very fair agreement with the values 210·3 obtained by Fabre and Silbermann, and 210·79 obtained by Stohmann. It follows from the last result that the heat absorbed in the formation of one milligram molecule of liquid acetic acid from amorphous carbon and water vapour is 121·61 cal.

Propionic Acid.—The results obtained with acetic acid suggested that propionic acid would probably be resolved into normal butane and carbonic anhydride, and the electrolysis of a solution of sodium propionate in water, acidified with propionic acid, showed that this reaction did actually occur, but it was veiled to a considerable extent by the decomposition of part of the acid into ethylene and carbonic anhydride, evidently according to the equation $C_2H_6O_2 + O = C_2H_4 + CO_2 + H_2O$. The author considers that the results of his experiments with acetic and propionic acids point to the conclusion that the ethane and butane formed during electrolysis are the results of the decomposition of double molecules, which exist in concentrated solutions, but are broken up into simple molecules when the solutions are diluted.

Oxalic Acid.—The electrolysis of an aqueous solution of potassium oxalate at the temperature 0° gave a gas consisting only of carbonic anhydride and hydrogen, so that the oxalic acid set free at the anode must have been completely burned to carbonic anhydride and water, according to the equation $H_2C_2O_4 + O = 2CO_2 + H_2O$. The heat of combustion of oxalic acid per milligram molecule was found to be 74·49 cal.

G. W. T.

Thermochemistry of Methyl Alcohol and Solid Methyl Salts. By F. STOHMANN, C. KLEBER, and H. LANGBEIN (*J. p. Chem.* [2], **40**, 341—364).—The authors give details of the determination of the following thermal values (see table, p. 101). The figures in the sixth column represent the excess or deficiency of the heat of combustion of the methyl salt when compared with the sum of the heats of combustion of the acid from which it is formed and methyl alcohol (compare Berthelot, *Mécanique Chimique*, **1**, 407).

The authors then point out the difference between the heats of combustion of the various isomerides in this table, and also give a table showing the value of the affinity constant K (Ostwald, Abstr., 1889, 818) for 24 acids, 20 of which agree with the rule.

Table of thermochemical results with methyl-compounds.

Substance.	Formula.	Molecular weight.	Heat of combustion.	Heat of formation.*

Thermochemistry of Nicotine. By A. Colson (*Compt. rend.*, **109**, 743—745).—*Nicotine.*—Heat of dissolution +6·6 Cals. at about 15°; heat of neutralisation by hydrochloric acid, 1st equivalent = 8·05 Cals.; 2nd equivalent = 3·47 Cals. Total heat of neutralisation by 4 mols. HCl = 12·06 Cals. With sulphuric acid, 1st equivalent = 9·54 Cals.; total heat of neutralisation by excess of acid = 13·46 Cals. It is evident that the two basic functions of nicotine have very different energies, a fact which is also shown by colour reagents. With litmus as indicator, nicotine has only one basic function, but with dimethyl-orange it has two.

The author has also made the following determinations:—

	Pyridine. Cals.	Piperidine. Cals.
Heat of dissolution	2·25	6·50
Heat of neutralisation, 1 mol. HCl	5·20	13·01
„ „ 1·5 mol. HCl	5·20	—
„ „ 1 mol. H_2SO_4	—	13·68

C. H. B.

Apparatus for making Vapour-density Determinations under Reduced Pressure. By J. F. Eykman (*Ber.*, **22**, 2754—2758).—The author describes with the aid of diagrams an apparatus in which vapour-density determinations may be made under reduced pressure, and in an atmosphere of hydrogen or some other indifferent gas.

The apparatus consists of a bulb-tube (A), somewhat similar in shape to that employed in V. Meyer's method; this is heated by some suitable vapour in the ordinary way. A weighed quantity of the liquid, the vapour-density of which is to be determined, is placed in a small, sealed, pipette-shaped tube, and suspended in a chamber in the upper extremity of the bulb-tube (A). The latter is connected at the top with a graduated manometer tube, placed perpendicularly and open below, and also with a 3-way cock, so that it can be exhausted and filled with hydrogen or any other gas. The apparatus having been completely filled with hydrogen, it is exhausted as completely as possible, the open end of the manometer being immersed in mercury; the bulb-tube is then heated at a constant temperature, and hydrogen is allowed to enter until the required pressure is obtained. As soon as no more mercury flows out of the manometer tube, the pressure is noted on the scale, and the neck of the bulb containing the substance is broken without opening the apparatus, by an ingenious device, so that it drops to the bottom of the bulb-tube (A), and is there converted into vapour. The pressure is thereby increased, and the mercury which flows from the manometer tube is collected in a tared vessel; the increase of pressure is ascertained either by weighing the mercury, the diameter of the manometer tube having been previously determined, or from the difference in the readings on the manometer scale. The vapour-density is calculated from the increase of pressure produced by the vaporisation of a known weight of the substance in a vessel of known volume under known conditions of temperature and pressure.

Experiments with safrole (b. p. 232°), ethyl cinnamate (b. p. 271°), naphthylamine (b. p. 300°), phenylpropionic acid (b. p. 200°), and other substances gave very satisfactory results.

The apparatus can be employed also for making determinations by V. Meyer's method in the usual way. F. S. K.

Specific Volumes of some Ethereal Salts of the Oxalic Acid Series. By A. Wiens (*Annalen*, **253**, 289—318; compare W. Lossen, Abstr., 1888, 335).—A comparison of the molecular volumes of metameric ethereal salts of oxalic, malonic, succinic, and glutaric acids, containing normal alkyl radicles, shows that the larger the quantity of carbon in the acid radicle the smaller the molecular volume at 0°. This is generally the case at the boiling point also, but two exceptions were noticed, the molecular volume of ethyl propyl malonate being smaller than that of ethyl succinate, and that of butyl malonate smaller than that of propyl butyl succinate; these exceptions may be due to the uncertainty of the determinations at the boiling point.

The difference in molecular volume corresponding with the difference in composition increases in homologous series with the quantity of carbon in the compound. The difference between the molecular volume of ethyl methyl succinate and ethyl butyl succinate, for example, is 71·3; that between ethyl butyl succinate and ethyl heptyl succinate, 76·4. The same has been found to hold good for ethereal salts of monobasic acids, ethers, phenol ethers, and alkyl iodides.

A comparison of the molecular volumes at 0° shows that an increase by the group CH_2 in the empirical formula corresponds with various differences in molecular volume, according to the manner in which this increase takes place. The increase in molecular volume by the conversion of the group C_nH_{2n+1} into $(CH_2)_x{\cdot}C_nH_{2n+1}$ (excluding methyl salts) is, on the average, 16·8 for each CH_2 group, but the difference between the ethyl and methyl salts is, on the average, 18·1. The increase, due to the conversion of the group CH_2 into $(CH_2)_n$, is, on the average, 16 for each additional CH_3 group, but when the group CH_3 is converted into CHMe (ethyl into isopropyl, for example), the corresponding increase in molecular volume is, on the average, 17·7.

The numerous experimental determinations are given in tables.

F. S. K.

Absorption of Gases by Mixtures of Alcohol and Water. By O. Lubarsch (*Ann. Phys. Chem.* [2], **37**, 524—525).—The author observes that the publication of Müller's determinations of the absorption of carbonic anhydride by mixtures of alcohol and water (Abstr., 1889, 816) has induced him to publish the results obtained so far in an investigation of the absorption of various gases by mixtures of alcohol and water; these are given in the accompanying table, showing the percentages by volume of the gases absorbed at 20° and 760 mm. pressure by solutions containing the various percentages of alcohol (by weight) given in the first horizontal line:—

Percentage of alcohol....	0·00	9·09	16·67	23·08	28·57	33·33	50·00	66·67	80·00
Oxygen.....	2·98	2·78	2·63	2·52	2·49	2·07	3·50	4·95	5·66
Hydrogen...	1·93	1·43	1·29	1·17	1·04	1·17	2·02	2·55	—
Carbonic oxide	2·41	1·87	1·75	1·68	1·50	1·04	3·20	—	—

The table shows that the minimum absorption for all three gases occurs at about the same proportion of alcohol to water, and this is the same as that found by Müller for carbonic anhydride, and therefore it seems probable that other gases will be found to behave in the same way.

G. W. T.

Simultaneous Solubility of Sodium and Potassium Chlorides. By A. Étard (*Compt. rend.*, **109**, 740—743).—The sum of the salts dissolved between −20° and +180° is represented by a straight line, $y_{-20}^{+180} = 27{\cdot}0 + 0{\cdot}0962t$. Calculating from this coefficient the temperature at the *limit of solubility*, that is, the point at which, by reason of the increase in the proportion of salt and the decrease in the proportion of water, the latter has disappeared, the temperature obtained is 738°, which, according to Carnelly, is the melting point of potassium chloride.

In presence of potassium chloride, the curve of solubility of sodium chloride between −20° and +75° is parallel with the axis of temperature. Beyond 75° it decreases, and at 97° becomes identical with that of potassium chloride, after which it decreases to 120°, and then becomes constant (16·7 per cent.).

The solubility of potassium chloride alone is represented between

—10° and +75° by a right line with a coefficient 0·1470, and between 75° and 180° by a second right line, which has a coefficient of 0·0793, and a limiting point at 913°, or considerably above the melting point of the salt.

In presence of sodium chloride, the curve of solubility of potassium chloride between —20° and +75° is a right line $y = 10·3 + 0·0962t$; from 75° to 120° the solubility increases rapidly, and above 120° it is represented by a right line with the same coefficient as between —20° and +75°. Its limiting point is 913°, and hence the curves of solubility of potassium chloride alone and in presence of sodium chloride are not parallel; but converge to 913°.

At the limiting point for the mixed salts, 738°, the proportion of the two salts would be 16·7 per cent. of sodium chloride and 83·3 per cent. of potassium chloride. The total quantity of chlorine is practically equal to the sum of the metals.

The curve representing the quantity of chlorine in solution is a right line; that representing the sum of the salts is also a right line; and hence the sum of the metals is likewise represented by a right line. The curve of the chlorine and the curve of the sum of the metals intersect at 738°. C. H. B.

Determination of Molecular Weights of Substances from the Boiling Points of their Solutions. By H. W. Wiley (*Chem. News*, **60**, 189—190).—"The apparatus employed consisted of an oval-round bottom flask of about 200 c.c. capacity," with a side tube from the neck connected with a condenser to keep volume of liquid constant. A thermometer graduated to tenths, but capable of being read to 0·02 of a degree was employed, the bulb being enveloped in fine copper foil to prevent interference of bubbles of steam. Sodium chloride was used to determine the factor, the number obtained, 8·968, was used for calculating the results in the following table; the volume of water being in all cases 150 c.c.; the temperature of boiling water was 99·50° except during the experiments with sodium nitrate, when it was 99·44°.

Substance taken.	Wt. taken in grams.	Total rise of temperature.	Molecular weight.	
			Calculated.	Theoretical.
KCl	6·0	0·35°	76·91	74·5
KBr	6·0	0·29	123·7	119·0
KI	9·0	0·33	163·1	166·0
KNO_3	6·0	0·33	108·7	101·0
$K_2Cr_2O_7$	18·0	0·38	283·2	295·0
$NaNO_3$	6·0	0·42	85·4	85·0
Saccharose	20·0	0·20	643·2	342·0
Oxalic acid	6·0	0·20	179·4	90·0

It will be noticed that the two organic compounds give double the theoretical molecular weight by this method. The results obtained with salts containing water of crystallisation do not agree with the molecular weights with or without this water. These results were obtained quite independently of those of Beckman.

D. A. L.

Behaviour of Colloïd Substances with Respect to Raoult's Law. By E. PATERNO (*Zeit. physikal. Chem.*, 4, 457—461).—The reduction of the freezing point by colloïd substances in water is very slight, and therefore leads to very high numbers for the molecular weights of such substances (Brown and Morris, Trans., 1889, 462). This, the author has observed, is the case with gallic and tannic acids; which behave like colloids in aqueous solution and give molecular weights many times greater than those ordinarily accepted for these substances. If, however, solutions in acetic acid are taken, the behaviour is found to be perfectly normal, and the reduction of the freezing point is that corresponding with the ordinary simple molecular weights. Hence substances only behave as colloids towards certain solvents, and the author holds that when a solid dissolves as a colloïd, the laws of freezing are not applicable to its solutions.

H. C.

Can Raoult's Method distinguish between Atomic and Molecular Union? By R. ANSCHÜTZ (*Annalen*, 253, 343—347; compare Anschütz and Pulfrich, Abstr., 1888, 1273).—The depression produced by naphthalene picrate in the freezing point of benzene corresponds with that which would be produced by its constituent parts present together in an uncombined state. The author concludes therefore that the combination of the components of naphthalene picrate and analogous substances such as dimethyl diacetylraceinate is not dependent on atomic union in the sense of the valence theory, but on molecular union.

If Raoult's method is capable of deciding between atomic and molecular union, it could be employed for determining the valency of elements.

F. S. K.

Kinetic Nature of Osmotic Pressure. By G. BREDIG (*Zeit. physikal. Chem.*, 4, 444—456).—In replying to certain objections raised by Pupin against the Van't Hoff theory of osmotic pressure (Abstr., 1888, 778), the author develops an equation for the behaviour of a dissolved substance which is similar to that of Van der Waals for the behaviour of gases. A special point of interest is, that account is taken of the presence and specific attraction of the solvent, and in this way an explanation of the mechanism of solution is obtained, which, it is claimed, is of wider application than that of Nernst (this vol., p. 3), in which this attraction is neglected.

H. C.

Sphere of Action of Molecular Forces. By B. GALITZINE (*Zeit. physikal. Chem.*, 4, 417—426).—By a process of theoretical reasoning similar to that already employed by Van der Waals, and using data given by Nadeschdin for several of the ethereal salts of the fatty acids in the critical condition, the author arrives at the conclusion that the sphere of action of the molecular forces is proportional to

the masses of the attracting molecules. He also concludes that the attraction is inversely proportional to the square of the distance.
H. C.

Fluid Crystals. By O. LEHMANN (*Zeit. physikal. Chem.*, 4, 462—472).—Under the name of "fluid crystals," the author describes a cholesteryl benzoate first prepared by Reinitzer, which, although apparently melting at 145°, behaves between 145° and 178° towards polarised light as though still having crystalline structure. In other respects the substance is in a perfectly liquid condition between these temperatures.
H. C.

New Gas Burners. By M. GROGER (*Zeit. ang. Chem.*, 1889, 329—331).—These are in general form similar to Bunsen burners, but instead of having any means of regulating the entry of air at the bottom of the mixing tube, the top of the burner is made conical, and there is a screw arrangement by which a solid cone can be raised within, so as partially to close the opening. By this means a flame of any character can be obtained, from a luminous one to one approaching that of a blowpipe, whilst the size of the flame can be greatly reduced without altering its character, and without risk of its flashing down. A burner on the same principle giving a flat flame is also described.
M. J. S.

Inorganic Chemistry.

Hydrogen Peroxide. By G. TAMMANN (*Zeit. physikal. Chem.*, 4, 441—443).—The spontaneous decomposition of hydrogen peroxide in alkaline solution is found to be independent of the amount or nature of the base which is present. It appears probable from the author's experiments that it is really caused by the presence of traces of metallic oxides, such as the oxide of iron, dissolved in the alkali. It is shown that the addition of small quantities of such oxides increases enormously the rate of decomposition.

The freezing points of aqueous solutions of hydrogen peroxide were determined, and from these a molecular reduction of 8·79 was found. Hydrogen peroxide being a non-electrolyte, this number would correspond with the formula H_4O_4.
H. C.

Hydrochlorides of Chlorides. By R. ENGEL (*Bull. Soc. Chim.* [3], 1, 695—699).—A review of the known hydrochlorides of chlorides, and a discussion of their probable constitution.
T. G. N.

Iodic Acid. By H. LESCŒUR (*Bull. Soc. Chim.* [3], 1, 563).—The crystals of iodic acid deposited from its solution in dilute or moderately concentrated nitric acid are monohydrated, whereas those obtained from the solution of iodic acid in concentrated nitric acid are anhydrous. The author thinks that the crystals deposited from solution in nitric acid of intermediate strength are mixtures of the hydrated and anhydrous varieties. T. G. N.

Iodic Acid; Double Salts of Iodic Acid with other Acids. By C. W. Blomstrand (*J. pr. Chem.* [2], **40**, 305—340; compare Abstr., 1887, 327).—In the oxygen-acids of phosphorus and iodine only one atom of oxygen is strongly united to the phosphorus and iodine, the radicles being $PO{\cdot}O$ and $IO{\cdot}O$ respectively, thus differing from the oxygen-acids of nitrogen, chlorine, and bromine, where two atoms of oxygen are equally strongly united to the nitrogen, chlorine, or bromine, the radicles being NO_2, ClO_2, and BrO_2 respectively.

In support of the above statement, the author has prepared double salts of iodic acid with other acids which may be regarded as condensation-products, requiring for their formation an extra-radicle oxygen atom, analogous to that which is allowed to exist in aldehyde and to be the cause of the easy polymorisation of that substance; thus, $C_2H_4{:}O + O{:}C_2H_4 = C_2H_4{:}O_2{:}C_2H_4$. The formula for iodic acid thus becomes $HO{\cdot}IO{:}O$.

Potassium sulphatoiodate was obtained by mixing potassium pyrosulphate (1 mol.) and iodate (1½ mol.) in concentrated solution, and its formula found to be identical with that of Marignac's salt $KO{\cdot}IO(OH){\cdot}O{\cdot}SO_2{\cdot}OK$.

Potassium molybdoiodate, $KO{\cdot}IO(OH){\cdot}O{\cdot}MoO_2{\cdot}OH + H_2O$, is obtained as a white precipitate on adding a concentrated solution of potassium nitrate to a solution of sodium molybdate and iodic acid in nitric acid; it crystallises with difficulty in short needles, and is sparingly soluble in water. *Ammonium molybdoiodate* is obtained in the same way, and has similar properties, but contains no water of crystallisation. The *thallium* and *lead* salts were obtained. *Molybdoiodic acid* is obtained as a yellowish, transparent mass on evaporating the solution formed by the action of dilute sulphuric acid on a mixture of barium iodate and molybdate. Several of its reactions with inorganic and organic salts are given.

Potassium tungstoiodate, $KO{\cdot}WO_2{\cdot}O{\cdot}IO(OH)OK + H_2O$, is obtained by adding, by degrees, a solution of iodic acid to one of potassium tungstate; after some hours, a crystalline magma is obtained, more than 90 per cent. of which consists of slender needles of the tungstoiodate, the rest being tabular crystals of acid tungstate.

Potassium chromoiodate has been described by Berg (Abstr., 1887, 776); the author's analyses of this salt leave some doubt both as to the amount of water it contains and as to its formula.

The author has also obtained an *ammonium triiodate*,

$$NH_4O{\cdot}IO(OH){\cdot}O{\cdot}IO(OH){\cdot}O{\cdot}IO_2,$$

of which the crystallography is given, and a *sodium triiodate*, $NaO{\cdot}IO(OH){\cdot}O{\cdot}IO(OH){\cdot}O{\cdot}IO_2 + \frac{1}{2}H_2O$. A. G. B.

Specific Gravity of Ammonia Solutions. By G. Lunge and T. Wiernik (*Zeit. ang. Chem.*, 1889, 181—183).—The authors have redetermined with extreme care the sp. gr., referred to water at 15°, percentage of ammonia, and coefficient of expansion of ammonia solutions of 24 different strengths. The following is an abstract of their table:—

Specific gravity at 15°.	Percentage of NH_3.	Correction of the sp. gr. for ± 1°.	Specific gravity at 15°.	Percentage of NH_3.	Correction of the sp. gr. for ± 1°.
0·990	2·31	0·00020	0·930	18·64	0·00042
0·980	4·80	0·00023	0·920	21·75	0·00047
0·970	7·31	0·00025	0·910	24·99	0·00052
0·960	9·91	0·00029	0·900	28·33	0·00057
0·950	12·74	0·00034	0·890	31·75	0·00061
0·940	15·63	0·00039	0·880	35·60	—

M. J. S.

A Derivative of Boric and Phosphoric Acids. By G. MEYER (*Ber.*, **22**, 2919).—When a mixture of boric and phosphoric acids is heated to redness, a very inert, white substance, PO_4B, is formed. It reddens moist litmus paper, but seems not to be dissolved by boiling water, and only to be very slowly attacked by boiling aqueous alkalis. Fusion with alkalis or alkaline carbonates causes instant decomposition, and fusion with sodium chloride also yields a soluble melt.

L. T. T.

Silicon. By E. P. HARRIS (*Chem. Cent.*, 1889, ii, 283—284).—The author has successfully prepared silicon by means of Gattermann's method, ignition of fine sand with magnesium powder, and in addition to the already known halogen-derivatives, he has prepared a *silicon nitride*, $NH_2\cdot SiN$, by acting on silicon chloride or silicon iodide with dry ammonia, whereby a considerable development of heat takes place. It is a snow-white powder. If the flux, obtained in the preparation of the silicon, be treated with dilute hydrochloric acid to dissolve out the magnesium oxide, silicon chloroform is obtained as a light, colourless, inflammable liquid, boiling at 42—44°.

J. W. L.

Preparation of the Chlorides of Silicon, Aluminium, &c. By H. N. WARREN (*Chem. News*, **60**, 158).—Iron alloys of silicon or aluminium are heated to redness in a clay crucible and a current of chlorine gas is passed into the mass, suitable means being adopted to collect the volatile products. With chlorine and silicon-iron, the ferric chloride is condensed first, then the silicon chloride; if hydrogen chloride is used instead of chlorine, the ferrous chloride formed remains in the crucible and silicon chloroform distils off. The aluminium chloride obtained from aluminium-iron is purified by mixing with iron borings and distilling, or if the aluminium-iron alloy is mixed with common salt previous to submitting it to the action of chlorine, a sublimate of aluminium sodium chloride is obtained.

D. A. L.

Combining Energy of Rubidium. By N. BEKETOFF (*Chem. Centr.*, 1889, ii, 245, from *Bull. Acad., St. Pétersbourg* [2], 1, 117—118). —*Preparation of the metal.*—Rubidium hydroxide is precipitated from the sulphate by barium hydroxide, calcined in a silver dish, and heated with fine aluminium clippings in an iron cylinder in a furnace; the cylinder being connected with a glass tube by means of an iron tube. A mixture of 1 equivalent of rubidium hydroxide and $1\frac{1}{2}$ equivalents of aluminium gives the best results. From 113 grams of hydroxide and 31 grams of aluminium, 31 grams of very pure rubidium was obtained. J. W. L.

Potassium Plumbate. Crystalline Hydrated Thallic Oxide. By D. CARNEGIE (*Chem. News*, **60**, 113).—Potassium plumbate is formed when potassium plumbite, obtained by dissolving litharge in molten potash, is strongly heated, with free access of air, for some time The colourless aqueous solution has strongly oxidising properties; it evolves chlorine with excess of dilute hydrochloric acid or with dilute sulphuric acid when the latter is added rapidly in excess, lead sulphate being also formed, the chlorine in this case being derived from the potassium chloride present as an impurity in the potash; when boiled with litharge, it yields lead peroxide and potassium plumbite; whilst with manganous sulphate it gives hydrated manganic oxide, and dilute sulphuric acid added slowly produces a brown precipitate of hydrated lead peroxide, PbO_2,H_2O.

Fused potash dissolves small quantities of thallic oxide, and the resulting yellow mass when treated with water yields a reddish-brown precipitate of the hydrated thallic oxide. If, however, the fusion is continued for some time, a mass of very light, glistening, microscopic, hexagonal plates is produced, of the composition $Tl_2O_3,3H_2O$; they are brown in colour but transmit yellow light. They are unaffected by a temperature of 340°, and are readily soluble in dilute hydrochloric and sulphuric acids, but generally a slight reduction to thallous salt takes place. D. A. L.

Influence of Hydrogen Chloride on the Solubility of Cuprous Chloride and of Lead Chloride. By R. ENGEL (*Bull. Soc. Chim.*, [3], 1, 693—695).—The amount of cuprous chloride dissolved by hydrochloric acid increases with the hydrogen chloride present. A saturated solution of cuprous chloride in hydrochloric acid when cooled to −40° deposits cuprous chloride crystals, no hydrochloride of cuprous chloride being formed.

The presence of hydrogen chloride at first determines a diminished solubility of lead chloride, and it is not until a considerable amount of hydrogen chloride is present that an increasing solubility obtains; this the author thinks is due to the formation of the soluble hydrochloride of lead chloride.

Solubility tables for each of the above salts in hydrochloric acid of various strengths are given. T. G. N.

Oxysulphides of Mercury. By T. POLECK (*Ber.*, **22**, 2859—2861; compare Poleck and Goercki, Abstr., 1888, 1166).—The author's further experiments have shown that the oxysulphides of mercury are not known, and that their existence is highly improbable.

F. S. K.

Aluminium Amalgam and its use in Thermochemistry. By J. B. BAILLE and C. FÉRY (*Ann. Chim. Phys.* [6], 17, 246—256).—Aluminium amalgam was first described by one of the authors in 1875. Experiments in sealed tubes in an atmosphere of indifferent gas show that solution of aluminium by mercury proceeds more rapidly the higher the temperature, and is especially active at the boiling point of mercury. It is, however, the liquid metal and not its vapour which attacks the aluminium. The quantity of aluminium dissolved at first increases with the time, but attains a maximum at the end of about two hours; it is independent of the pressure inside the tube and of the extent of metallic surface in contact, but is proportional to the quantity of mercury present.

When the mercury cools, crystals of the amalgam separate as a thick paste on the surface; it has the composition Al_2Hg_3. In moist air it rapidly oxidises with formation of the hydroxide, $Al_2O(OH)_4$. It decomposes water at the ordinary temperature, the change being especially rapid with very thin sheets of aluminium amalgamated on the surface. It is attacked by nitric acid, which has no action on aluminium alone, and rapidly decomposes a solution of potassium hydroxide with evolution of hydrogen.

If aluminium amalgam is mixed with antimony amalgam, metallic antimony separates at the surface in small crystals, and after a time the aluminium oxidises, so that the mercury is obtained free from both metals. When, on the other hand, lead amalgam is added to the aluminium amalgam, the aluminium separates at the surface and is rapidly oxidised. This phenomenon is analogous to the expulsion of aluminium from its alloys with copper, tin, &c., by mixing the fused alloys with lead.

The action of moist air on amalgamated aluminium foil in the calorimeter was utilised for the determination of the heat of formation of aluminium oxide and the hydroxides. The results obtained were as follows:—Al_2O_3, 392·6 Cals.; $Al_2O(OH)_4$, 394·6 Cals.; $Al_2(OH)_6$, 395·6 Cals.

The formation of the aluminium amalgam and the displacement of the aluminium by lead are accompanied by no appreciable thermal disturbance. C. H. B.

Preparation of Manganese from Manganese Chloride and Magnesium. By E. GLATZEL (*Ber.*, 22, 2857—2859).—Manganese can be prepared by heating a mixture of finely divided, anhydrous manganese chloride (100 grams) and dry, powdered potassium chloride (200 grams) in a covered Hessian crucible until it just melts, and then adding magnesium (15 grams) in portions of 3—4 grams, at intervals of 2—3 minutes; if the fused mass is too hot a very violent reaction occurs, and the contents of the crucible are thrown out. The crucible is covered again, heated more strongly, and then allowed to cool slowly in the furnace. The yield of manganese is 20—25 grams, the metal containing traces only of silica, and being quite free from magnesium.

The specific gravity of manganese, as the average of four determinations, was found to be 7·3921 at 22°. F. S. K.

Reduction of Ferric Bromide by Boiling. By L. L. DE KONINCK (*Zeit. ang. Chem.*, 1889, 149).—A solution of ferric bromide containing excess of bromine begins to show the presence of a ferrous salt as soon as the excess of bromine has been expelled by boiling. Ferric bromide, free from bromine and from ferrous salt, can only be obtained by passing air through the solution in the cold. The excess of bromine is very tenaciously retained. M. J. S.

Mineralogical Chemistry.

Native Lead in Sweden. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1889, ii, Mem., 32—36).—The Pajsberg manganese and iron ore mine twenty years ago yielded small quantities of native lead. At the Sjö mine in Örebro, the author discovered on January 24, 1889, this rare native metal in the neotokite (black manganese silicate) in the form of small laminæ with brilliant lustre. It closely resembles electrolytically deposited lead. The neotokite occurs in dolomite, and is accompanied by specular iron ore. B. H. B.

Atacamite in Chili. By L. DARAPSKY (*Jahrb. f. Min*, 1889, ii, Mem., 1—18).—The author gives a complete bibliography of the subject, as well as the results of his own investigations. On comparing the results of all the analyses published, it is found impossible to refer all the occurrences of atacamite to a typical formula, although the formula $CuCl_2,3CuO,3\frac{1}{2}H_2O$ is the closest approximation. The irregular development of the crystals and variations in the angles appear to indicate that atacamite is not a mineralogical unit, but, like the felspars, is composed of two or more members. The terminal members are believed to be $CuCl_2,3CuO,3H_2O$ and $CuCl_2,4CuO,6H_2O$.

With reference to the formation of atacamite, the author shows that processes producing a similar compound in the laboratory are impossible in nature. The only processes worthy of consideration are the formation by heating a mixture of basic copper nitrate and sodium chloride at 200°, or a mixture of the former with copper sulphate and sodium chloride at 100°. The presence of gypsum and calcite in the deposits and the intimate mixture of ferric oxide and cuprous oxide, however, clearly point to pyrites and similar minerals as the mother substances, which probably were highly decomposed before they came into contact with the salt of the sea-water. In all probability, the principal cementing material of the aqueous oxychloride is water, and it is impossible for atacamite to have been formed by a replacement of the water of hydration of the chloride by oxide. B. H. B.

Cerium and Yttrium Phosphates from South Norway. By C. W. BLOMSTRAND (*Jahrb. f. Min.*, 1889, ii, Ref. 44—46, from *Geol.*

Fören. i Stockholm förhandl., 9, 160.)—The author gives the results of analyses of monazite from Moss (light brown crystals), from Dillingsö (1. large fragments with crystal planes, and 2. small, prismatic crystals), from Moss (large, orange crystals), from Lonneby (large prismatic crystals, 1. brownish-yellow, and 2. ash-grey), from Arendal, from Naresto, and from Hvalö (1. large, yellowish-brown crystals, and 2. violet-brown lump) From the results of these nine analyses, the author concludes that the monazites are normal salts of tribasic phosphoric acid, with the excess of bases in combination with silicic acid. In conclusion, the author gives the results of two analyses of xenotime from Hvalö and from Narestö. B. H. B.

Pleonectite, a New Mineral from Sweden. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1889, ii, Mem., 40—43).—At the Sjö mine, Orebro, this new mineral has been found in narrow veins in a mixture of hausmannite, rhodonite, and calcite. It occurs in association with arseniopleite. It has a greyish-white colour, a hardness of 4, and a vitreous lustre. It does not occur in crystals. A qualitative analysis indicated that the mineral is a chlorine-bearing lead antimonio-arsenate, with an inconsiderable proportion of water. In composition and appearance, it most closely resembles hedyphane, a mineral discovered by Breithaupt in 1830, but is distinguished from that mineral by its infusibility before the blowpipe. The suggested name is derived from πλεονεκτέω (to have more) in allusion to the antimony minerals already discovered in the Sjö mine. A quantitative analysis of pleonectite will subsequently be published B. H. B.

Synthesis of Quartz, Corundum, &c. By W. BRUHNS (*Jahrb. f. Min.*, 1889, ii, Mem., 62—65).—By the investigations of Daubrée, St. Claire-Deville, Hautefeuille, De Chroustchoff, and Doelter, the action of fluorine as mineralising agent has been widely recognised. Whereas these investigators invariably worked with high temperatures, the author has succeeded in obtaining similar results with temperatures not exceeding 300°, and with high steam pressure. His apparatus consists of a firmly closed platinum crucible hermetically sealed in a steel case. By placing freshly precipitated ferric hydrate in the apparatus with ammonium fluoride, and heating for 10 hours at 250°, the author obtained crystallised ferric oxide. Freshly precipitated and ignited alumina, heated with water and a trace of ammonium fluoride for 10 hours at 300°, yielded hexagonal pyramids of corundum. Quartz crystals were obtained in a similar manner from amorphous silica. A remarkable result was obtained by acting with hydrofluoric acid on pulverised potash-felspar. The felspar employed was microcline, having the following percentage composition:—

SiO_2.	Al_2O_3.	K_2O.	Na_2O.	Total.
64·33	18·61	13·49	3·56	99·99

After heating for 53 hours with hydrofluoric acid at 300°, small crystals of tridymite were obtained; whilst the lid of the platinum vessel was covered with a crust of an isotropic regular compound of silica, alumina, potash, and fluorine. Experiments made with the expectation of obtaining titanic anhydride, tin oxide, andalusite, and topaz were unsuccessful. Another experiment, in which powdered iron was mixed with ferric oxide, amorphous titanic anhydride, and hydrofluoric acid, yielded crystals of titaniferous iron and magnetite. B. H. B.

Formation of Silicates. By J. Lemberg (*Jahrb. f. Min.*, 1889, ii, Ref., 34—36; from *Zeit. deutsch. geol. Ges.*, 39, 559).—By the action of solutions of various sodium silicates on kaolin at high temperatures, the author has obtained zeolites of the analcime series. In nature only one member of this series is known. By treatment with potassium salts, the analcimes obtained were converted into the corresponding members of the (anhydrous) leucite series. Of this series, too, only one member occurs in nature. Leucites containing a proportion of silica different from that of the mineral leucite, appear to be split up at a high temperature into orthoclase and leucite. By the action of kaolin on solutions of potassium carbonate or sodium carbonate, respectively, at a high temperature, a potassium-nepheline or cancrinite was formed; in both cases carbonic anhydride was also formed. This suggests a new source for carbonic anhydride in nature, kaolin itself being able to drive out the carbonic acid from the alkali carbonates. This change may also be effected if kaolin is mixed with calcium carbonate and subjected to the action of a hot solution of sodium chloride or potassium chloride, when calcium chloride is formed, and subsequently alkali carbonate, which acts on the kaolin. These reactions lead the author to speculate as to the genesis of cancrinite and analcime, and of felspar and elæolite in the presence of cancrinite. B. H. B.

Mineralogy of the French Creek Mines. By J. Egerman (*Jahrb. f. Min.*, 1889, ii, Ref. 17—18).—In the shafts of a magnetite mine at French Creek, Pennsylvania, the following minerals have been met with: iron pyrites, copper pyrites, apophyllite, desmine, and garnet in large crystals, and small crystals of calcite, orthoclase, pyroxene, and aragonite; masses of pyrallolite and erythrite, and needles of byssolite in calcite. Perfect crystals of apophyllite, 14 mm. side, gave on analysis the following results:—

SiO_2.	CaO.	K_2O.	H_2O.	Total.	Sp. gr.
51·63	25·42	6·27	16·58	99·90	2·35

An analysis of the desmine gave—

SiO_2.	Al_2O_3.	CaO.	MgO.	K_2O.	H_2O.	Total.
58·00	13·40	7·80	1·40	1·03	18·30	99·93

B. H. B.

Calamine and Apophyllite from the United States. By J. Egerman (*Jahrb. f. Min.*, 1889, ii, Ref. 256; from *Proc. Acad. Nat. Sci. Philadelphia*, 1889, 32—35).—The author gives analyses of (I) calamine from Friedensville, New Jersey, and of (II) apophyllite from St. Peters, Chester Co., Pennsylvania. The results are as follows:—

	SiO_2.	Fe_2O_3.	ZnO.	CaO.	K_2O.	H_2O.	Total.
I.	24·32	2·12	65·05	—	—	7·86	99 35
II.	51·63	—	—	25·42	6·25	16·58	99·88

The sp. gr. of the apophyllite is 2 35. B. H. B.

Anthochroite, a New Mineral from Sweden. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1889, ii, Mem., 36—39).—At Jacobsberg, in Wermland, there are two mines, one yielding braunite, the other hausmannite. Both mines are in the same Archæan limestone surrounded by granulite. The new mineral is met with only in the braunite mine. It is obtained by dissolving the braunite in hydrochloric acid. The violet residue is anthochroite It also occurs in association with garnet, idocrase, manganese-epidote, mica, and all the minerals known at this mine, and it is met with in narrow veins in the limestone. The grains are optically biaxial. The hardness is 5½, and the chemical composition as follows:—

SiO_2.	MnO.	CaO.	MgO.	Al_2O_3 and Fe_2O_3.	K_2O and Na_2O.	Total.
51·6	3 4	23·3	13·5	1·4	[6·8]	100·00

The mineral is thus a bisilicate of lime, magnesia, and manganese. Violan and richterite resemble it in composition, but not in appearance and optical properties. The name, derived from ἄνθος, flower, and χρῶμα, colour, is considered suitable on account of the brilliant colour of the new mineral and of the mixture in which it occurs.

B. H. B.

Tourmaline-bearing Copper Ores from Chili. By A. v. GRODDECK (*Jahrb. f. Min.*, 1889, ii, Ref. 113—115; from *Zeit. deutsch. geol. Ges.*, 1887, 239—266).—The association of tourmaline with Chilian copper ores has been previously noticed. The author has examined a series of ores from Tamaya, in which this association is well exhibited, the tourmaline occurring both in the sulphuretted and oxidised copper ores and also in the calcite and quartz gangue and in the spathose, quartzose, micaceous, and chloritic containing-rocks. The crystals are mostly 0 1 to 0·5 mm. in length, and are strongly pleochroïc. On analysis they yielded—

SiO_2.	Al_2O_3.	B_2O_3.	FeO.	CaO.	MgO.	Na_2O.	K_2O.	H_2O.	F.	Total.
36·34	32·22	10·87	8·31	0·79	3·92	3·14	0·22	3·89	trace	99·70

B. H. B.

Natrolite from Monte Baldo. By G. LUZZATTO (*Jahrb. f. Min.*, 1889, ii, Ref. 28; from *Rivista di Mineralogia e Cristallografia italiana*, **4**, 54—55).—Carefully selected, clear and transparent crystals gave on analysis the following results:—

SiO_2.	Al_2O_3.	Na_2O.	CaO.	H_2O.	Total.
47 16	26·76	16·18	0 28	9·57	99 95

These results correspond with the formula $Na_2Al_2Si_3O_{10} + 2H_2O$.

B. H. B.

Eruptive Rocks of the Rhone. By H. LENK (*Jahrb. f. Min.*, 1889, ii, Ref. 74—79; from *Sitzber. Wurtzburger phys.-med. Ges.*, 1886).—The author gives the results of a microscopic examination of the constitution of the eruptive rocks of the Rhone. Eight analyses are given of the various rocks. The author distinguishes seven groups of these rocks :—1. phonolites; 2. glass basalts (limburgite); 3. nepheline basalts; 4. felspar basalts; 5. nepheline-plagioclase basalts (identical with basanite); 6. hornblende basalts; 7. dolorites.

B. H. B.

The Transcaspian Naphtha District. By H. SJÖGREN (*Jahrb. f. Min.*, 1889, ii, Ref. 102—105, from *Jahrb. k. k. geol. Reichsanst.*, **37**, 47—62).—The author has subjected the mud from the Baku mud volcanoes to careful examination, and found it to yield on analysis :—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	MgO.	CaO.	K_2O.	Na_2O.	H_2O.	Total.
57·98	15·60	9·66	0·40	4·52	1·08	3·25	1 34	5·75	99·58

The microscopic investigation showed that the principal constituents were isotropic, glassy grains, frequently very impure, pure white and reddish-brown, isotropic grains, a pyroxenic mineral, green amphibole, felspar with and without twinning striation, quartz, calcite in rhombohedra, magnetite, and iron pyrites. The remainder of the paper deals with the geology of the district, the author concluding that the naphtha emanates from great depths.

B. H. B.

An undescribed Meteoric Iron from East Tennessee. By F. A. GENTH (*Jahrb. f. Min.*, 1889, ii, Ref. 42; from *Proc. Acad. Nat. Sciences of Philadelphia*).—This meteorite appears to have fallen in 1860 at a distance of 10 miles from Cleveland, East Tennessee. Its original weight was about 115½ kilos. The mean of three analyses gave—

Fe.	Ni.	Co.	Cu.	P.	S.	Total.	Sp. gr.
89·60	8·80	0·67	0·12	0·32	0·01	99·52	7·521

B. H. B.

Meteorites of Alfianello and Concepcion. By C. FRIEDHEIM (*Jahrb. f. Min.*, 1889, ii, Ref., 278—279; from *Sitz-Ber. d. k. preuss. Akad. Wiss. Berlin*, **13**, 345—367).—The analysis of the meteorite of Alfianello gave 7·92 per cent. nickel-iron (I), 7·78 troilite, 0·60 chrome-iron, 37·38 olivine (II), 46·29 bronzite and augite (III) :—

	I.		II.	III.
Fe......	88·84	SiO_2......	34·92	53·86
Ni......	10·09	Al_2O_3.....	—	5·76
Co.....	1·07	FeO.....	13·79	10·55
Mn....	0·26	CaO......	—	7·73
		MgO.....	51·26	21·68

These results differ considerably from those previously published by Maissen, Flight, and v. Foullon.

The meteorite that fell in 1880 between Nogayá and Concepcion was briefly described by Websky and Daubrée. The complete analysis gave the results shown under IV, and that of the portion soluble in hydrochloric acid the results shown under V:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	Cr_2O_3.	MnO.	CaO.	MgO.	Alkalis.
IV.	27·22	2·35	30·64	0·38	0·09	2·56	19·24	0·18
V.	26·67	2·24	30·42	—	—	2·25	18·79	0·12

	Ni.	Co.	Cu.Sn.	Ignition.	Insoluble.
IV.	1·61		trace	14·47	—
V.	1·46	0·12	—	—	1·82

With ether, 0·21 per cent. of a yellow bituminous substance was extracted, which volatilised at 200°. When ignited in a current of oxygen the meteorite yielded carbonic anhydride (= 1·56 of carbon) and 14·03 per cent. of water. Treated with boiling water, 40 grams of the meteorite yielded (in grams)—

SO_3.	S_2O_2.	K_2O.	Na_2O.	MgO.	CaO.	Cl.
0·5001	0·0551	0·0059	0·0479	0·0750	0·1450	0·0009

There was also contained in the meteorite 3·27 per cent. of sulphur, 0·064 per cent. of phosphorus, 2·08 per cent. of sulphuric anhydride, and 0·034 per cent. of nitrogen. B. H. B.

Organic Chemistry.

Purification of Amyl Iodide. By H. Malbot (*Bull. Soc. Chim.* [3], 1, 604).—Amyl iodide may be completely freed from the alcohol which distils over in its preparation by treatment with an equal volume of concentrated hydrochloric acid, which dissolves this impurity; the alcohol may be recovered by subsequently diluting the hydrochloric solution. T. G. N.

Carbonylhydroferrocyanic Acid and Carbonylferrocyanides. By J. A. Muller (*Ann. Chim. Phys.* [6], 17, 93—102).—The author has previously described a new class of ferrocyanides and ferricyanides in which the group CO is substituted for KCN (Abstr., 1887, 649). The crude violet precipitate (*loc. cit.*), which still contains ferrocyanide, is treated with a warm solution of potassium carbonate, the liquid filtered, and when cold slightly acidified with acetic acid and mixed with excess of lead acetate. After remaining for a day, the liquid is again filtered, the filtrate mixed with a slight excess of potassium carbonate, and boiled. The traces of lead which remain in the filtrate from the lead carbonate are removed by means of hydrogen sulphide, after slightly acidifying with acetic acid.

Carbonylhydroferrocyanic acid, $H_3FeCO(CN)_5$, is obtained by the action of hydrogen sulphide on the copper salt, and when the solution is evaporated over potassium hydroxide in the dark the acid separates in colourless, platy crystals with an acid taste and an astringent after-taste. It is acid to litmus, and decomposes alkaline carbonates. When the aqueous solution is boiled, the acid decomposes with formation of a violet-blue precipitate and evolution of a large quantity of hydrocyanic acid, but no carbonic anhydride is evolved, and neither formic acid nor ferrocyanide is formed.

The *sodium salt* is obtained in the same manner as the potassium salt (*loc. cit.*), and crystallises with 6 mols. H_2O in very pale-yellow, monoclinic needles which become anhydrous at 110°. The insoluble carbonylferrocyanides are obtained from the alkaline salts by double decomposition.

The *silver* salt, precipitated by excess of silver nitrate in presence of a small quantity of acetic acid, forms a white, curdy precipitate which rapidly becomes black even in the dark. After being washed with water, it contains no potassium. It is slightly soluble in dilute mineral acids with evolution of hydrocyanic acid, but is practically insoluble even in boiling acetic acid. Potassium hydroxide converts it into potassium carbonylferrocyanide and silver oxide. It retains water after being dried in a vacuum, and at 100° to 110° it slowly decomposes, still retaining a small quantity of water. At a dull red heat decomposition is rapid, cyanogen and hydrogen cyanide being evolved. If in the preparation of the salt the alkaline carbonylferrocyanide is in excess, the precipitate only becomes slightly grey, but it retains potassium nitrate and possibly some silver nitrate.

The *uranium* salt, $(UO_2)_3(FeCOCy_5)_2 + 5H_2O$, from uranium nitrate and the potassium salt, is an orange-yellow, gelatinous substance which retains no potassium, and is only slightly soluble in water, but somewhat more soluble in dilute acetic acid. At 70° it forms a ruby-red, granular solid, which re-acquires the yellow colour when powdered; at 110°, it becomes black and partially decomposes, but still retains a small quantity of water.

The *cobalt salt* forms a lilac precipitate which contains 3·5 mols. H_2O, and retains potassium even after prolonged washing, its composition being represented by the formula $(Co_{2\cdot77}K_{0\cdot23})FeCO(CN)_5$. It is slightly soluble in water and is decomposed by cold dilute nitric acid. In a dry vacuum or when gently heated, it is partially dehydrated and becomes deep-blue. This change takes place even in boiling water, but the salt is rehydrated on cooling. It retains a small quantity of water even at 110°.

The *copper* salt forms a yellowish-green, gelatinous precipitate insoluble in dilute nitric or sulphuric acid. It retains no potassium, becomes dehydrated with change of colour when gently heated, and at 110° forms a somewhat hygroscopic, dark-brown powder, which undergoes slight decomposition at this temperature but still retains a small quantity of water.

The *ferric* salt is obtained from the potassium salt and ferric chloride as a violet precipitate which is free from potassium, and when dried at a moderate temperature forms a very friable resinous mass with a brilliant conchoidal fracture of very high metallic lustre. It alters even below 100°, and undergoes profound change at 100° to

110°. After being dried in a vacuum, it retains 12 to 13 per cent. of water. The violet precipitate dissolves in an aqueous solution of oxalic acid, forming a solution with a magnificent violet colour, but it is not soluble in acetic, lactic, succinic, tartaric, or citric acid. It dissolves, however, in solutions of the normal salts of these acids even in presence of a small quantity of free acid. The solutions are almost colourless or have only a slight violet tinge, but on the addition of sulphuric acid carbonylferrocyanide is again formed, and is precipitated or remains in solution according to the nature of the acid present. The violet precipitate of the ferric salt is not soluble in solutions of potassium chloride or nitrate, or in very dilute phosphoric or sulphuric acid, but is distinctly soluble in solutions of sodium hydrogen phosphate. It is slightly decomposed by potassium sulphate, and the liquid becomes acid; it decomposes potassium hydrogen carbonate even at 25°, carbonic anhydride being evolved. Analysis of the salt shows that it contains more ferric iron than is required by the formula, a result probably due to the presence of ferric oxide which was contained in the ferric chloride solution used in the preparation of the salt and cannot be removed by washing. Precipitation of the alkaline salt with ferric chloride solution of known strength, followed by a determination of the iron in the filtrate, also showed that the amount of iron precipitated was greater than the calculated quantity.

All these results point to the existence of a trivalent acidic radicle of the formula $FeCO(CN)_5$. The insoluble carbonylferrocyanides resemble the insoluble ferrocyanides in retaining small quantities of water which cannot be expelled without decomposing the salt.

C. H. B.

Note by Abstractor.—It is interesting to compare the properties of ferric carbonylferrocyanide with those of soluble Prussian-blue (Guignet, Abstr., 1889, 475). C. H. B.

Vinyl Alcohol, a Constant Constituent of Ethyl Ether. By T. Poleck and K. Thümmel (*Ber.*, 22, 2863—2880).—When a solution of mercury oxychloride in pure sodium or potassium carbonate is shaken for 10—20 minutes with ether from the most varied sources, a yellowish-white, amorphous precipitate is always produced in small quantities, varying from 0·89—6·64 per cent. The samples employed had generally a neutral reaction, liberated iodine from a solution of potassium iodide, gave a brown coloration with potash, and were free from acetaldehyde; after having been shaken with the mercury solution, the ether gave no coloration with potash.

The white precipitate has the composition $CH_2{:}CH{\cdot}OHg{\cdot}O{\cdot}Hg_2Cl_3$, and may be named *vinyl oxymercurochloride*. It turns yellow at 100°, becoming colourless again on cooling, and at about 170° it swells up, like mercury thiocyanate, with evolution of a gas which burns with a blue flame. It is insoluble in water, alcohol, and ether; when freshly precipitated, it dissolves freely in hydrochloric acid, nitric acid, and hydrocyanic acid, but when dry it dissolves completely only on boiling even in concentrated hydrochloric acid. When boiled for a long time with potash, it is converted into a greenish-black powder which is insoluble in potash, and the alkaline solution contains a colourless compound which is precipitated on adding nitric acid.

The greenish-black compound has the composition

$$CH{:}C{\cdot}Hg_2(OH)_2,Hg_2(OH)_2,$$

and is named "*acetylenemercury*." It dissolves in concentrated acetic acid, forming a crystalline acetate, and it is soluble in nitric acid and in aqua regia, but insoluble in hydrochloric acid. It explodes very violently when heated (at about 157°), but not by percussion. The *acetate*, $CH{:}C{\cdot}Hg_2(OAc)_2,Hg(OAc)_2$, is obtained when the black powder is dissolved in concentrated acetic acid, and the filtered solution evaporated. It decomposes at 100°, or when boiled with water, and it is insoluble in ether and acids, except acetic acid; if the acetic acid solution is diluted, a colourless compound is precipitated and mercury remains in solution. When hydrogen sulphide is passed into the acetic acid solution, a yellowish or colourless precipitate is produced, and the precipitate turns greenish-black after some days. The acetate is decomposed by warm potash, being reconverted into the black, explosive compound.

The colourless compound which is precipitated on adding nitric acid to the alkaline solution of vinyl oxymercurochloride (see above) has the composition $CH{:}C{\cdot}HgO,HgCl_2$, and is named *acetylenemercury oxychloride*. It is an amorphous powder, insoluble in hydrochloric acid, nitric acid, ammonia, and alkaline carbonates, but readily soluble in potash, yielding a solution which is coloured yellow by hydrogen sulphide; it is not explosive, and when heated it volatilises, leaving a carbonaceous residue.

When ether is distilled with phenylhydrazine, the distillate gives no coloration with potash, and no precipitate with the mercury solution; the residue contains ethylidene phenylhydrazine.

Vinyl oxymercurochloride (see above) is decomposed by bromine, yielding bromal hydrate or bromoform and formic acid, according to the length of time during which the reaction takes place. When treated with a solution of iodine in potassium iodide, this vinyl-compound gives iodoform, and when triturated with dry potassium iodide an energetic reaction takes place, the dark-coloured explosive substance being formed. If vinyl oxymercurochloride is suspended in water and treated with potassium iodide, the mixture turns yellow or greyish-green and the solution becomes strongly alkaline; on adding hydrochloric acid, a reddish-brown powder is precipitated. When excess of hydrogen sulphide is passed into water containing the vinyl-compound in suspension, γ-trithioacetaldehyde (m. p. 75—76°), identical with the compound obtained by Marckwald (Abstr., 1888, 127), is formed; a small quantity of a very volatile, unpleasant smelling oil, probably thioacetaldehyde (compare Marckwald, *loc. cit.*), is also produced. Vinyl oxymercurochloride is decomposed by ammonium sulphide, with separation of mercuric sulphide, yielding acetamide and probably also traces of thioacetamide. It is only slowly oxidised by chromic acid and potassium permanganate, yielding acetic acid, carbonic anhydride, and small quantities of formic acid.

When a large quantity of ether is repeatedly submitted to fractional distillation, two liquids, boiling at 30—31° and 37—38° respectively, are obtained; both these liquids give a copious precipitate with the mercury solution, but they are generally obtained in small quantities only, owing to polymerisation taking place during the distillation. The lower boiling liquid has an ethereal odour and a neutral reaction, but it soon becomes acid, owing to the formation of acetic acid; it does not liberate iodine from potassium iodide until it has undergone oxidation, a fact which indicates the formation of hydrogen peroxide. The higher boiling liquid has a slight ethereal odour, does not alter on keeping, has a neutral reaction, and, unlike the lower boiling liquid, is not oxidised by potassium permanganate. An ammoniacal solution of silver nitrate is not reduced by either of the two liquids, but both give a brown coloration with potash; the lower boiling liquid only reduces alkaline copper solutions and yields iodoform with potassium iodide.

Vinyl ethyl ether gives a precipitate with the mercury solution referred to above, but the precipitate differs from vinyl oxymercurochloride in composition, and in not forming an explosive compound when treated with potash.

Vinyl chloride and vinyl iodide in alcoholic solution give precipitates from which explosive substances are obtained by treatment with potash.

The above experiments show that the substance, which is present in ether and which is precipitated by the mercury solution, is vinyl alcohol.

When air containing ozone is passed for a long time through pure ether, or when pure ether is shaken for a long time with hydrogen peroxide, it yields subsequently a precipitate of vinyl oxymercurochloride.

A violent reaction occurs when pure ether is added drop by drop to anhydrous chromic acid, a liquid distilling which, if the operation is carefully conducted, smells only slightly of ether, but has, on the other hand, a peculiar aldehyde-like odour. When the distillate is fractionated, a liquid boiling at 33°, probably a polymeride of vinyl alcohol, is obtained. It has a neutral reaction, does not liberate iodine from potassium iodide, and does not give a brown coloration with potash, but it yields a copious precipitate with the mercury solution; it resembles the liquid boiling at 37—38° (see above) in its other properties.

Vinyl alcohol and hydrogen peroxide are formed when pure ether is exposed to direct sunlight either alone or in contact with water; the presence of hydrogen peroxide can be recognised by the chromic acid reaction.

Commercial ether gives only a slight blue coloration with dilute chromic acid solution, but on agitating with air an intense blue coloration is produced. The formation of hydrogen peroxide in this way accounts for the explosions which sometimes occur when ether, which has been kept for a long time, is distilled. F. S. K.

Synthesis of some Glycerols by means of Hypochlorous Acid. By S. REFORMATZKY (*J. pr. Chem.* [2], 40, 396—419; compare Abstr., 1885, 882).—A *chlorhydrin*, $C_6H_{13}O_2Cl$, is obtained on adding, by degrees, a solution of hypochlorous acid free from chlorine to allyl dimethyl carbinol (20 grams), and some ice-water, in a retort, cooled by ice (compare Orloff, Abstr., 1886, 138, 681). When the odour of hypochlorous acid has nearly disappeared, a little sodium thiosulphate is added to destroy the last traces of it, the liquid is filtered, and then shaken with ether, which extracts the chlorhydrin (23 grams); it is a thick liquid.

To obtain the corresponding *glycerol*, $C_6H_{14}O_3$, potassium hydroxide (25 grams) is added to the residue in the retort, without previously extracting the chlorhydrin, and the mixture is distilled until two-thirds have passed over; the residue is nearly all evaporated in a dish, the excess of potassium hydroxide neutralised with sulphuric acid, and the excess of the latter with dry sodium carbonate; evaporation is then continued to dryness, and the residue extracted with 95 per cent. alcohol; the solution is mixed with ether, which throws down foreign matters, and then evaporated to obtain the glycerol (80 per cent. of theory). It distils at about 198° at a pressure of 60—65 mm., and is a colourless, sweet, thick liquid, soluble in water and alcohol but not in ether. The *acetate*, $C_6H_{11}(OAc)_3$, is obtained by heating the glycerol (3 grams) with acetic anhydride (9 grams) at 100° in a tube for 10 hours, and evaporating off the excess of the latter; it is a mobile liquid insoluble in water, soluble in alcohol and ether.

When oxidised by nitric acid, the glycerol yields a triatomic monobasic acid containing 6 atoms of carbon. Potassium permanganate oxidises the glycerol to hydroxyvaleric acid.

A *chlorhydrin*, $C_8H_{12}ClO_2$, is prepared from allyl diethyl carbinol in the same way as from allyl dimethyl carbinol, and from this the corresponding *glycerol*, $C_8H_{15}(OH)_3$, is obtained; it is a colourless, thick, bitter liquid, soluble in water, alcohol, and ether, and boiling at 204—207° under 55—60 mm. pressure. An *acetyl-derivative*, $C_8H_{15}O_3Ac_3$, was obtained.

Allyl methyl propyl carbinol yields a *chlorhydrin*, $C_8H_{15}(OH)_2Cl$, as a somewhat thick, colourless liquid. The corresponding *glycerol*, $C_8H_{15}(OH)_3$, is a thick, colourless liquid, easily soluble in water and alcohol, sparingly in ether, and boiling at 210° under 60 mm. pressure. An *acetyl-derivative* was obtained.

Unsuccessful attempts were made to prepare a glycerol from allyl dipropyl carbinol, and a glycerol by the hydrolysis of diallyl carbinol by cold sulphuric acid.

A *chlorhydrin*, $C_7H_{11}(OH)_3Cl_2$, was obtained from diallyl carbinol by the action of hypochlorous acid, but it gave no glycerol.

A. G. B.

Identity of Brain Sugar with Galactose. By H. THIERFELDER (*Zeit. physiol. Chem.*, 14, 209—216; compare Brown and Morris, Trans., 1890, **57**, 57).—Bäyer and Liebrich (*Virchow's Arch.*, **39**, 183) first described a carbohydrate in the brain which they obtained from protagon. Since then, Otto (*ibid.*, **41**, 272), Geoghegan (*Zeit. physiol. Chem.*, **3**, 337), and Thudichum (Abstr., 1882, 537) obtained one by treating cerebrin with hydrochloric acid. The last-named observer prepared it in a crystalline form, and termed it cerebrose. In the present research, the sugar was prepared from cerebrin by the action of 2 per cent. sulphuric acid. It reduces Fehling's solution, yields mucic acid on oxidation with nitric acid, and thus resembles galactose, which is the only glucose that yields mucic acid on this treatment. In its melting point, specific rotation, fermentation, and phenylhydrazine-compound, its properties are also the same as those of galactose. The mother substance of this sugar in the brain has yet to be isolated. W. D. H.

Eucalyptus Honey. By MAQUENNE (*Ann. Chim. Phys.* [6], **17**, 495—500).—Eucalyptus honey is secreted by a peculiar species of black bee, which constructs enormous hives on the summits of the gigantic *Eucalypti* of Australia. Some of these hives furnish as much as 5000 kilos. of crude honey each. It is a thick syrup, similar in appearance to ordinary honey but containing a somewhat smaller proportion of crystals, and it has a strong aromatic odour. It consists essentially of levulose and dextrose in practically the same proportions as in invert sugar, with a small quantity of aromatic substances, and traces of gum insoluble in alcohol. No peculiar sugar could be detected. C. H. B.

The Precipitation of Colloïd Carbohydrates by Salts. By J. POHL (*Zeit. physiol. Chem.*, **14**, 151—164).—The neutral salts used in the separation of proteïds can also be employed for the separation of plant mucilages and other colloid carbohydrates. Those examined in the present research can be grouped as follows:—

A. Those not precipitable by saturation with neutral salts:—Gum arabic and sodium arabinate.

B. Those precipitable by saturation with ammonium sulphate:—The mucilages of tragacanth, althea, linseed, and cydonia. Gum tragacanth is also distinguishable from gum arabic by its lesser solubilities. Cydonia mucilage is a mixture of cellulose, and a carbohydrate very like gum tragacanth.

C. Those precipitable by saturation with ammonium sulphate, ammonium phosphate, and potassium acetate:—Carragheen mucilage.

D. Those precipitable by saturation with sodium sulphate, magnesium sulphate, ammonium sulphate, and ammonium phosphate:—Soluble starch, lichen starch, dextrin, salep mucilage, and pectin. These forms of carbohydrates are further distinguished by the percentage of salt necessary for the commencement of precipitation; thus tragacanth requires complete saturation with ammonium sulphate for its precipitation, that is, 53·5 grams of salt to every 100 c.c. of solution. Salep mucilage begins to be precipitated by 40·4 grams, and soluble starch by 24·1 grams of the same salt per 100 c.c. of solution. Further, by fractional precipitation with magnesium sulphate, salep mucilage can be differentiated into two varieties, named α and β. These two varieties further differ in the melting-points of their phenylhydrazine-compounds.

W. D. H.

Oxalenediamidoxime and Oxaleneanilidoximamidoxime. By W. ZINKEISEN (*Ber.*, **22**, 2946—2957.)—*Oxalenediamidoxime*, $OH{\cdot}N{:}C(NH_2){\cdot}C(NH_2){:}N{\cdot}OH$, is prepared by gradually adding cyananiline (100 parts) to a solution of hydroxylamine hydrochloride

(50 parts) in 90 per cent. alcohol (500 parts). The amount of sodium carbonate necessary to liberate the hydroxylamine is then added, and the whole filtered from the sodium chloride. The filtrate is evaporated down a little, well shaken when cold, and left for some hours; the diamidoxime which separates is dissolved in boiling water, and boiled with animal charcoal. It crystallises in dazzling, white, concentrically-grouped lanceolate crystals, melts at 196° (uncorr.), with evolution of gas, is sparingly soluble in alcohol, insoluble in ether, chloroform, benzene, and light petroleum, readily soluble in hot water; it dissolves in acids and bases. The aqueous solution, with copper sulphate, ferric chloride, and Fehling's solution gives a grass-green, flaky precipitate, a deep brownish-red coloration, and a dirty precipitate respectively. The *hydrochloride* forms slender, colourless prisms, insoluble in absolute alcohol and ether. The *dibenzoyl-derivative*, $C_{16}H_{14}N_4O_4$, obtained by gradually adding the finely-powdered dioxime to hot benzoic chloride, crystallises in slender, slightly-yellow plates, melts at 217°, is insoluble in water, ether, benzene, and light petroleum, readily soluble in chloroform, sparingly in alcohol. It is insoluble in hydrochloric acid and in alkali, but dissolves unchanged in acetic and in cold strong sulphuric acids.

Oxalenediazoximedibenzyl, $\mathrm{CPh}{<}\begin{smallmatrix}\mathrm{N}-\\ \mathrm{O\cdot N}\end{smallmatrix}{>}\mathrm{C\cdot C}{<}\begin{smallmatrix}-\mathrm{N}\\ \mathrm{N\cdot O}\end{smallmatrix}{>}\mathrm{CPh}$, is formed when oxalenediamidoxime is heated for a long time with an excess of benzoic chloride. It crystallises from chloroform in slender, white needles, melts at 246°, is soluble in benzene, insoluble in water, alcohol, ether, and in strong hydrochloric acid and alkalis; but readily soluble in strong sulphuric and acetic acids. When heated above its melting point, it sublimes without decomposition.

Diacetyloxalenediamidoxime, $C_6H_{10}N_4O_4$, prepared by gradually adding the powdered diamidoxime to boiling acetic anhydride, crystallises in needles, melts at 184—187°, dissolves readily in alcohol, sparingly in benzene, and is insoluble in chloroform, ether, and light petroleum. Acids and bases readily decompose it. When heated for a long time with acetic anhydride, *oxalenediazoximediethenyl*, $C_6H_6N_4O_2$, is obtained. This crystallises in colourless needles, melts at 164—165°, dissolves in alcohol and chloroform, less readily in hot water and benzene; and is insoluble in ether and light petroleum. It sublimes in long, slender needles.

Oxalenediamidoxime diethyl ether, $\mathrm{OEt{\cdot}N{:}C(NH_2){\cdot}C(NH_2){:}N{\cdot}OEt}$, is prepared by boiling an alcoholic solution of oxalenediamidoxime (1 mol.) with ethyl iodide (2 mols.) and the calculated amount of sodium ethoxide for three hours in a reflux apparatus, evaporating the whole to half its original bulk, treating with water, and filtering. It is washed several times with water, dissolved in boiling alcohol, and sufficient water added to produce a slight turbidity. It crystallises in slender, colourless, matted needles, melts at 114—115°, dissolves readily in alcohol, ether, chloroform, and benzene, sparingly in hot water. The hydrochloride crystallises well.

Oxalenediazoximedipropenyldicarboxylic acid,

$$\mathrm{COOH{\cdot}C_2H_4{\cdot}C}{<}\begin{smallmatrix}\mathrm{N}-\\ \mathrm{O\cdot N}\end{smallmatrix}{>}\mathrm{C\cdot C}{<}\begin{smallmatrix}-\mathrm{N}\\ \mathrm{N\cdot O}\end{smallmatrix}{>}\mathrm{C{\cdot}C_2H_4{\cdot}COOH},$$

is obtained by heating an intimate mixture of oxalenediamidoxime (1 mol.) and succinic anhydride (2 mols.) at 140—150°, dissolving the product in hot, dilute aqueous soda, and precipitating with hydrochloric acid. It crystallises from boiling water in almost colourless needles, melts at 200°, dissolves sparingly in hot water, readily in alcohol and chloroform, and is insoluble in ether and benzene. The alkali salts are readily soluble in water.

Oxalenediuramidoxime,

$$\mathrm{OH{\cdot}N{:}C(NH{\cdot}CO{\cdot}NH_2){\cdot}C(NH{\cdot}CO{\cdot}NH_2){:}N{\cdot}OH},$$

prepared by adding a saturated solution of potassium cyanide (2 mols.) to a hydrochloric acid solution of oxalenediamidoxime (1 mol.), crystallises from very dilute alcohol in slender, white needles, melts at 191—192° with decomposition, dissolves sparingly in hot water, readily in alcohol, and is insoluble in ether, benzene, and chloroform. Both acids and bases dissolve it readily.

Ethyl oxalenediamidoxime dicarbonate, $C_8H_{14}N_4O_6$, is formed when finely powdered, dry oxalenediamidoxime (1 mol.) is slightly heated on a water-bath with ethyl chlorocarbonate for 20 minutes. It crystallises from water in long, thin needles, melting at 168°; it is sparingly soluble in hot water, and soluble in alcohol, ether, and in acids and bases.

Oxaleneanilidoximamidoxime, $\mathrm{OH{\cdot}N{:}C(NHPh){\cdot}C(NHPh){:}N{\cdot}OH}$, is formed as bye-product in the action of cyananiline on hydroxylamine, and is best prepared by gradually adding solid cyananiline to an alcoholic solution of hydroxylamine hydrochloride (2 mols.), filtering from the ammonium chloride, and evaporating down until crystals separate. When cold it is again filtered from the oxalenediamidoxime, and evaporated almost to dryness. The crystals which separate after a long time are crystallised from boiling water. It forms colourless, hexagonal plates, melts at 180°, and has almost exactly the same properties as oxalenediamidoxime, except that it dissolves more readily in alcohol, and seems to be less stable. The precipitate with copper sulphate has a less pure colour than that which the diamidoxime gives. The *hydrochloride* crystallises in slender, colourless needles, which become green when exposed to air. The *dibenzoyl-derivative*, $C_{22}H_{18}N_4O_4$, prepared by heating oxaleneanilidoximamidoxime (1 mol.) with benzoic chloride (2 mols.) on a water-bath, crystallises from dilute alcohol in slender, slightly-yellow, matted needles, melts at 189°, is insoluble in water and light petroleum, soluble in alcohol, benzene, and chloroform. When boiled with alkalis, it is gradually decomposed, but does not change when boiled for a short time with hydrochloric acid.

Oxaleneanilidoximazoxime ethenyl, $\mathrm{OH{\cdot}N{:}C(NHPh){\cdot}C}\!\left\langle{}^{N}_{N\cdot O}\right\rangle\!\mathrm{CMe}$, is obtained by dissolving oxaleneanilidoximamidoxime in hot acetic anhydride, filtering when cold, washing repeatedly with cold water, and dissolving in boiling water containing a little alcohol. It crystallises in slender, colourless needles, melts at 172°, dissolves in alcohol, ether, and benzene, rather sparingly in hot water. It is dissolved by both acids and bases, and is less stable than the double azoxime obtained from oxalenediamidoxime. N. H. M.

Succinenediamidoxime. By F. Sembritzki (*Ber.*, 22, 2958—2967).—*Succinenediamidoxime*,

$$OH\cdot N:C(NH_2)\cdot CH_2\cdot CH_2\cdot C(NH_2):N\cdot OH,$$

is prepared by adding a strong solution of hydroxylamine hydrochloride (2 mols.) and sodium carbonate (1 mol.) to an alcoholic solution of ethylene dicyanide (1 mol.), and keeping the mixture for three or four days in a well-closed vessel. It is then filtered from the crystals of the diamidoxime and sodium chloride, and left to evaporate in a warm place. The sodium chloride is dissolved in cold water, and the remaining diamidoxime recrystallised from hot water. It forms transparent, monoclinic crystals, $a : b : c = 1\cdot2744 : 1 : 0\cdot9269$; $\beta = 79° 50'$, melts at 188°, with evolution of ammonia, and is sparingly soluble in hot alcohol, insoluble in cold water, ether, acetone, benzene, and chloroform. It yields salts with acids and with bases; the *hydrochloride* is white, and dissolves in absolute alcohol; the *copper salt* is bright-green; the *silver salt* is white, but at once becomes dark when exposed to light, and is completely reduced when heated, with formation of a silver mirror. The *dibenzoyl-derivative*, $C_{19}H_{18}N_4O_4$, crystallises from amyl alcohol in small, white needles, melts at 192°, is insoluble in water, alcohol, ether, chloroform, and benzene, &c., and does not unite with acids and alkalis.

Succinenediazoximedibenzenyl,

$$CPh\left\langle\begin{matrix}O\cdot N\\ N\end{matrix}\right\rangle C\cdot CH_2\cdot CH_2\cdot C\left\langle\begin{matrix}N\cdot O\\ N\end{matrix}\right\rangle CPh,$$

is obtained when the above dibenzoyl-derivative is heated with water for five hours at 150—160°. It crystallises in needles, melts at 158—159°, is soluble in benzene and hot alcohol, sparingly soluble in ether, insoluble in water, light petroleum, and chloroform.

Diacetylsuccinenediamidoxime, $C_8H_{14}N_4O_4$, crystallises from absolute alcohol in white, monoclinic scales, $a : b : c = 1\cdot2998 : 1 : 0\cdot9105$; $\beta = 82° 58'$; it melts at 167—168°, is soluble in hot water and in acids, insoluble in ether, benzene, and in alkalis. The *diethyl salt*, $OEt\cdot N:C(NH_2)\cdot CH_2\cdot CH_2\cdot C(NH_2):N\cdot OEt$, prepared by digesting the equivalent amounts of succinenediamidoxime, sodium ethoxide, and ethyl iodide for some hours, crystallises in colourless needles, melts at 119°, dissolves readily in water, alcohol, ether, and chloroform, is insoluble in light petroleum, and is soluble in acids, but not in alkalis.

Succinenediuramidoxime, $C_6H_{12}N_6O_4$, is readily obtained by mixing concentrated aqueous solutions of the hydrochloride of the diamidoxime and potassium cyanate. It crystallises, with 2 mols. H_2O, in needles which soften at 100—105°; the anhydrous salt melts at 163·5 with decomposition, is soluble in hot water, insoluble in cold water, alcohol, ether, and benzene, &c., unites readily with acids, but is sparingly soluble in cold alkalis.

Succineneimidodioxime,  $\begin{matrix}CH_2\cdot C(N\cdot OH)\\ |\\ CH_2\cdot C(N\cdot OH)\end{matrix}>NH$, is formed in small quantity in the preparation of succinenediamidoxime, but is obtained alone when the mixture is digested for several days at 60—70°. It crystallises with 2 mols. H_2O, and resembles the diamidoxime in its properties and solubility. When dissolved in aqueous potash, the solution becomes first blue, then green. With ferric chloride, a dark-violet coloration is produced. The *copper salt* is dirty green; the *silver salt*, $C_4H_7N_3O_2Ag_2$, forms small, lustrous plates which detonate when heated, leaving a residue of silver. The *dibenzoyl-derivative*, $C_{18}H_{15}N_3O_4$, melts at 187—189° with previous blackening, is soluble in benzene and hot alcohol, insoluble in water, ether, and chloroform, does not unite with acids, but dissolves in hot alkalis with decomposition. The *diacetyl-derivative*, $C_8H_{11}N_3O_4$, is a white, crystalline powder, melts at 170—171°, dissolves in water, alcohol, ether, and chloroform, sparingly in benzene, and is insoluble in light petroleum. N. H. M.

Glutarenediamidoxime and its Derivatives. By J. BIEDERMANN (*Ber.*, **22**, 2967—2973).—Trimethylene cyanide is conveniently prepared by digesting trimethylene bromide dissolved in 96 per cent. alcohol (5 parts) with a slight excess of finely powdered potassium cyanide for eight hours on a water-bath, filtering, and distilling off five-sixths of the alcohol. The residue is treated with an equal volume of ether. The ethereal alcoholic layer is separated from the aqueous, evaporated down, and the resulting yellowish oil distilled under diminished pressure.

Glutarenediamidoxime, $CH_2[CH_2{\cdot}C(NH_2){:}N{\cdot}OH]_2$, is obtained, together with glutarenimidodioxime, when equivalent amounts of hydroxylamine hydrochloride, sodium carbonate, and trimethylene dicyanide, dissolved in aqueous alcohol, are digested for 10 hours at 60—70°. A part of the diamidoxime separates on cooling. The mother liquor is evaporated to dryness, extracted with boiling water, the solution allowed to cool, filtered, and again evaporated to dryness. The residue now consists of sodium chloride, glutarenimidodioxime, and a small amount of the diamidoxime. Glutarenediamidoxime crystallises from water in well-formed, lustrous prisms (with 1 mol. H_2O), dissolves readily in hot water and alcohol, less in ether and chloroform, and is dissolved by acids and bases. It gives a reddish-brown coloration with ferric chloride. The *diacetyl-derivative*, $C_9H_{16}N_4O_4$, crystallises in microscopic, slender, colourless needles, melts at 115°, and is readily soluble in hot water and alcohol, insoluble in ether, chloroform, benzene, &c.

Glutarenediazoximediethenyl,  $CH_2\left(CH_2{\cdot}C{<}\begin{matrix}N{\cdot}O\\ \text{—}N\end{matrix}{>}CMe\right)_2$, is prepared by boiling a solution of glutarenediamidoxime in acetic anhydride, evaporating down, dissolving the crystals which separate in benzene, and precipitating with light petroleum. It forms slender, colourless needles, melting at 138—139°.

Glutarenimidodioxime,  $NH{<}\begin{matrix}C(N{\cdot}OH){\cdot}CH_2\\ C(N{\cdot}OH){\cdot}CH_2\end{matrix}{>}CH_2$, is obtained by extracting the residue from the preparation of the diamidoxime with hot absolute alcohol; the solution is evaporated, and the residue dissolved in chloroform and precipitated with light petroleum. It melts at 193° without decomposition, is very sparingly soluble in alcohol, ether, and chloroform, insoluble in benzene and light petroleum, soluble in both acids and alkalis, and gives a red-violet coloration with ferric chloride. The *picrate* crystallises from alcohol in splendid, yellow needles, melting at 175° with decomposition; the *hydrochloride* forms white needles. The *diacetyl-compound*, $C_9H_{13}N_3O_4$, is a white, crystalline powder, melts at 127°, is readily soluble in water, alcohol, ether, and chloroform, sparingly in benzene, and is readily dissolved by acids and alkalis. The *benzoyl-compound*, $C_{19}H_{17}N_3O_4$, crystallises in stellate groups of needles, melts at 179—180°, is soluble in hot alcohol and benzene, almost insoluble in water, ether, and chloroform.

When trimethylene dicyanide is treated with hydroxylamine (1 mol.) at the ordinary temperature, a compound having the formula $C_5H_9N_3O$ (which is the formula of γ-cyanobutenylamidoxime) is obtained. It crystallises in colourless needles, melts at 103°, is readily soluble in hot water and alcohol, very sparingly in ether, chloroform, and benzene. With ferric chloride it gives a red coloration, but neither Fehling's solution, silver nitrate, nor lead acetate gives a precipitate. It has only basic properties, being insoluble in alkalis.

N. H. M.

Hydroxamic Acids of the Fatty Series. By C. Hoffmann (*Ber.*, 22, 2854—2856).—*Acetohydroxamic acid*, OH·CMe:NOH, and not ethenylamidoxime, as previously stated (compare Abstr., 1887, 911), is formed when acetamide (1 mol.) is treated with hydroxylamine hydrochloride (1 mol.) in cold, concentrated, aqueous solution. The mixture is kept until it no longer reduces Fehling's solution, then acidified with acetic acid, and mixed with excess of copper acetate; the precipitated copper salt is washed, suspended in alcohol, decomposed with hydrogen sulphide, and the filtrate evaporated. It separates from dilute alcohol and hot water in crystals containing ½ mol. H_2O, melts at about 58—59°, and is very readily soluble in water and alcohol, but insoluble in ether. It loses its water over sulphuric acid under reduced pressure, and then melts at 87—88°. It has a neutral reaction, gives a dark, cherry-red coloration with ferric chloride, and reduces ammoniacal silver nitrate solution in the cold.

Formamide seems to react with hydroxylamine and sodoacetanilide and benzamide, but only at a higher temperature, and even then very slowly; benzhydroxamic acid was obtained in rhombic plates, melting at 124—125°.

F. S. K.

Intramolecular Change of Allylcarbamides into Isomeric Bases. By S. Gabriel (*Ber.*, 22, 2984—2991).—*Propylene-ψ-thiocarbamide*,

$CHMe<\genfrac{}{}{0pt}{}{S\cdot C(NH)}{CH_2\cdot NH}>$

is formed when allylthiocarbamide (m. p. 74°; 1 gram) is heated with fuming hydrochloric acid (sp. gr. = 1·17; 3 c.c.) at 100° for an hour, and the clear liquid evaporated on a water-bath. The syrup is treated with 33 per cent. aqueous potash, and extracted with benzene. It has an unpleasant, distinctly basic odour, and when distilled, decomposes with formation of hydrogen sulphide and ammonia. It is soluble in water. The *platino-*

chloride $(C_4H_8N_2S)_2,H_2PtCl_6$, forms orange-yellow crystals; the *aurochloride* crystallises in yellow, indented needles; the picrate melts at 198—200°, and is sparingly soluble. When the base is oxidised by means of hydrobromic acid and bromine-water (Abstr., 1889, 848), *β-methyltaurocarbamic acid*, $SO_3H{\cdot}CHMe{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}NH_2$, is formed; this crystallises in colourless crusts, readily soluble in hot water.

β-Methyltaurine, $SO_3H{\cdot}CHMe{\cdot}CH_2{\cdot}NH_2$, is obtained by heating the acid (5 grams) with crystallised baryta (20 grams) and water (20 c.c.) for five hours at 140—150°. It crystallises in rhombic plates, which swell up when heated.

Propylenethiocarbamide methiodide, $C_4H_8N_2S,MeI$, prepared by evaporating a mixture of the base dissolved in methyl alcohol and methyl iodide, melts at 171—172°.

β-Dimethyltaurine, $SO_3H{\cdot}CHMe{\cdot}CH_2{\cdot}NHMe$, is obtained by treating the above methiodide with strong potash, and extracting the base with benzene. The base (15 grams) is then dissolved in water (300 c.c.), neutralised with hydrobromic acid, treated with bromine-water (2 litres), and heated on a water-bath, until the oil which separates is redissolved. The whole is evaporated to dryness, dissolved in hot water (15 c.c.), and allowed to cool. Crystals of *dimethyltaurocarbamic acid*, $SO_3H{\cdot}CHMe{\cdot}CH_2{\cdot}NMe{\cdot}CO{\cdot}NH_2$ (about 3 grams) separate; these melt at 230—240°. The filtrate from these crystals is evaporated down, and heated with water (15 c.c.) and baryta (30 grams) at 150—160° for three hours. The product is freed from barium, evaporated to dryness, and dissolved in absolute alcohol (40 c.c.). It is then further purified from the potassium bromide still remaining by means of platinic chloride. It crystallises from 96 per cent. alcohol in flattened prisms, melts at 220—223°, and is extremely soluble in water.

Propylenecarbamide,  $CHMe{<}\begin{matrix}O{\cdot}C(NH)\\CH_2{\cdot}NH\end{matrix}{>}$ is formed by the oxidation of allylcarbamide. The *picrate* crystallises in long, lustrous needles, melting at 185—186°. N. H. M.

Ethylenelactic Acid. By M. Siegfried (*Ber.*, **22**, 2711—2717).—The mother liquors from the crystalline zinc paralactate, prepared from (horse) flesh, contain, as has been previously shown by Wislicenus (*Annalen*, **167**, 302), small quantities of a zinc salt, which does not crystallise. The author finds that this amorphous zinc salt is a salt of acetyllactic acid. When it is dissolved in alcohol and reprecipitated with ether, it is partially converted into a basic salt, from which acetyllactic acid can be obtained in colourless needles, melting at 166—167°. This formation of zinc acetyllactate is explained by the facts that flesh extract always contains traces of acetic acid, and that acetyllactic acid is produced in small quantities when an aqueous solution of zinc paralactate is boiled with zinc acetate.

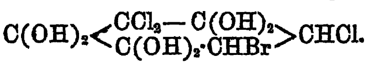
Acetyllactic acid, $OAc{\cdot}CHMe{\cdot}COOH$, is also formed in small quantities when paralactic acid is repeatedly evaporated with 30 per cent. acetic acid. It can be obtained in somewhat larger quantities by gradually adding finely divided zinc paralactate (1 part) to anhydrous zinc acetate (4 parts), heated to its melting point, and keeping the mixture in a liquid condition until it forms a homogeneous paste. The melt is digested with hot water, the cold solution treated with dilute sulphuric acid and quickly extracted with pure ether; the resulting syrup dissolved in water, the filtered solution evaporated with glacial acetic acid (⅓ vol.), and the crystals which separate are spread on a porous plate. Acetyllactic acid can also be prepared by heating paralactic acid (1 part) with glacial acetic acid (1 part), and sodium acetate (1½ parts), at 180° for four hours; it is isolated as already described.

The acid prepared by these methods has the same melting point and the same crystalline form as that obtained from flesh extract. It is readily soluble in alcohol and most ordinary solvents, but when kept it becomes insoluble in alcohol, does not melt below 300°, and decomposes at a higher temperature, but without melting; this insoluble modification is only slowly hydrolysed by alkalis, whereas the original acid (m. p. 166—167°) is readily decomposed even by water. The acid prepared synthetically and that obtained from flesh do not rotate the plane of polarisation.

When acetyllactic acid, prepared from paralactic acid, is boiled with soda, it is decomposed into acetic acid and optically inactive lactic acid; the occurrence of the latter in flesh extract, a fact which has been observed by Heintz, may be due to the previous formation of acetyllactic acid.

Lactic acid yields an acetyl-derivative identical with the compound described above in crystalline form, in melting point, and in its behaviour with solvents; the same acetyl-derivative can also be obtained in small quantities by carefully decomposing ethyl acetyllactate with cold water. F. S. K.

Conversion of Pentamethylene-derivatives into Benzene-, Pyridine-, and Thiophen-derivatives. By A. HANTZSCH (*Ber.*, 22, 2827—2840).—A compound of the composition $C_6H_8Cl_3BrO_6$ is formed when trichloropentenedihydroxycarboxylic acid (1 part) is heated for a few minutes at 100° with bromine (5 parts) and water (5 parts) (compare Abstr., 1889, 853). It crystallises in well-defined, quadratic prisms, melts at 87°, and is readily soluble in alcohol and ether, but rather sparingly in water. It quickly loses 1 mol. H_2O when kept over sulphuric acid, a second molecule of water being very slowly given off under the same conditions. The anhydrous compound can also be obtained by recrystallising the hydrate from hot chloroform, from which it separates in hexagonal prisms melting at 136°. Chlorobromanilic acid is formed when the hydrate is warmed with excess of alkali, but a portion is completely decomposed; this reaction takes place quantitatively when the hydrate is boiled with a concentrated solution of sodium carbonate, the characteristic red crystals of the sodium salt of chlorobromanilic acid separating from the hot solution. The hydrate does not combine with phenylhydrazine, it gives the same decomposition-products as trichloropentenedihydroxycarboxylic acid when heated at 130° with excess of bromine and water, and it is reconverted into the original acid when reduced with a small quantity of sodium amalgam in alcoholic solution. These facts seem to show that this bromo-compound is a pentene-derivative of constitution analogous to that of trichloropentenedihydroxycarboxylic acid, but the following experiments point to a totally different constitution. It is not acted on by concentrated sulphuric acid with formation of an open-chain ketone acid as is the case with the pentenecarboxylic acid. It has no well-defined acid properties, only a feeble acid reaction, and dissolves in sodium carbonate without evolution of carbonic anhydride, and not more readily than in water. It can be extracted from slightly alkaline solutions with ether, and it cannot be accurately titrated with baryta and phenolphthalein. Its electrical conductivity was examined by Ostwald, and found to be seventy times less than that of the original acid, a fact which shows beyond doubt that the two compounds are analogously constituted. The constitution of this bromo-compound is, therefore, most probably



$$C(OH)_2<\begin{matrix}CCl_2-C(OH)_2\\C(OH)_2\cdot CHBr\end{matrix}>CHCl.$$

β-Chloropyridine is formed when a solution of 1·2-chlorodiketopentamethylene is boiled with ammonia or when a solution of the sodium-derivative is boiled with any ammonium salt. The reaction is best carried out by adding ammonium acetate to a warm, saturated solution of the sodium-derivative and heating the mixture to boiling, when chloropyridine distils with the steam. This pyridine-derivative is identical with the β-chloropyridine obtained by Ciamician from chloroform and potassium-pyrroline.

β-Chloropyridine picrate crystallises in slender, yellow needles melting at 135° with previous softening. The *mercurochloride* crystallises in small, colourless needles melting at about 180°. The *aurochloride* forms moss-like needles and decomposes at about 200°.

α Thiophenaldehyde is produced when 1·2-chlorodiketopentamethylene is treated with hydrogen sulphide at a temperature below 100°, and the reaction takes place almost quantitatively when hydrogen sulphide is passed into a solution of the sodium-derivative heated to 30—40° and finally to boiling; the aldehyde distils with the steam, and only small quantities of resinous products remain. The thiophenaldehyde thus obtained gives all the characteristic colour reactions for this compound, and it is converted into the corresponding acid on exposure to the air. It combines with hydroxylamine, yielding the aldoxime (m. p. 128°), and with phenylhydrazine, forming the hydrazone which melts at 134·5°. F. S. K.

Decomposition-products of Chloranilic Acid. By A. Hantzsch (*Ber.*, **22**, 2841—2853).—*Tetrachloroketotrihydroxypentamethylenecarboxylic acid*,  $\begin{matrix}CO-CCl_2\\C(OH)_2\cdot CCl_2\end{matrix}>C(OH)\cdot COOH$, is produced when chloranilic acid (½ mol.) or trichlorodiketopentamethylenehydroxycarboxylic acid (1 mol.) is treated with sodium hypochlorite, but the formation takes place slowly and only in neutral solutions (compare Abstr., 1888, 1190). It is best prepared by dropping a solution of sodium hypochlorite into a cold aqueous solution of pure potassium chloranilate until the colour disappears, then adding a volume of the hypochlorite solution equal to or rather larger than that already employed, and keeping the mixture for 24 hours; it is then treated with concentrated hydrochloric acid, extracted at least four times with ether, and the crude product spread on a porous plate. It crystallises in small, colourless needles, melts and is completely decomposed at 216°, and is very readily soluble in water and alcohol; it generally crystallises with 2 mols. H_2O, both of which it loses slowly when kept over sulphuric acid. It resembles the original trichlorinated acid in appearance and is, like the latter, completely decomposed by alkalis, yielding oxalic acid. It does not combine with orthotoluylenediamine or with phenylhydrazine, and it is very stable towards oxidising agents; it is not acted on by boiling bromine-water, only very slowly by potassium chlorate and hydrochloric acid, and it crystallises unchanged from hot concentrated nitric acid. It is not acted on by hot sulphuric acid, in which it is only very sparingly soluble. It is a bibasic acid, and measurements of its electrical conductivity show that it is a simple chloro-substitution derivative of the trichlorinated acid. The *ammonium* salt, $C_6H_2Cl_4O_6(NH_4)_2 + H_2O$, crystallises in short prisms, melting at 147—148° with decomposition, when an alcoholic solution of the acid is saturated with ammonia and allowed to evaporate in the air. The *barium* salt crystallises well and is very readily soluble in acetic acid and moderately easily in water. The *lead*, *silver*, and *mercuric* salts are amorphous and sparingly soluble, but the *mercurous* salt crystallises well. The acid gives a red coloration with ferric chloride. When the acid is heated with excess of bromine and water at 130°, it is decomposed into carbonic anhydride, oxalic acid, and tetrachlorodibromacetone.

Chlorodiketopentamethylenehydroxycarboxylic acid,

$$\begin{array}{l}\mathrm{CO{\cdot}CHCl} \\ \vert \\ \mathrm{CO{-}CH_2}\end{array}\!\!>\mathrm{C(OH){\cdot}COOH},$$

is obtained when a well-cooled ammonical solution of the corresponding trichloro-derivative is treated with zinc-dust, in small portions at a time, until there is no further development of heat; the solution is then filtered, acidified, extracted with ether, and the crude acid purified by converting it into the ammonium salt. The yield is small. It crystallises from ether in colourless, microscopic needles, melts at 147° with decomposition, and behaves with solvents like the other acids of this class. The *ammonium* salt, $C_6H_3ClO_5(NH_4)_2$, crystallises from water, in which it is readily soluble, in short, thick prisms, and decomposes at about 140°, but has no well-defined melting point. Solutions of lead, silver, and mercurous salts produce precipitates in neutral solutions of the ammonium salt; when orthotoluylenediamine hydrochloride is added to a warm concentrated solution of the ammonium salt, a yellowish-green *azine* is precipitated and phenylhydrazine acetate precipitates an oily *hydrazone* which gradually solidifies. When the acid is treated with concentrated sulphuric acid, it yields a syrupy acid, probably chlorodiacetylglyoxylic acid, and when warmed with excess of bromine it is decomposed into chloropentabromacetone (m. p. 91—92°), carbonic anhydride, and oxalic acid.

Dichlorodiketopentamethylenehydroxycarboxylic acid can be obtained in like manner from the corresponding tetrachloro-derivative, but the yield is very small; it is a syrup and is decomposed by concentrated soda in the cold, yielding large quantities of oxalic acid.

Tetrachlorodiacetylglyoxylic acid, $COOH·C(OH)_2·CCl_2·CO·CO·CHCl_2$, is obtained when trichlorodiacetylglyoxylic acid (1 mol.) is treated with sodium hypochlorite (1 mol.) as described above. It crystallises in small, colourless needles, melts at 146—147° with decomposition, and is very readily soluble in all ordinary solvents. It forms an *azine* and a crystalline *hydrazone*, and it is readily decomposed by sodium hypochlorite.

Dichloropyruvic acid, $CHCl_2·CO·COOH$, is obtained when tetrachlorodiacetylglyoxylic acid (1 mol.) is treated with sodium hypochlorite (1 mol.) in neutral aqueous solution. It crystallises in needles with ½ mol. H_2O, melts at 78—79°, and loses its water over sulphuric acid: it is very readily soluble in water, but is reprecipitated on adding concentrated hydrochloric acid. It combines with phenylhydrazine forming a *hydrazone* which contains chlorine.

Bromodichloropyruvic acid, $CBrCl_2·CO·COOH$, can be prepared by heating the preceding compound with bromine and water at 120°; it separates from water with 3 mols. H_2O in colourless crystals, loses its water over sulphuric acid, and is immediately decomposed into bromodichloromethane and oxalic acid when treated with cold alkalis.

F. S. K.

Two Isomeric Symmetrical Dimethylglutaric Acids. By N. Zelinsky (*Ber.*, **22**, 2823—2827).—*Ethyl dimethyldicyanoglutarate*, $CH_2[CMe(CN)·COOEt]_2$, is formed when ethyl sodocyano-α-propionate (2 mols.) is treated with methylene iodide (1 mol.) in alcoholic solution; the yield of the crude product is about 50 per cent. of the theoretical quantity. It boils at 282—288° with only slight decomposition (at 165—170° under 10—12 mm.), but could not be obtained pure. When boiled for 10—12 hours with moderately concentrated hydrochloric acid it yields two isomeric symmetrical dimethylglutaric acids, $CH_2(CHMe·COOH)_2$, which can be separated by fractional crystallisation. The one melts at 102—104°, the other at 128°; the *silver* salts, $C_7H_{10}Ag_2O_4$, of both acids are moderately stable and undergo no change when heated at 100°.

Diphenylglutaric acid (symmetrical) has been prepared by the author and Feldmann, and is at present under investigation.

Dimethyladipic acid (symmetrical) seems to exist in two isomeric modifications.

F. S. K.

Dicarboxylic Acids, $C_8H_{14}O_4$. By K. Auwers and V. Meyer (*Ber.*, **22**, 3005).—Of the two acids obtained by the action of silver on ethyl α-bromisobutyrate (Abstr., 1889, 1145), the volatile acid is tetramethylsuccinic acid, whilst the non-volatile acid is symmetrical dimethyladipic acid, $C_2H_4(CHMe·COOH)_2$ (compare Zelinsky, preceding abstract). According to Hell (*Ber.*, **10**, 2229), a portion of the α-bromisobutyric acid decomposes into hydrogen bromide and methylacrylic acid, which unite, according to Fittig and Engelhorn (*Annalen*, **200**, 65), to form β-bromisobutyric acid. The normal product of the action of silver on the latter would be the above dimethyladipic acid. In order to test the correctness of this view, the authors are studying β-bromisobutyric acid and especially its behaviour towards silver. N. H. M.

Allylethylsuccinic Acids. By E. Hjelt (*Ber.*, **22**, 2906).—Allylbutenyltricarboxylic acid was heated until the evolution of carbonic anhydride ceased, and the residue was crystallised from boiling water. Two isomeric *allylethylsuccinic acids*, $C_9H_{14}O_4$, were obtained. The *para-acid* crystallises in small, rhombic scales, sparingly soluble (1 : 110) in water, and melts at 155—156°; the *anti-acid* crystallises in small plates, more readily soluble (1 : 37) in water, and melts at 110—115°. L. T. T.

Action of Bromine on Ethyl Oxalacetate. By W. Wislicenus (*Ber.*, **22**, 2912—2915).—*Ethyl dibromoxalacetate*,

$$COOEt\cdot CO\cdot CBr_2\cdot COOEt,$$

is formed by treating a solution of the acetate in an indifferent solvent with a slight excess of bromine. It forms a colourless, oily liquid which boils at 165—168° under 20 mm. pressure; it is insoluble in water, and gives no coloration with ferric chloride. It is easily decomposed by bases, the resolution taking place between the ketone- and dibromo-groups. Ammonia, for instance, yields oxamide, dibromacetamide, and alcohol; whilst phenylhydrazine yields oxalic diphenylhydrazide $(CO\cdot N_2H_2Ph)_2$.

Ethyl monobromoxalacetate, $COOEt\cdot CO\cdot CHBr\cdot COOEt$, is obtained by the action of exactly the theoretical quantity of bromine on pure ethyl oxalacetate in carbon bisulphide solution; its purification is possible by fractional distillation in a vacuum, but is most easily effected by the crystallisation of the sodium-derivative. It is an oil boiling at 144—147° under 8—12 mm. pressure. Its alcoholic solution is coloured intensely red by ferric chloride. Attempts to isolate the acid $COOH\cdot CO\cdot CH(OH)\cdot COOH$ by substituting hydroxyl for the bromine proved futile, although this acid seems to be formed, but immediately decomposed again. L. T. T.

Tricarballylic Acid. By W. O. Emery (*Ber.*, **22**, 2920—2924).—*Tricarballylic chloride*, $C_6H_5Cl_3O_3$, prepared by the action of phosphoric chloride on the acid, forms a thick, pale-yellow oil boiling, with slight decomposition, at 140° under 14 mm. pressure. *Tricarballylanilide*, $C_3H_5(CONHPh)_3$, obtained by the action of aniline on the chloride, crystallises in very thin, white needles melting at 252°. *Trimethyl tricarballylate*, $C_3H_5(COOMe)_3$, is a colourless liquid boiling at 150° under 13 mm. pressure; sp. gr. = 1·18221 at 20° (water at 4° = 1). With concentrated aqueous ammonia, it yields *tricaballyl-*

amide, $C_3H_5(CONH_2)_3$, which crystallises in long prisms easily soluble in water, very sparingly in alcohol, ether, chloroform, &c., and melting with decomposition at 205—207° to a black liquid.

L. T. T.

Phenylthiophen. By A. RENARD (*Compt. rend.*, **109**, 699—700).—When a mixture of the vapours of toluene and sulphur in equal proportions by weight is passed through an iron tube heated to dull redness, the products are hydrogen sulphide, carbon bisulphide, and a blackish substance which solidifies on cooling. If the latter is distilled, it yields some carbon bisulphide and unaltered toluene, and a yellow, solid substance which is purified by repeated crystallisation from alcohol. A portion of the product is only very slightly soluble in alcohol, and consists of another thiophen-derivative.

Phenylthiophen, C_4SH_3Ph, forms brilliant, white plates, which melt at 170°, sublime easily, and boil at about 300°. It is only slightly soluble in cold alcohol, more soluble in boiling alcohol, very soluble in benzene, light petroleum, chloroform, and carbon bisulphide, but less soluble in ether. With isatin and sulphuric acid, it gives a blue coloration, and with phenanthraquinone and sulphuric acid, a green coloration. Chromic acid in presence of acetic acid converts it into benzoic acid.

Dibromophenylthiophen, $C_6H_4Br{\cdot}C_4SH_2Br$, is obtained by the action of excess of bromine, and forms very small, white crystals, which melt at 195°, and are almost insoluble in all ordinary solvents, but dissolve to some extent in carbon bisulphide. It gives a green coloration with phenanthraquinone and sulphuric acid, and, when oxidised, yields parabrombenzoic acid, melting at 251°.

Dinitrophenylthiophen, $C_6H_4NO_2{\cdot}C_4SH_2{\cdot}NO_2$, is obtained by the gradual addition of phenylthiophen to fuming nitric acid. It forms a yellow, non-crystallisable powder which melts at 178°, is almost insoluble in all ordinary solvents, and, when oxidised, yields paranitrobenzoic acid melting at 233°.

Phenylthiophendisulphonic acid is formed by heating phenylthiophen with ordinary sulphuric acid at a temperature of 50° to 60°; it yields a barium salt which is very soluble in water and very difficult to crystallise.

Phenylthiophentetrasulphonic acid is obtained by the action of Nordhausen acid on phenylthiophen; its barium salt is very soluble in water.

C. H. B.

Derivatives of Ethylbenzene. By W. SUIDA (*Ber.*, **22**, 2919—2920).—With regard to Sempotowski's work (this vol., p. 54), the author points out that orthethylphenol and its sulphonic acid have already been described by Suida and Plohn (Abstr., 1881, 268) and others.

L. T. T.

Xylylene Sulphides. By E. HJELT (*Ber.*, **22**, 2904—2905).—Ortho-xylylene sulphide, described by Leser (Abstr., 1884, 1313), crystallises at 0°, but is very unstable, changing quickly into a black resin. The *mercurochloride*, $(C_8H_8S)_2,HgCl_2$, crystallises in soft, long needles. A *platinochloride* and a *bromide* were also obtained. *Orthoxylylmethylsulphine iodide*, SC_8H_8MeI, forms yellowish crystals melting at 154—155°. When this iodide is treated with water and silver oxide, a strongly basic *sulphonium hydroxide* is formed.

When meta- and para-xylylene sulphides are treated with potassium sulphide, insoluble, white, amorphous compounds are formed. The author has not yet obtained them quite pure, but analyses leave little doubt but that they are the corresponding *meta-* and *para-xylylene sulphides*. L. T. T.

Ethereal Oil of Betel-leaves. By J. F. EYKMAN (*Ber.*, **22**, 2736—2754. Compare Bertram and Gildemeister, Abstr., 1889, 863).—The leaves of *Chavica Betle Miq.* when distilled with water, yield a small quantity of a yellowish-green oil which has a burning taste, a peculiar, pleasant smell, and is feebly lævorotatory. When shaken with concentrated potash it is partially dissolved, and on adding sulphuric acid to the solution, a phenol (chavicol) is precipitated. The portion insoluble in alkali can be separated by fractional distillation into two principal portions, boiling at 175—190° and 255—265° respectively.

Chavicol, $C_9H_{10}O$, is a colourless liquid, boils at about 237°, and is soluble in alcohol, ether, chloroform, and light petroleum in all proportions, but only sparingly in water and ammonia. With ferric chloride, the aqueous solution gives a blue coloration, which disappears on adding alcohol. Molecular-weight determinations by Raoult's method, vapour-density determinations carried out in an atmosphere of hydrogen under reduced pressure, and an examination of its refractive properties showed that the molecular formula of this phenol is $C_9H_{10}O$. It is a powerful antiseptic, its action on bacteria being five times as strong as that of phenol and about twice as strong as that of eugenol. The *ethyl*-derivative, $C_9H_9{\cdot}OEt$, prepared by heating chavicol with potash and ethyl iodide in alcoholic solution, is a colourless liquid boiling at about 232°; when oxidised with chromic acid, it yields parethoxybenzoic acid (m. p. 195°). Its molecular formula was found to be $C_{11}H_{14}O$, by the same methods as those employed in the case of chavicol. The *methyl*-derivative, $C_9H_9{\cdot}OMe$, prepared in like manner, is a colourless liquid boiling at about 226°; its molecular weight, determined optically, was found to be 151. When oxidised with potassium permanganate, it yields anisic acid and an acid of lower melting point, probably paramethoxyphenylacetic acid.

The fraction boiling at 175—190° and insoluble in alkali (see above) probably contains several terpenes, perhaps also cymene and cineole, but it is free from pinene; no pure compound could be isolated from the mixture.

The fraction boiling at 255—265° contains a colourless sesquiterpene, $C_{15}H_{24}$, boiling at about 260°.

Chavicol has most probably the constitution $OH{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH{:}CH_2$ [= 1 : 4], as is shown by its chemical properties and also by its low refractive power.

An optical examination of isosafrole and isoeugenol showed that both compounds probably contain the propenyl-group—CH:CHMe.

F. S. K.

Safrole. By T. POLECK (*Ber.*, **22**, 2861—2863).—When safrole is oxidised with potassium permanganate, it yields piperonal, piperonylic acid, formic acid, acetic acid. oxalic acid, and carbonic anhydride, but no propionic acid is formed, as stated by Schiff (Abstr., 1884, 1338); this result is in accordance with the view that safrole is the methylene ether of an allyldihydroxybenzene. F. S. K.

Phloroglucinol. By Z. H. SKRAUP (*Monatsh.*, **10**, 721—725).—The author has previously described the action of benzoic chloride on phloroglucinol in presence of alkalis (Abstr., 1889, 1152), and has now, by careful fractional crystallisation of the product from benzene, succeeded in obtaining the following compounds in a state of purity. *Diresorcinyl tetrabenzoate*, $C_{12}H_6O_4Bz_4$, is readily soluble in hot benzene, and crystallises from it on cooling in prisms melting at 199°. *Phloroglucinyl tribenzoate*, $C_6H_3O_3Bz_3$, is insoluble in water, only slightly soluble in alcohol, and crystallises from benzene in plates or scales melting at 173—174°.

Commercial phloroglucinol may best be purified by first converting it by means of potassium hydrogen carbonate into phloroglucinolcarboxylic acid (which may be obtained free from other compounds by taking advantage of the fact that it is soluble with difficulty in a solution of potassium carbonate and alcohol), and afterwards reproducing the phloroglucinol by boiling the pure carboxylic acid with water (compare Will, Abstr., 1885, 906). G. T. M.

Action of Alkalis and Ammonia on Halogen-substituted Quinones. By F. KEHRMANN (*J. pr. Chem.* [2], **40**, 365—375).—Paradiethoxydichloroquinone (Abstr., 1889, 707) melts at 97—98°; it has the same formula as Stenhouse's ethyl chloranilate, obtained by the action of ethyl iodide on silver chloranilate, but is not identical with it. The author distinguishes the former as the β-compound, and the latter as the α-compound. Both are obtained by the action of potassium ethoxide on chloranil, but the β-compound largely predominates when the solution is weak and the temperature low. If the reaction for preparing the β-compound (*loc. cit.*) is allowed to proceed near the boiling point of alcohol, a considerable quantity of the α-compound crystallises with the β-compound, and may be separated from it by fractional crystallisation from hot alcohol, in which the α-compound is more soluble, as small, red needles melting at 104—105°. The α-compound cannot be changed into the β-compound, or *vice versâ*, by crystallisation.

The β- and α-methyl-compounds are also both produced by the action of potassium methoxide on chloranil, the β-compound predominating when the temperature is lower. By crystallisation from benzene, the dimethoxydichloroquinone (β-compound) is separated at first, either as grains or needles, melting at 157—158°, not 130° (*loc. cit.*). The *methyl chloranilate* (α-compound) separates from the mother liquor of the β-compound in leafy crystals melting at

141—142°, and identical with those obtained by the action of methyl iodide on silver chloranilate.

By acting on the α-ethyl-compound with ammonia and with aniline, chloranilamide, and chloranilanilide are obtained respectively; they are identical with the amide and anilide produced by the action of ammonia and aniline on chloranil, and are, therefore, paradiamidoparadichloroquinone $[O_2 : Cl_2 : (NH_2)_2 = 1 : 4 : 2 : 5 : 3 : 6]$ and paradianilidoparadichloroquinone $[O_2 : Cl_2 : (NHPh)_2 = 1 : 4 : 2 : 5 : 3 : 6]$ respectively.

When the β-ethyl-compound is heated with excess of aniline in alcohol for some time, it becomes dark-green, and dark-green crystals with a violet iridescence separate. With ammonia instead of aniline, a deep-violet colour is produced, and by diluting the alcoholic solution with water dark violet needles are obtained. When the β-compound is heated with excess of aqueous potash, most of it is converted into potassium chloranilate; but if dilute potash is added, drop by drop, in slight excess to a cold alcoholic solution, the liquid becomes successively violet, yellow-red, and colourless; if now heated it becomes permanently violet, and a violet potassium salt may be crystallised out. These matters are still under investigation.

When the β-compound is shaken with stannous chloride in ethereal solution, the β-quinol only is obtained, but if an acetic acid solution is so treated both the β-quinol and α-quinol are obtained. The α-compound yields only the α-quinol.

α-Diethoxydichloroquinol melts at 151—152°, not 148—150° (*loc. cit.*).

β-Diethoxydichloroquinol forms lustrous, colourless leaves or needles melting at 108—109°; in water they melt at 70°, the greater part dissolving and separating again on cooling.

α-Dimethoxydichloroquinol forms short, colourless prisms melting at 195—196°, soluble in the ordinary solvents except water.

β-Dimethoxydichloroquinol forms colourless prisms melting at 156—157°.
A. G. B.

Paratoluidine Oxalate. By E. BORNEMANN (*Ber.*, 22, 2710).—Paratoluidine oxalate, $C_6H_7NH_2,C_2O_4H_2$, crystallises with ½ mol. of water.
F. S. K.

Action of Bromine on Paratoluidine in the Presence of Concentrated Sulphuric Acid. By R. HAFNER (*Ber.*, 22, 2902—2904; compare this vol., p. 37).—125 grams of bromine was added to a solution of 30 grams of paratoluidine in 400 grams of sulphuric acid, and the whole allowed to remain for 10 days. A good deal of paratoluidine remained unchanged, whilst metabromoparatoluidine and orthobromoparatoluidine were formed. Sulphuric acid, therefore, seems to have a tendency to promote the formation of a meta-derivative, as was noticed (*loc. cit.*), with chlorine-derivatives.
L. T. T.

Action of Aluminium Chloride on Dimethylaniline. By H. GIRAUD (*Bull. Soc. Chim.* [3], 1, 691—693).—Aluminium chloride and dimethylaniline combine with development of heat, and yield a substance which crystallises in long prisms melting at 88°; no reaction, however, obtains when the original compounds are heated in sealed tubes at 250° for 10 hours.

Dimethylaniline, when heated with excess of aluminium chloride in presence of air, yields a base which crystallises from alcohol in small, felted needles melting at 195°, and coloured green by oxidising agents; it is a tetramethylbenzidine, $NMe_2\cdot C_6H_4\cdot C_6H_4\cdot NMe_2$.

From dimethylaniline containing dimethyltoluidine, by similar treatment, a base melting at 90°, coloured blue-violet by oxidising agents, and which appears to be tetramethyldiamidophenylmethane, is obtained. The author is continuing the research. T. G. N.

Condensation of Phenylenediamines with Butaldehydes. By LASSAR-COHN (*Ber.*, **22**, 2724—2726).—A compound, $C_{10}H_{14}N_2$, is formed when orthophenylenediamine (10·8 grams) is mixed with a quantity of alcohol insufficient for complete solution, and then treated with isobutaldehyde (7·2 grams); the mixture is boiled for a short time, and the crystalline compound which separates on cooling is purified by pouring its alcoholic solution into warm water. It sublimes in colourless needles, melts at 233°, and is very readily soluble in alcohol, but almost insoluble in ether. The *hydrochloride*, $C_{10}H_{14}N_2,HCl$, crystallises from water and alcohol, melts at 184°, has not poisonous properties, and forms a golden *platinochloride*, $(C_{10}H_{14}N_2)_2,H_2PtCl_6$.

An isomeric compound is obtained in like manner from isobutaldehyde and metaphenylenediamine; it melts at 216°, and separates from benzene and chloroform in crusts. The *platinochloride* has the composition $(C_{10}H_{14}N_2)_2,H_2PtCl_6$.

Isobutaldehyde and paraphenylenediamine yield an oily base, the *platinochloride* of which has the composition $(C_{10}H_{14}N_2)_2,H_2PtCl_6$, but neither the base nor the hydrochloride could be obtained in crystals.

Normal butaldehyde does not react with orthophenylenediamine in solution in absolute alcohol. F. S. K.

Fluorescent Derivatives of Aromatic Metadiamines. By H. SCHIFF and A. VANNI (*Annalen*, **253**, 319—335; compare Schiff, *Annalen*, **140**, 97, and **159**, 64).—Metatoluylenediamine combines with œnanthaldehyde, yielding a compound of the composition $C_7H_6N_2(C_7H_{14})_2$; if the reaction takes place in the cold, the alcoholic solution of the product is only slightly fluorescent until after the addition of a few drops of hydrochloric acid. When metatoluylenediamine is warmed for a few hours with a slight excess of œnanthaldehyde, an orange, vitreous mass is obtained the alcoholic solution of which is highly fluorescent. This product consists of a portion readily soluble in cold alcohol, probably methyltetrahydrodibutylphenanthroline, and a portion which is only sparingly soluble; they both resemble the original product, are very stable, and are not decomposed by warm hydrochloric acid.

A red compound, probably dibutyloctohydrophenanthroline, is formed when œnanthaldehyde is added to a warm alcoholic solution of metaphenylenediamine hydrochloride, and the solution shows a green fluorescence; a thick oil remains on evaporation, readily soluble in benzene, but more sparingly in ether, and insoluble in water. The *platinochloride* seems to have the composition $(C_{20}H_{22}N_4)_2,H_2PtCl_6$.

Acetaldehyde, or paraldehyde, combines with metaphenylenediamine hydrochloride in alcoholic solution forming a red, semi-solid compound the solutions of which are deep-orange and, especially when dilute, show a green fluorescence. On adding ammonia to an aqueous solution of the crude product, the free *base*, probably dimethyltetrahydrophenanthroline, is precipitated in the form of a reddish-brown, unstable powder. The *platinochloride*, $(C_{14}H_{16}N_2)_2,H_2PtCl_6$, is an orange, amorphous compound which dissolves sparingly in alcohol, yielding a highly fluorescent solution. When the base is oxidised with potassium permanganate, it yields an acid, and this, like the base itself, gives considerable quantities of pyridine-derivatives on distillation.

Metaphenylenediamine and metatoluylenediamine hydrochlorides give analogous compounds (alkyl hydrophenanthroline salts) with other aldehydes of the fatty series.

Salicylolmetaphenylenediamine hydrochloride,

$$C_6H_4(N{:}CH{\cdot}C_6H_4{\cdot}OH)_2,HCl,$$

prepared by treating phenylenediamine hydrochloride with salicylic aldehyde in alcoholic solution, is an orange, crystalline compound. The free *base* is a yellow, flocculent substance soluble in alcohol and hydrochloric acid; it is decomposed by acids or by prolonged boiling with water. The *platinochloride*, $(C_{20}H_{16}O_2N_2)_2,H_2PtCl_6$, is a cinnabar-red powder.

Salicylolmetatoluylenediamine, $C_7H_6(N{:}CH{\cdot}C_6H_4{\cdot}OH)_2$, crystallises from a mixture of alcohol and benzene in long, yellow needles and is readily soluble in ether and benzene but only sparingly in alcohol. It has only feeble basic properties, is soluble in moderately concentrated potash, and is converted into a low-melting acetyl-derivative by acetic acid.

Cuminolmetatoluylenediamine, $C_7H_6(N{:}CH{\cdot}C_6H_4Pr)_2$, is a yellow, crystalline powder, melts at about 99° with decomposition, and is very readily soluble in benzene and ether; it has no basic properties and its solutions do not fluoresce.

Cinnamaldehyde combines with metaphenylenediamine hydrochloride in warm alcoholic solution, yielding an orange, unstable powder, most probably tetrahydrodiphenylphenanthroline hydrochloride. Cinnamaldehyde and metatoluylenediamine hydrochloride, under the same conditions, give a red, microcrystalline salt, the very dilute solutions of which show a feeble fluorescence; the platinochloride is a yellowish-red, crystalline powder soluble in alcohol.

Cinnamolmetatoluylenediamine, $C_7H_6(N{:}CH{\cdot}CH{:}CHPh)_2$, is precipitated as an orange powder when cinnamaldehyde is treated with metatolulenediamine in dilute alcoholic solution; it melted at about 180° but could not be obtained in a pure condition. It combines with bromine (2 mols.) yielding a red, unstable powder.

Amidophenyleneoxamic acid combines with fatty aldehydes in alcoholic hydrochloric acid solution, yielding compounds which show a slight green fluorescence. When the ammonium salt of this acid is treated with a mixture of furfuraldehyde and aniline hydrochloride, a red dye is formed.

Paraphenylenediamine and orthotoluylenediamine do not give fluorescent condensation-products with aldehydes of the fatty series.

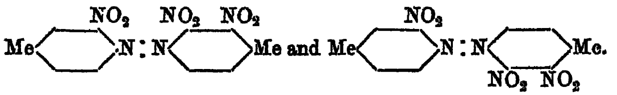
F. S. K.

Azotoluenes and Azoxytoluenes. By J. V. JANOVSKY (*Monatsh.*, **10**, 585—601; compare Abstr., this vol., p. 392 and 865). *Mononitroparazotoluene* is best obtained by heating at 30° a mixture of azotoluene with one-fifth of its weight of nitric acid of sp. gr. 1·43. It may be recrystallised from alcohol, melts at 80°, and has the formula—

$$\overset{3}{N}O_2\cdot C_6H_3\overset{1}{M}e\cdot \overset{4}{N}_2\cdot C_6H_4\overset{1}{M}e,$$

since on reduction with tin and hydrochloric acid it yields a mixture of paratoluidine and β-toluylendiamine [$Me : (NH_2)_2 = 1 : 3 : 4$] melting at 88°.

If in the above mentioned operation the temperature is allowed to rise above 30°, or if a stronger acid is used, *dinitroazotoluene* [$Me_2 : (NO_2)_2 : N_2 = 1,1 : 3,3 : 4,4$], melting at 114° is formed. On reduction with alcoholic stannous chloride, this yields β-toluylendiamine and must consequently be regarded as the symmetrical compound. The two trinitroazotoluenes previously described (*loc. cit.*) which melt at 138° and 139° respectively, are both converted on reduction into β-toluylendiamine and the same triamidotoluene [$Me : (NH_2)_3 = 1 : 2 : 3 : 4$], the hydrochloride of which crystallises in scales which become coloured on exposure to the air; they must consequently be regarded as physical isomerides having respectively the formulæ—



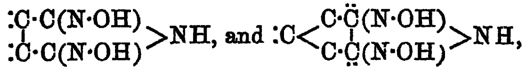
G. T. M.

Amidoximes and Azoximes. By F. TIEMANN (*Ber.*, **22**, 2942—2946).—This paper gives a short *résumé* of the work previously done on the subject of diamidoximes and diazoximes by the author and his collaborators.

The oxaleneamidoximes, succineneamidoximes, glutareneamidoximes, isophthaleneamidoximes, and hometerephthaleneamidoximes are soluble in boiling water and alcohol, very sparingly so in ether. Their aqueous solutions show very strongly the characteristic amidoxime reactions. The hydrochlorides of the diamidoximes contain 2 mols. of hydrogen chloride and are highly crystalline, but easily lose a part of the hydrogen chloride. The replacement of the two hydrogens of the two oximide-groups takes place in a normal way, but hitherto all attempts to displace only one of these atoms have proved unavailing. The acid derivatives of the diamidoximes,

$$NO(COR):C(NH_2)\cdot R''\cdot C(NH):NO\cdot COR,$$

pass less easily into the azoximes than the corresponding derivatives of monamidoximes. The diazoximes so formed have the general formula $<\begin{matrix}O-N\\CR{:}N\end{matrix}>C\cdot R''\cdot C<\begin{matrix}N-O\\N\cdot CR\end{matrix}>$. The diamidoximes of such dicarboxylic acids as easily form imides decompose very readily into imido-dioximes of the formulæ—



$$\begin{matrix}:C\cdot C(N\cdot OH)\\ | \\ :C\cdot C(N\cdot OH)\end{matrix}>NH, \text{ and } :C<\begin{matrix}C\cdot \ddot{C}(N\cdot OH)\\ | \\ C\cdot \underset{..}{C}(N\cdot OH)\end{matrix}>NH,$$

thus forming compounds with 5- and 6-atom closed rings which are soluble in water, are sometimes basic, sometimes acid in character, and usually yield stable silver-derivatives.

When hydroxylamine (1 mol.) acts on such dinitriles as yield imidodioximes (1 mol.), basic derivatives are formed isomeric with cyano-amidoximes. The constitution of these compounds is not yet fully proved, but, as an example, that obtained from orthocyanobenzyl cyanide is probably represented by the formula—

$$NH{:}C<\begin{matrix}C_6H_4\cdot CH_2\\O\text{———}N\end{matrix}>C\cdot NH_2.$$

L. T. T.

Formation of Benzaldoxime. By B. LACHOWICZ (*Ber.*, **22**, 2887—2888).—Benzaldoxime is best prepared by triturating hydrobenzamide (1 mol.) with hydroxylamine hydrochloride; the reaction is at an end in 10 to 15 minutes, and on adding water the benzaldoxime is precipitated as an oil.
F. S. K.

Amidoximes and Azoximes. By F. TIEMANN (*Ber.*, **22**, 2758—2761).—The author makes a few general remarks on the papers of Biedermann (this vol., p. 175), Spilker (next abstract), and Miller (this vol., p. 144).
F. S. K.

Nitrogen-derivatives of Salicylic Acid. By A. SPILKER (*Ber.*, **22**, 2767—2790).—Salicylamide is best prepared by heating ethyl salicylate at 100° with concentrated ammonia; it melts at 138°.

Dibromosalicylamide, $OH\cdot C_6H_2Br_2\cdot CONH_2$, prepared by treating a warm, concentrated aqueous solution of the amide with excess of bromine-water, crystallises from dilute alcohol in colourless needles, melts at 183° with decomposition, and is readily soluble in alcohol, ether, and alkalis, more sparingly in benzene and chloroform. In aqueous alcoholic solutions, ferric chloride produces a reddish-violet coloration.

Salicylothiamide, $OH\cdot C_6H_4\cdot CSNH_2$, is obtained, together with several other compounds, when the amide is melted with phosphorous pentasulphide. It crystallises from hot water in colourless needles, melts at 117—118°, and is readily soluble in alcohol, ether, chloroform, benzene, hot water, and alkalis. It is slowly converted into the amide when boiled with water or alkalis. Ferric chloride in dilute aqueous solutions produces a violet coloration, and a brownish-black precipitate is formed on heating. Lead acetate, copper sulphate, and silver nitrate also produce precipitates in the cold or on warming; these compounds darken in colour with separation of the metal.

Salicylonitrile, $OH\cdot C_6H_4\cdot CN$, is best prepared by distilling the thiamide under reduced pressure; it crystallises in colourless needles, melts at 98°, boils at 195° (180 mm.), and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in cold water. With ferric chloride, aqueous solutions give a violet coloration, and with bromine-water a colourless, crystalline precipitate. The compound (m. p. 195°) obtained by Grimaux (*Bull. Soc. Chim*, 13, 26) by heating salicylamide with phosphoric anhydride, and also by Ahrens (Abstr., 1888, 266) from orthamidophenol by Sandmeyer's reaction, is not salicylonitrile, although the latter can be obtained by both these methods.

Dibromosalicylthiamide, $OH{\cdot}C_6H_2Br_2{\cdot}CS{\cdot}NH_2$, is obtained when the thiamide is treated with excess of bromine in dilute alcoholic solution; if a solution containing salicylthiamide and salicylamide is gradually treated with bromine-water, monobromosalicylthiamide is precipitated first, the amide remaining in solution. Dibromosalicylthiamide crystallises from alcohol in dark-violet, microscopic needles, melts at about 230° with previous softening, and is moderately easily soluble in alcohol, ether, benzene, and chloroform, yielding violet solutions, but is insoluble in water; it dissolves unchanged in alkalis, forming a dark-violet solution. In alcoholic solutions, silver nitrate, copper sulphate, and lead acetate produce dark-red precipitates.

Salicenylamidoxime, $OH{\cdot}C_6H_4{\cdot}C(NH_2){:}NOH$, prepared by boiling the thiamide with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution, crystallises from water and benzene in thick, colourless needles, melts at 98—99°, and is readily soluble in alcohol, ether, chloroform, acids, and alkalis; in aqueous solutions, ferric chloride produces an intense violet coloration, Fehling's solution and copper sulphate a greenish precipitate, and silver nitrate, on warming, a metallic mirror. The *hydrochloride*, $C_7H_8N_2O_2,HCl$, melts at 175° and is very readily soluble in water. The *platinochloride*,

$$(C_7H_8N_2O_2)_2,H_2PtCl_6,$$

forms small, ill-defined crystals, and is readily soluble in water and alcohol. The *sodium*-derivative, $C_7H_6N_2O_2Na_2$, is precipitated as a colourless, hygroscopic powder when the amidoxime is treated with sodium ethoxide in alcoholic solution and a large volume of ether then added. The compound $C_7H_7N_2O_2Na$ is obtained in like manner when sodium ethoxide (1 mol.) is employed; it is a colourless, crystalline substance and is very hygroscopic. The *copper*-compound has the composition $C_{14}H_{14}N_4O_4Cu$.

Dibromosalicenylamidoxime, $OH{\cdot}C_6H_2Br_2{\cdot}C(NH_2){:}NOH$, prepared from dibromosalicenylthiamide in like manner, crystallises from dilute alcohol in colourless plates, melts at 180°, and is readily soluble in alcohol, ether, acids, and alkalis, but more sparingly in chloroform, benzene, and light petroleum, and very sparingly in water. In alcoholic solutions, copper sulphate produces a greenish precipitate, ferric chloride a reddish-violet coloration; alkaline solutions reduce silver nitrate and give a green precipitate with Fehling's solution. The *copper*-derivative, $(C_7H_5N_2O_2Br_2)_2Cu$, is sparingly soluble in water and alcohol.

Salicenylamidoximesulphonic acid, $SO_3H{\cdot}C_6H_3(OH){\cdot}C(NH_2){:}NOH$, is obtained when the amidoxime is heated with concentrated sulphuric acid at about 150°, it separates from boiling water in colourless crystals, does not melt below 250°, and is insoluble in alcohol, ether, chloroform, and benzene, and only very sparingly soluble in cold water. The salts of the alkalis and alkaline earths are readily soluble in water. The *barium* salt, $(C_7H_7N_2SO_5)_2Ba$, separates from hot water in colourless, ill-defined crystals.

Benzoylsalicenylamidoxime, $OH\cdot C_6H_4\cdot C(NH_2)\colon NOBz$, crystallises from dilute alcohol in needles, melts at 173°, and is readily soluble in ether, alcohol, chloroform, and benzene, sparingly in alkalis, and insoluble in water and acids. It gives a reddish-violet coloration with ferric chloride and a precipitate with bromine-water. The *acetyl*-derivative, $OH\cdot C_6H_4\cdot C(NH_2)\colon NOAc$, crystallises from warm water in colourless plates, melts at 117°, and is readily soluble in alcohol, ether, alkalis, and acids, but only sparingly in chloroform, benzene, and water; in dilute alcoholic solutions, ferric chloride produces a reddish-violet coloration, and bromine-water a colourless precipitate.

Salicenylbenzenylazoxime, $OH\cdot C_6H_4\cdot C{<}\genfrac{}{}{0pt}{}{NO}{N}{>}CPh$, prepared by boiling the benzoyl-derivative for a long time with water or heating it alone at 180°, separates from hot dilute alcohol in crystals, melts at 128°, and is readily soluble in alcohol, ether, chloroform, and benzene, but insoluble in water. In dilute alcoholic solutions, copper sulphate produces a green, bromine-water a colourless precipitate, and ferric chloride a violet coloration which quickly disappears. The *ethenylazoxime*, $C_9H_8N_2O_2$, prepared by heating the acetyl-derivative at 125° or by boiling it with water or acetic anhydride, crystallises from dilute alcohol in colourless needles, melts at 77°, and is readily soluble in alcohol, ether, chloroform, benzene, and alkalis, but only sparingly in water. It gives the usual reactions with ferric chloride, copper sulphate, and bromine-water.

Dibenzoylsalicenylamidoxime, $OBz\cdot C_6H_4\cdot C(NH_2)\colon NOBz$, is obtained, together with ethyl benzoate, when the amidoxime is treated with benzoic chloride and sodium ethoxide in alcoholic ethereal solution. It separates from dilute alcohol in colourless, ill-defined crystals, melts at 127°, and is readily soluble in alcohol, ether, benzene, and chloroform, but insoluble in water and acids; it gives a colourless precipitate with bromine-water, and it is decomposed by alkalis. The corresponding *azoxime*, $OBz\cdot C_6H_4\cdot C{<}\genfrac{}{}{0pt}{}{N\cdot O}{N}{>}CPh$, can be prepared by boiling the dibenzoyl-derivative with water or by heating it above 150°; also by treating salicenylbenzenylazoxime with benzoic chloride and sodium ethoxide in alcoholic solution. It crystallises from alcohol in colourless needles, melts at 120°, and is readily soluble in benzene, ether, and chloroform, but insoluble in water and acids; it is decomposed by warm alkalis, and it gives a colourless precipitate with bromine-water.

Diacetylsalicenylamidoxime, $OAc\cdot C_6H_4\cdot C(NH_2)\colon NOAc$, is formed, together with the corresponding azoxime, when the amidoxime is treated with sodium ethoxide and acetic chloride in ice-cold ethereal solution, but it cannot be obtained in a pure state. The *azoxime*, $C_{11}H_{10}N_2O_2$, is best prepared by treating sodosalicenylethenylazoxime with acetic chloride in alcoholic ethereal solution. It crystallises from dilute alcohol in colourless needles, melts at 74°, and is very readily soluble in alcohol, ether, chloroform, and light petroleum, but only sparingly in water; it gives a colourless precipitate with bromine-water, and it is quickly decomposed by alkalis.

Salicenylethylamidoxime, $OH\cdot C_6H_4\cdot C(NH_2)\colon NOEt$, is formed, together with its ethyl-derivative, when the amidoxime is heated with sodium ethoxide and ethyl iodide in alcoholic solution. It is a colourless oil, boils at 278° (at 220° under 150 mm.), and is readily soluble in acids and alkalis, but insoluble in water. and only sparingly soluble in light petroleum. In dilute alcoholic solutions, ferric chloride produces a violet coloration, and bromine-water a colourless precipitate. The *ethyl*-derivative, $OEt\cdot C_6H_4\cdot C(NH_2)\colon NOEt$, is a colourless oil, boils at 195° (180 mm.), and is readily soluble in acids, but insoluble in water and alkalis.

Salicenylethylamidoxime chloride, $OH\cdot C_6H_4\cdot CCl\colon NOEt$, prepared by warming the preceding compound with sodium nitrite in dilute hydrochloric acid solution, is a colourless oil, boils at 233—234° (at 178° under about 20 mm.), and is readily soluble in alkalis, but insoluble in water and dilute acids; it gives a reddish-violet coloration with ferric chloride and a colourless precipitate with bromine-water.

Salicenylphenyluramidoxime, $OH\cdot C_6H_4\cdot C(NOH)\cdot NH\cdot CO\cdot NHPh$, prepared by triturating the amidoxime with phenylcarbimide, crystallises from dilute alcohol in colourless plates, melts at 119° with decomposition when heated quickly, and is readily soluble in alcohol, ether, and alkalis, moderately easily in benzene, chloroform, and acids, and insoluble in water; it gives the usual reactions with ferric chloride and bromine-water.

Salicenylethylamidoxime and its ethyl-derivative combine with phenylthiocarbimide, yielding compounds which are insoluble in water and do not crystallise well. Salicenylamidoxime combines energetically with phenylthiocarbimide forming the thiouramidoxime and diphenylthiocarbamide.

Salicenyluramidoxime, $OH\cdot C_6H_4\cdot C(NOH)\cdot NH\cdot CONH_2$, crystallises from dilute alcohol in colourless plates, melts at 148° with decomposition, and is readily soluble in alcohol, benzene, acids, and alkalis, moderately easily in chloroform and ether, and sparingly in water; it gives a reddish-violet or reddish-brown coloration with ferric chloride.

F. S. K.

Anisenyl-, Salicenyl-, and Methylsalicenyl-amidoxime. By J. A. Miller (*Ber.*, **22**, 2790—2801).—Anisaldoxime melts at 64°; Westenberger (Abstr., 1884, 581) gives 45° as the melting point of this compound. Anisonitrile melts at 61—62°; Henry (*Ber.*, **2**, 667) found the melting point to be 56—57°.

Anisenylamidoxime, $OMe\cdot C_6H_4\cdot C(NH_2)\colon NOH$, is prepared by heating anisonitrile for 6—8 hours at about 90° with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution; the yield is 81 per cent. of the theoretical quantity. It crystallises from benzene in scales and from hot water in needles, melts at 122—123°, and is readily soluble in alcohol, ether, chloroform, acids, and alkalis, sparingly in hot benzene and hot water, and almost insoluble in light petroleum. The *hydrochloride*, $C_8H_{10}N_2O_2,HCl$, is crystalline, melts at 168° with decomposition, and is soluble in alcohol, but insoluble in ether. The *ethyl*-derivative, $C_{10}H_{14}N_2O_2$, crystallises from dilute alcohol in prisms, melts at 51—52°, and is readily soluble in alcohol, ether, benzene, and chloroform, but insoluble in light petroleum. The *acetyl*-derivative, $C_{10}H_{12}N_2O_3$, crystallises from dilute alcohol in prisms, melts at 106°, and is readily soluble in alcohol and chloroform, but only sparingly in benzene and ether. The *azoxime*, $\mathrm{OMe{\cdot}C_6H_4{\cdot}C}\left<\begin{matrix}\mathrm{N{\cdot}O}\\ \mathrm{N}\end{matrix}\right>\mathrm{CMe}$, prepared by heating the acetyl-derivative alone, or with water, or with acetic anhydride, crystallises in colourless needles, melts at 68°, and is readily soluble in alcohol, ether, benzene and chloroform, but more sparingly in light petroleum.

Ethylideneanisenylamidoxime, $\mathrm{OMe{\cdot}C_6H_4{\cdot}C}\left<\begin{matrix}\mathrm{N{\cdot}O}\\ \mathrm{NH}\end{matrix}\right>\mathrm{CHMe}$, is obined by dissolving the amidoxime in aqueous acetaldehyde; it crysllises from alcohol in colourless needles, melts at 127·5°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in light petroleum.

Ethyl anisenylamidoximecarboxylate, $\mathrm{OMe{\cdot}C_6H_4{\cdot}C(NH_2){:}NO{\cdot}COOEt}$, prepared by treating the amidoxime with ethyl chlorocarbonate in cold chloroform solution, crystallises from dilute alcohol in colourless plates, melts at 119—120°, and is readily soluble in alcohol, but more sparingly in ether and benzene.

Anisenylcarbonylamidoxime, $\mathrm{OMe{\cdot}C_6H_4{\cdot}C}\left<\begin{matrix}\mathrm{N{\cdot}O}\\ \mathrm{NH}\end{matrix}\right>\mathrm{CO}$, crystallises from dilute alcohol in colourless scales, melts at 208°, and is readily soluble in alcohol, ether, and chloroform, but only sparingly in benzene and light petroleum.

Benzoylanisenylamidoxime, $C_{15}H_{14}N_2O_3$, separates from dilute alcohol in crystals, melts at 148°, and is readily soluble in alcohol, ether, chloroform, and benzene, but insoluble in light petroleum.

Anisenylbenzenylazoxime, $\mathrm{OMe{\cdot}C_6H_4{\cdot}C}\left<\begin{matrix}\mathrm{N{\cdot}O}\\ \mathrm{NH}\end{matrix}\right>\mathrm{CPh}$, prepared by heating the preceding compound alone, or with water, or by dissolving it in concentrated sulphuric acid, crystallises in colourless plates, melts at 102·5, and is readily soluble in alcohol, ether, chloroform, and benzene.

Anisenylpropenylazoxime-ω-carboxylic acid,

$$\mathrm{OMe{\cdot}C_6H_4{\cdot}C}\left<\begin{matrix}\mathrm{N{\cdot}O}\\ \mathrm{N}\end{matrix}\right>\mathrm{C{\cdot}C_2H_4{\cdot}COOH},$$

is obtained when the amidoxime is melted with succinic anhydride; it crystallises from dilute alcohol in yellowish needles, melts at 140—141°, and is readily soluble in alcohol, ether, and chloroform, but only moderately in benzene, and very sparingly in light petroleum.

Salicylonitrile (compare Spilker, preceding abstract) can be prepared by decomposing acetylsalicylonitrile (compare Lach, Abstr., 1884, 1154) with alcohol.

A polymeride of salicylonitrile is formed in considerable quantities when salicylaldoxime is heated with acetic anhydride. This compound crystallises from boiling nitrobenzene in pale yellow needles, melts at 296—299°, and is sparingly soluble in boiling chloroform, benzene, and ether. When melted with potash, it is decomposed into salicylic acid and ammonia, and when heated at 200° with concentrated sulphuric acid, it is decomposed into phenol, ammonia, and carbonic anhydride.

Ethyl salicenylamidoximecarboxylate, $C_{10}H_{12}N_2O_4$, crystallises from dilute alcohol in colourless needles melting at 96°.

Salicenylpropenylazoxime-ω-carboxylic acid,

$$OH{\cdot}C_6H_4{\cdot}C\left<\begin{matrix}N{\cdot}O\\ N\end{matrix}\right>C{\cdot}C_2H_4{\cdot}COOH,$$

separates from a mixture of benzene and light petroleum in small, well-defined crystals, melts at 116—117°, and is readily soluble in alcohol, ether, and chloroform, but more sparingly in benzene.

Methylsalicylonitrile, prepared by treating salicylonitrile with sodium ethoxide and methyl iodide, boils at 255—256°, and is volatile with steam; Ahrens (Abstr., 1888, 266) gives 265—266° as the boiling point of this compound.

Methylsalicenylamidoxime, $OMe{\cdot}C_6H_4{\cdot}C(NH_2){:}NOH$, prepared by digesting the nitrile with hydroxylamine for a long time, crystallises from benzene in needles, melts at 123°, and is readily soluble in alcohol, ether, chloroform, and hot water, but insoluble in light petroleum.

Methylsalicenylbenzenylazoxime, $OMe{\cdot}C_6H_4{\cdot}C\left<\begin{matrix}N{\cdot}O\\ N\end{matrix}\right>CPh$, melts at 117°, and is readily soluble in chloroform, alcohol, ether, and benzene, but insoluble in light petroleum. F. S. K.

Action of Hydroxylamine on Orthocyanobenzyl Cyanide.

By G. EICHELBAUM (*Ber.*, 22, 2973—2975).—*Homo-orthophthaleneamidimidoxime*, $C_6H_4\left<\begin{matrix}CH_2{\cdot}C(NH_2)\\ C(NH){-\!\!-}O\end{matrix}\right>N(?)$, is most readily obtained by keeping an alcoholic solution of orthocyanobenzyl cyanide (1 mol.) and hydroxylamine (rather more than 1 mol.) for several days in a place protected from direct sun-light; it is then filtered from the crystals which separate, and evaporated down. It crystallises from water in long needles (with 2 mols. H_2O) melting at 95°; the anhydrous substance melts at 158°, is very readily soluble in alcohol, insoluble in ether, chloroform, and benzene, &c. It has the same percentage composition as orthocyanophenylethenylamidoxime, but cannot be an amidoxime, as it has only basic properties, and thus resembles the compound obtained by Beidermann from trimethylene dicyanide and hydroxylamine (this vol., p. 126). The *hydrochloride*, $C_9H_9N_3O,HCl$, crystallises in small, lustrous, yellow crystals, is sparingly soluble in water, almost insoluble in alcohol. The *picrate*, $C_9H_9N_3O,C_6H_3N_3O_7$, forms reddish-yellow needles rather more readily soluble in alcohol than in water, and explodes slightly when the dry substance is heated. When the base is dissolved in dilute hydrochloric acid and treated with sodium nitrite, homo-orthophthalic acid is formed. N. H. M.

Isophthalenediamidoxime. By G. GOLDBERG (*Ber.*, 22, 2976—2977).—Metadicyanobenzene is prepared by distilling an intimate mixture (15 to 20 grams) of potassium benzenemetadisulphonate with pure potassium cyanide under diminished pressure. It is first resublimed and then crystallised from alcohol, from which it separates in slender needles melting at 158—159°.

Isophthalenediamidoxime, $C_6H_4[C(NH_2):N\cdot OH]_2$ [= 1 : 3], is formed when metadicyanobenzene (1 mol.), dissolved in benzene, is digested with hydroxylamine (rather more than 2 mols.) in closed flasks at 90°. It crystallises from alcohol in colourless prisms, melts at 193° with decomposition, dissolves readily in hot water and alcohol, sparingly in ether, and shows the characteristic properties of the amidoximes. The crystals contain water of crystallisation (probably ½ mol.), which they lose when exposed to air. The *hydrochloride* is crystalline.

N. H. M.

Homoterephthalenediamidoxime and its Derivatives. By E. ROSENTHAL (*Ber.*, 22, 2977—2984).—*Homoterephthalenediamidoxime*, $OH\cdot N:C(NH_2)\cdot C_6H_4\cdot CH_2\cdot C(NH_2)N\cdot OH$ [= 4 : 1], prepared by keeping a mixture of hydroxylamine hydrochloride (3 mols.) with the necessary amount of sodium carbonate and paracyanobenzyl cyanide dissolved in alcohol for some days in a closed flask, crystallises from hot water in microscopic prisms, melts at 192° with decomposition, is rather readily soluble in methyl alcohol and acetone, very sparingly in ethyl and amyl alcohols, and is insoluble in ether, benzene, and light petroleum. It shows all the characteristic reactions of the amidoximes. The *hydrochloride*, $C_9H_{12}N_4O_2,2HCl$, dissolves very readily in water, but is not hygroscopic, and is also soluble in alcohol and glacial acetic acid. The *diacetyl-derivative*, $C_{13}H_{16}N_4O_4$, crystallises in groups of needles, melts at 161·5—162°, is soluble in hot water, alcohol, ether, and benzene, and in acids, but not in alcohol; when boiled with water for some hours, it is quantitatively converted into *homoterephthalenediazoximediethenyl*,

$CMe{<}^{O\cdot N}_{N—}{>}C\cdot C_6H_4\cdot CH_2\cdot C{<}^{N\cdot O}_{—N}{>}CMe$. The latter melts at 111·5°, is soluble in hot water, methyl, ethyl, and amyl alcohols, ether, and benzene, &c., and is insoluble in mineral acids. The *dibenzoyl-compound*, $C_{23}H_{20}N_4O_4$, crystallises from hot methyl alcohol, melts at 184°, dissolves in acetone, ethyl acetate, amyl alcohol, and in acids, very sparingly in ethyl alcohol, and is insoluble in water, benzene, and ether. When heated at 150° for four hours, it is converted into *homoterephthalenediazoxime dibenzenyl*, $C_{23}H_{16}N_4O_2$. This forms long, white, matted needles, melts at 179·5°, and is soluble in alcohol, ether, chloroform, and benzene.

Paracyanophenylethenylamidoxime, $CN\cdot C_6H_4\cdot CH_2\cdot C(NH_2):N\cdot OH$, prepared by the action of hydroxylamine (1 mol.) on paracyanobenzyl cyanide (1 mol.), melts at 168°. It is converted by nitrous acid into paracyanophenylacetamide (m. p., 196°, Mellinghoff, *Inaug. Diss. Berlin*, 1889). The *benzoyl-derivative*,

$$CN\cdot C_6H_4\cdot CH_2\cdot C(NH_2)\colon N\cdot OBz,$$

forms small, white needles, melts at 171.5—172°, dissolves in methyl and ethyl alcohols, and glacial acetic acid, less readily in benzene and chloroform; it is also dissolved by acids. When heated with water for six hours, it is converted into *paracyanophenylethenylazoximebenzenyl*,  $CN\cdot C_6H_4\cdot CH_2\cdot C{<}\overset{N\cdot O}{\underset{N}{\rule{0pt}{0pt}}}{>}CPh$, which melts at 105°, and is soluble in alcohol, ether, benzene, and chloroform. N. H. M.

Hydrazines. By M. Freund (*Ber.*, **22**, 2727).—The author replies to the statements of Willgerodt (this vol., p. 40).

Orthonitrophenylhydrazine. By A. Bischler (*Ber.*, **22**, 2801—2809; compare Abstr., 1889, 501).—Orthonitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot N_2H_3$, is best prepared by dissolving orthonitraniline (10 grams) in warm, concentrated hydrochloric acid (100 grams), adding to the well cooled solution an aqueous solution (35 grams) of sodium nitrite (5 grams), and keeping the mixture at the ordinary temperature, with frequent stirring until the crystals of the nitraniline hydrochloride have disappeared; a solution of stannous chloride (32 grams) in concentrated hydrochloric acid (32 grams) is then gradually added, care being taken that the temperature does not rise much above 0°, and the stannochloride which separates from the solution is recrystallised from hot water. The *hydrochloride*, $C_6H_7N_3O_2,HCl$, obtained by decomposing the stannochloride with hydrogen sulphide, crystallises in small, yellow plates or in long, slender needles, is readily soluble in warm alcohol and warm water, but only sparingly in the cold solvents, and is insoluble in ether, benzene, and concentrated hydrochloric acid; it reduces Fehling's solution in the cold, but ammoniacal silver nitrate solution only on warming. The yield of this salt is about 75 per cent. of the theoretical quantity. The free *base* is obtained by treating a hot aqueous solution of the hydrochloride with sodium acetate; it crystallises from benzene in long, cinnabar-red needles, melts at 90°, and is readily soluble in warm alcohol, benzene, and hot water, but only sparingly in ether and light petroleum. The *sulphate*, $(C_6H_7N_3O_2)_2,H_2SO_4$, crystallises in small, pinkish needles, and is readily soluble in hot alcohol, warm water, and dilute sulphuric acid, but insoluble in ether and benzene.

Benzylideneorthonitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NH\cdot N\colon CHPh$, separates as a reddish-brown precipitate when benzaldehyde is added to an alcoholic solution of the hydrazine; it crystallises from boiling benzene in dark-red plates, melts at 186—187°, and is moderately easily soluble in hot benzene, but very sparingly in hot alcohol and ether, and insoluble in water. The *formyl*-derivative,

$$NO_2\cdot C_6H_4\cdot NH\cdot NH\cdot CHO,$$

separates in long, pale yellow needles when the hydrochloride is heated at 100° with sodium formate and formic acid for about an hour; it crystallises from alcohol, melts at 177°, and is readily soluble in hot water and boiling alcohol, but only sparingly in ether and benzene. Solutions of the formyl-, acetyl-, and benzoyl-derivatives give a red or bluish-violet coloration with alkalis. The *acetyl*-derivative, $NO_2 \cdot C_6H_4 \cdot NH \cdot NHAc$, prepared by heating the hydrochloride of the hydrazine with sodium acetate and glacial acetic acid, crystallises from alcohol in lemon-yellow needles, melts at 140—141°, and is readily soluble in hot benzene, alcohol, and water. The *diacetyl*-derivative, $NO_2 \cdot C_6H_4 \cdot NAc \cdot NHAc$, prepared by heating the hydrochloride with sodium acetate and acetic anhydride, crystallises from dilute alcohol in reddish prisms, melts at 57—58°, and is readily soluble in hot water, benzene, alcohol, and cold glacial acetic acid, but only sparingly in hot ether. The *benzoyl*-derivative,

$$NO_2 \cdot C_6H_4 \cdot NH \cdot NHBz,$$

crystallises from alcohol in pale-yellow needles, melts at 166°, and is readily soluble in ether, benzene, and hot alcohol, but insoluble in water. The *oxalyl*-derivative, $C_2O_2(N_2H_2 \cdot C_6H_4 \cdot NO_2)_2$, prepared by heating the hydrazine with ethyl oxalate, crystallises from hot aniline and nitrobenzene in small, yellow needles, and is only sparingly soluble in most ordinary solvents.

α-Phenotriazine,  $C_6H_4<\begin{matrix}N\cdot CH\\ |\quad\ \|\\ N\cdot N\end{matrix}$, is obtained, together with dihydrophenotriazine and orthophenylenediamine, when orthonitrophenylhydrazine is reduced with sodium amalgam in dilute acetic acid solution, care being taken that the temperature does not rise much above 30°. The solution is decanted from the mercury, evaporated at a moderate temperature, the residue dissolved in water, and mixed with excess of soda; it is then treated with potassium ferricyanide in the cold until the violet colour changes to yellowish-red, mixed with a large volume of concentrated soda, and extracted three or four times with ether. When the crude product is fractionated, it is separated into a portion boiling at 235—245°, and a portion boiling above 360° which consists of phenylethenylamidine.

Phenotriazine crystallises from benzene in deep-yellow needles, melts at 65—66°, boils at 235—240°, and is volatile with steam. It is readily soluble in alcohol, benzene, warm ether, and warm water, but it separates from the aqueous solution on adding concentrated alkalis; it has a peculiar alkaloïd-like odour, and is a feeble base, the salts being readily soluble in water and alcohol.

α-Phenomethyltriazine,  $C_6H_4<\begin{matrix}N\cdot CMe\\ |\quad\ \|\\ N\cdot N\end{matrix}$, is formed, together with the dihydro-derivative, acetamide, acetamidophenylhydrazine, and phenylenediamine when acetylnitrophenylhydrazine is reduced with sodium amalgam in acetic acid solution; the solution is filtered from small quantities of acetylamidophenylhydrazine, and the triazine is isolated as described above. It melts at 88—90°, boils at 250—255° with slight decomposition, is readily soluble in alcohol, ether, and benzene, and moderately easily in cold water, but only sparingly in light petroleum; its alkaline solutions oxidise quickly on exposure to the air.

Orthacetylamidophenylhydrazine, $NH_2\cdot C_6H_4\cdot NH\cdot NHAc$ (see above), crystallises from benzene in colourless needles, and melts at 162°.

F. S. K.

Metanitrophenylhydrazine and Parabromorthonitrophenylhydrazine. By A. Bischler and S. Brodsky (*Ber.*, 22, 2809—2818).—*Metanitrophenylhydrazine hydrochloride*, $NO_2\cdot C_6H_4\cdot N_2H_3,HCl$, is prepared from metanitraniline exactly as described in the case of the corresponding ortho-compound (compare preceding abstract). The yield is 50—60 per cent. of the theoretical. It crystallises in yellowish plates, and is readily soluble in warm alcohol and water, but only sparingly in warm, concentrated hydrochloric acid; it reduces Fehling's solution in the cold, and ammoniacal silver nitrate and platinic chloride on warming. The free *base*, $NO_2\cdot C_6H_4\cdot N_2H_3$, crystallises from alcohol in slender, yellow needles, melts at 93°, and is readily soluble in glacial acetic acid, chloroform, warm benzene, and alcohol, but only sparingly in boiling water. The *sulphate*, $(C_6H_7N_3O_2)_2,H_2SO_4$, separates from hot water in yellow crystals, and is readily soluble in hot water and glacial acetic acid, but only sparingly in boiling alcohol, and insoluble in ether and benzene. The *acetyl*-derivative, $NO_2\cdot C_6H_4\cdot NH\cdot NHAc$, crystallises in golden plates, melts at 145°, and is readily soluble in alcohol, ether, glacial acetic acid, and boiling water, but only moderately easily in benzene. The *diacetyl*-derivative, $NO_2\cdot C_6H_4\cdot NAc\cdot NHAc$, forms brownish plates, melts at 150°, and is readily soluble in the ordinary solvents. The *benzoyl*-derivative, $NO_2\cdot C_6H_4\cdot NH\cdot NHBz$, crystallises from dilute alcohol in yellow, prismatic needles, melts at 151°, and is readily soluble in alcohol, ether, glacial acetic acid, and hot benzene, but insoluble in water. The *dibenzoyl*-derivative, $NO_2\cdot C_6H_4\cdot NBz\cdot NHBz$, crystallises from acetic acid in yellow plates, melts at 153°, and is readily soluble in hot alcohol and benzene, but insoluble in water.

α-Acetyl-β-benzoylmetanitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NBz\cdot NHAc$, prepared by heating the acetyl-derivative with benzoic anhydride at 160°, separates from cumene in crystalline aggregates, melts at 137°, and is readily soluble in alcohol and glacial acetic acid, but insoluble in benzene.

α-Benzoyl-β-acetylmetanitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NAc\cdot NHBz$, obtained by heating the benzoyl-derivative with acetic anhydride and sodium acetate, separates from cumene in yellowish, crystalline aggregates, melts at 147°, and sublimes at 100° in small, iridescent needles; it is readily soluble in boiling benzene, alcohol, and glacial acetic acid, and more readily in hot cumene than the preceding compound.

Ethylidenemetanitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NH\cdot N:CHMe$, prepared by warming the hydrazine with acetaldehyde, separates from alcohol in yellow crystals, melts at 98°, and is readily soluble in alcohol, benzene, and ether, but only sparingly in hot water.

Benzylidenemetanitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NH\cdot N:CHPh$, crystallises from boiling alcohol in small, carmine-red needles, melts at 117—118°, and is sparingly soluble in hot alcohol, but readily in ether, hot glacial acetic acid, and benzene.

Acetonenitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NH\cdot N\colon CMe_2$, crystallises from dilute alcohol in dark-red needles, melts at 112°, and is readily soluble in warm alcohol, ether, benzene, and glacial acetic acid, but only sparingly in hot water.

Acetophenonenitrophenylhydrazine, $NO_2\cdot C_6H_4\cdot NH\cdot N\colon CMePh$, crystallises from benzene, melts at 160°, and is only sparingly soluble in hot alcohol, but more readily in benzene and ether.

Benzilmetanitrophenylhydrazine crystallises from benzene in small, orange-yellow needles, melts at 158°, and is readily soluble in warm benzene, but only sparingly in hot alcohol and ether.

Metanitrophenylizinedihydroxytartaric acid separates in crystals when sodium dihydroxytartrate (1 mol.) is treated with hydrochloric acid (1 mol.) and nitrophenylhydrazine hydrochloride in aqueous solution; it melts at 175° with decomposition. *Metanitrodiphenylizinedihydroxytartaric acid*, prepared in like manner but employing 2 mols. of the hydrazine, is a yellow, micro-crystalline powder, melting at about 200°. The last two compounds are only sparingly soluble in hot water, alcohol, benzene, and glacial acetic acid.

The compound, $NO_2\cdot C_6H_4\cdot NH\cdot N\colon CMe\cdot CH_2\cdot COOEt$, is formed when the hydrazine is treated with ethyl acetoacetate in alcoholic solution; it crystallises from dilute alcohol in yellowish-red plates, melts at 117°, and is sparingly soluble in hot water, but readily in other warm solvents.

Metanitrodiphenylthiosemicarbazide, $NO_2\cdot C_6H_4\cdot NH\cdot NH\cdot CS\cdot NHPh$, prepared by warming the hydrazine (1 mol.) with phenylthiocarbimide (1 mol.) in alcoholic solution, is a dark-yellow, crystalline compound, melts at 146—147°, and is readily soluble in hot alcohol, but only sparingly in benzene and glacial acetic acid.

Diacetylamidophenylhydrazine, $NHAc\cdot C_6H_4\cdot NH\cdot NHAc$, is obtained when acetylnitrophenylhydrazine is reduced with sodium amalgam in acid alcoholic solution, and the crude product boiled with glacial acetic acid; it crystallises from acetic acid in small, dark-yellow needles, melting at 150—151°.

Attempts to prepare paranitrophenylhydrazine were unsuccessful.

Parabromorthonitrophenylhydrazine, $NO_2\cdot C_6H_3Br\cdot N_2H_3$, prepared by the method described in the case of orthonitrophenylhydrazine (compare preceding abstract), separates from benzene in dark-red crystals, melts at 130°, and is readily soluble in alcohol, ether, hot glacial acetic acid, and benzene, but only sparingly in hot water; it reduces silver and platinum salts. The *hydrochloride*, $C_6H_6BrN_3O_2,HCl$, crystallises from water in small, yellowish-red needles. The *sulphate*, $(C_6H_6BrN_3O_2)_2,H_2SO_4$, is a reddish, microcrystalline powder, sparingly soluble in cold alcohol and benzene, but readily in hot alcohol, water, and glacial acetic acid. The *formyl*-derivative,

$$NO_2\colon C_6H_3Br\cdot NH\cdot NH\cdot CHO,$$

crystallises from alcohol in slender, pale yellow needles, melts at 191°, and is readily soluble in hot alcohol and benzene. The *acetyl*-derivative, $NO_2\cdot C_6H_3Br\cdot NH\cdot NHAc$, crystallises from glacial acetic acid in small, lemon-yellow needles, and is readily soluble in hot benzene, glacial acetic acid, and alcohol, but only sparingly in the cold solvents. The *benzoyl*-derivative, $NO_2\cdot C_6H_3Br\cdot NH\cdot NHBz$, crystallises from alcohol in large, yellow plates, melts at 185°, and is readily soluble in hot alcohol, ether, and benzene, but only sparingly in the cold solvents. The *benzylidene*-derivative,

$$NO_2\cdot C_6H_3Br\cdot NH\cdot N\colon CHPh,$$

crystallises from alcohol in red needles, melting at 207°. The *acetophenone*-derivative, $NO_2\cdot C_6H_3Br\cdot NH\cdot N\colon CMePh$, crystallises in red needles and melts at 148°.

Parabromorthonitrodiphenylthiosemicarbazide,

$$NO_2\cdot C_6H_3Br\cdot NH\cdot NH\cdot CS\cdot NHPh,$$

is a yellow, microcrystalline compound, melts at about 160—164°, and is readily soluble in hot alcohol and glacial acetic acid, but only sparingly in ether and benzene.

Parabrom-α-phenotriazine, $C_6H_3Br{<}\begin{array}{l}N\cdot CH\\ \vert\quad\Vert\\ N\cdot N\end{array}$, is formed when formylparabromorthonitrophenylhydrazine is reduced with sodium amalgam and glacial acetic acid in well-cooled alcoholic solution; the solution is evaporated, the residue dissolved in water, treated with potassium ferricyanide, and the filtered solution mixed with excess of alkali. It crystallises from boiling water in slender, yellow needles, and is readily soluble in hot water and other ordinary solvents, but insoluble in alkalis.

Parabrom-α-phenomethyltriazine, $C_6H_3Br{<}\begin{array}{l}N\cdot CMe\\ \vert\quad\Vert\\ N\cdot N\end{array}$, prepared from the acetyl-derivative of the hydrazine in like manner, crystallises from water in golden plates, melts at 115°, and is readily soluble in ether, benzene, alcohol, and glacial acetic acid, but only sparingly in cold water.

F. S. K.

Formation of Phenylhydrazides. By E. FISCHER and F. PASSMORE (*Ber.*, **22**, 2728—2736).—The hydroxy-acids of the sugar-group combine very readily with phenylhydrazine in aqueous solution, yielding crystalline hydrazides, which are only sparingly soluble in cold water, can be easily purified and are readily reconverted into the acid when boiled with baryta. The hydrazides are prepared by treating a moderately dilute (about 10 per cent.) solution of the acid or lactone with a fair excess of phenylhydrazine and an equal quantity of 50 per cent. acetic acid, heating the mixture for from 30 minutes to two hours on the water-bath; the product sometimes crystallises from the hot solution, but generally the separation occurs only on cooling.

The hydrazides of the monobasic hydroxy-acids are all moderately easily soluble in hot water, but the double hydrazides of the polybasic acids are only sparingly soluble.

If the solution contains free mineral acids, it must previously be neutralised with soda or sodium carbonate, and if large quantities of hydrochloric, hydrobromic, or sulphuric acid are present, the acid is best removed with lead acetate, or baryta, otherwise rather sparingly soluble salts are formed; if the solution contains sugar, the osazone, which is also formed in the reaction, can generally be separated from the hydrazide by crystallisation from hot water.

The hydrazides are, as a rule, easily obtained in a pure condition, and may serve as a means of determining the formula of the acid, but they resemble each other so closely in physical properties that they cannot be suitably employed for purposes of identification. The hydrazides of gluconic acid, galactonic acid, and arabinosecarboxylic acid, for example, cannot be distinguished with certainty; in such cases it is necessary to reconvert the hydrazide into the acid. For this purpose the hydrazide is boiled for half-an-hour with 10 per cent. baryta-water (30 vols), the phenylhydrazine is extracted with ether, and the residual solution, together with any precipitate which has been produced, is heated to boiling, and the barium precipitated with the requisite quantity of sulphuric acid; on evaporation, the filtered solution yields the free acid or lactone.

All the monobasic acids of the sugar-group, under the conditions described above, give crystalline hydrazides which are sparingly soluble in cold, but moderately easily in hot water. Under the same conditions, saccharic acid, mucic acid, and metasaccharic acid yield hydrazides which are almost insoluble. Glycollic, lactic, and glyceric acids gave negative results, and the limit of the difference in behaviour probably lies between erythroglucic acid and arabonic acid. Formic acid, succinic acid, malic acid, tartaric acid, and many aromatic acids, for example cinnamic acid and gallic acid, yield hydrazides under the conditions described above, but malonic acid forms only an acid hydrazide. The readiness with which the hydrazide formation takes place is evidently dependent on the electronegative character of the acid; if the latter reaches a certain limit, the hydrazide formation takes place in dilute aqueous solution at temperatures below 100°, but, if the acid is less negative in character, the temperature must be raised; in such cases the presence of water does not affect the reaction. If, for example, a dilute aqueous solution of phenylhydrazine acetate is heated for several hours at 130°, a considerable quantity of acetylphenylhydrazine separates from the solution on cooling. Benzoic acid, glyceric acid, and lactic acid are converted into the corresponding hydrazides under the same conditions, but the products do not crystallise readily. At high temperatures, the yield is not quantitative, as the hydrazide is partially decomposed by the water.

The hydrazides can be readily distinguished from the hydrazones, as they all give a reddish-violet coloration with concentrated sulphuric acid and a drop of ferric chloride, a reaction first observed by Bülow (Abstr., 1887, 138); they are, moreover, readily decomposed by alkalis and baryta. They are all colourless, and generally melt, not quite constantly, with considerable evolution of gas.

Gluconic acid phenylhydrazide, $C_6H_{11}O_6\cdot N_2H_2Ph$, can be prepared by heating gluconic acid (1 part) on the water-bath for 45 minutes with water (10 parts), phenylhydrazine (1 part), and 50 per cent. acetic acid (1 part); it separates from the cold solution in crystals, and if the mother liquors are heated again for three hours, a further crop of crystals is obtained. The total yield is 81 per cent. of the theoretical. It crystallises in small prisms, softens at about 195°, and melts completely at 200° with decomposition. It is almost insoluble in ether, and only very sparingly soluble in cold water and hot alcohol, but readily in hot water. It can be easily converted into crystalline calcium gluconate by boiling it with baryta as described above, and treating the acid with calcium carbonate; the yield is 85 per cent. of the theoretical.

Galactonic acid phenylhydrazide, $C_6H_{11}O_6 \cdot N_2H_2Ph$, can be obtained in like manner from crude galactonic acid; it crystallises in plates, melts at 200—205° when quickly heated, and is moderately easily soluble in hot water, but only sparingly in cold water and hot alcohol.

Arabinosecarboxylic acid phenylhydrazide, $C_6H_{11}O_6 \cdot N_2H_2Ph$, prepared from the free acid or the lactone in like manner, melts at 214—216° with decomposition, and resembles the preceding compound.

Dextrosecarboxylic acid phenylhydrazide, $C_7H_{13}O_7 \cdot N_2H_2Ph$, obtained from the lactone, crystallises in prisms, melts and is slowly decomposed at 171—172°, and is readily soluble in hot water, but much more sparingly in alcohol.

Mannosecarboxylic acid phenylhydrazide, $C_7H_{13}O_7 \cdot N_2H_2Ph$, crystallises from hot water in small prisms; when quickly heated, it melts at 220—223° with decomposition, and is more sparingly soluble than the other hydrazides.

Rhamnosecarboxylic acid phenylhydrazide, $C_7H_{13}O_6 \cdot N_2H_2Ph$, crystallises from hot water in small, hexagonal plates, melting at 210° with decomposition.

Saccharinic acid phenylhydrazide, $C_6H_{11}O_5 \cdot N_2H_2Ph$, prepared from the lactone, crystallises from hot alcohol in very slender needles, melts at 164—165° with decomposition, and is much more readily soluble in water and alcohol than the preceding compounds.

Formic acid seems to be the only fatty acid which forms a hydrazide in aqueous solution, but even in this case the reaction does not take place quantitatively, as it is accompanied by a slight evolution of gas.

The hydrazides of succinic acid, malic acid, and tartaric acid are formed at 100° in 10 per cent. aqueous solution, but the reactions take place only slowly.

Succinylphenylhydrazine melts at 217—218°; Freund and Goldsmith give 208—209° as the melting point. Malic acid diphenylhydrazide melts, not quite constantly, at 220—223° with decomposition; Bülow found the melting point to be 213°. Tartaric acid diphenylhydrazide melts at about 240° when quickly heated, whereas Bülow gives 226° as its melting point.

Allyltricarboxylic acid and citric acid yield sparingly soluble hydrazides under the conditions described above.

The phenylhydrazine salt of phenylhydrazidemalonic acid separates in crystals when malonic acid (1 part) is heated with phenylhydrazine (3 parts), dilute acetic acid (3 parts), and water (10 parts) for two hours on the water-bath; it separates from hot alcohol or hot water in crystals, melts at 141—143° with decomposition, and has the composition $C_{15}H_{18}N_4O_3$.

Malonic acid phenylhydrazide, $COOH\cdot CH_2\cdot CO\cdot N_2H_2Ph$, is obtained when the mother liquors from the preceding compound are acidified with sulphuric acid and extracted with ether. It crystallises in colourless needles, melting at 154° with decomposition, is moderately soluble in water, and gives the hydrazide reaction; it reduces Fehling's solution when warmed therewith, and has a strongly acid reaction.

Malonylphenylhydrazine,  $CH_2<\substack{CO\\CO}>N_2HPh$, is formed, together with water and phenylhydrazine, when the phenylhydrazine salt of the preceding compound is heated at 200° for 15 minutes; it crystallises from hot water in slender, colourless needles, melts at 128°, and is readily soluble in alcohol.

Neither benzoic acid nor phenylhydroxyacetic acid yields a hydrazide when heated with phenylhydrazine in 10 per cent. aqueous solution; cinnamic acid, on the other hand, forms the hydrazide previously described by Knorr (Abstr., 1887, 665), but the yield is not particularly good.

Gallic acid phenylhydrazide, $C_{13}H_{12}N_2O_4$, crystallises from hot water in long prisms, melts at about 187° with decomposition, and is moderately easily soluble in alcohol and hot water.

Gluconic acid anilide, $C_6H_{11}O_6\cdot NHPh$, prepared by heating gluconic acid (5 grams) for four hours at 100° with aniline (5 grams), water (50 grams), and acetic acid sufficient for solution, separates from alcohol in crystals, melts at 171°, and is readily soluble in cold water.

The formation of the anilides does not take place as readily as that of the hydrazides, and the products are much more readily soluble in water. F. S. K.

Action of Phenylhydrazine on α-Hydroxy-acids and their Ethyl Salts. By A. Reissert and W. Kayser (*Ber.*, 22, 2924—2929).

—The authors have obtained phenylhydrazidopropionic acid (Abstr., 1884, 1152) by the action of phenylhydrazine on ethyl lactate, and hydrolysis of the ether formed. When equal molecular proportions of phenylhydrazine and α-hydroxybutyric acid are heated together at 150—160°, *pseudophenylhydrazido-α-hydroxybutyric acid*, $C_{10}H_{14}N_2O_2$, is formed. This compound is easily soluble in alcohol, sparingly in ether, crystallises in needles, and melts at 151—152°. It dissolves in boiling acids and alkalis, but is reprecipitated unchanged on cooling. When dissolved in concentrated sulphuric acid, it gives a violet-red coloration. Boiling alkalis do not decompose it, and it is very stable towards reducing agents; it is decomposed by boiling concentrated hydrochloric acid, but besides phenol no decomposition-products could be isolated. These characteristics seem to show that this compound is not a normal hydrazide. With sulphuric acid and potassium nitrite, *nitrosopseudohydrazido-α-hydroxybutyric acid*, $C_{10}H_{13}N_3O_3$ is formed.

This is sparingly soluble in water, easily so in aqueous alkalis and acids; it melts at 96—98°, and is very unstable. Acetic anhydride is without action on the pseudohydrazide, whilst concentrated sulphuric acid and phosphoric chloride and oxychloride yield resinous products.

Mandelic acid yields with phenylhydrazine a *pseudophenylhydrazidomandelic acid*, $C_{14}H_{14}N_2O_3$, analogous to the butyric compound. It crystallises from alcohol in long, white needles, and melts at 182°.

With lactic acid, only phenylhydrazine lactate was formed.

L. T. T.

Acetylenedicarboxylates and Phenylhydrazine. By E. Buchner (*Ber.*, **22**, 2929—2932).—When phenylhydrazine is added to an ethereal solution of methyl acetylenedicarboxylate, *methyl oxalacetate phenylhydrazone*, $NHPh{\cdot}N{:}C(COOMe){\cdot}CH_2{\cdot}COOMe$, is formed. It is easily soluble in boiling alcohol, sparingly soluble in ether, crystallises in colourless, glistening scales, and melts at 118°. Strong sulphuric acid dissolves it to a reddish-yellow solution, which gives a violet-red coloration with ferric chloride or a soluble dichromate. When heated with alkalis or dilute acids, it yields the acid $C_{10}H_8N_2O_3$, obtained by Wislicenus (Abstr., 1887, 235) from the corresponding ethyl-derivative. The latter acid is sparingly soluble in cold water and forms stable salts. It is probably *phenylpyrazolonecarboxylic acid.*

L. T. T.

Weselsky's Resorcinol Dyes. By R. Nietzki, A. Dietze, and H. Mäckler (*Ber.*, **22**, 3020—3038).—Resazurin (Weselsky's diazoresorcinol), $C_{12}H_7NO_4$, is obtained, together with resorufin (diazoresorufin) by Weselsky and Benedikt's method (*Monatsh.*, **1**, 889), and can be purified by means of the sodium salts. It crystallises from glacial acetic acid in small, greenish prisms, which do not melt without decomposition. The *sodium salt*, $C_{12}H_6NO_4Na$, crystallises in long, green, lustrous needles rather readily soluble in water, sparingly in aqueous sodium carbonate and sodium chloride. In thin layers the solution is almost pure blue and shows, especially in presence of a little alcohol, a splendid, brick-red fluorescence. The *barium salt* forms brownish, sparingly soluble needles; the *silver salt* is a voluminous, flaky precipitate. The *ethyl*-derivative crystallises in long, dark-red needles melting at 215°. The *acetyl*-derivative, $C_{12}H_6NO_4Ac$, prepared by heating a mixture of sodium resazurin and sodium acetate (dry) with acetic anhydride (12—15 parts), crystallises from alcohol in long, ruby-coloured needles melting at 222°; when heated with sodium carbonate, blue resazurin is formed. Tetrabromoresazurin, $C_{12}H_3Br_4NO_4$ (Weselsky and Benedikt's "non-fluorescent blue") was prepared by brominating resazurin; the *sodium salt*, $C_{12}H_2Br_4NO_4Na + 2H_2O$, crystallises from hot, dilute alcohol in lustrous, green needles. When the bromo-derivative is reduced, tetrabromoresorufin is formed, as observed by Weselsky and Benedikt; the potassium salt has the formula they ascribed to it, $C_{12}H_3Br_4NO_4K + 2H_2O$.

The substance obtained by the action of acetic chloride on resazurin, to which Brunner and Krämer ascribed the formula, $C_{12}H_9Cl_2NO_3$

(Abstr., 1884, 1333), crystallises in golden plates, and seems to be a mixture.

Resorufin, $C_{12}H_7NO_3$, was obtained from the mother liquors from the preparation of resazurin, and also by heating the latter with hydrogen sodium sulphite solution. It crystallises in small, brown needles. The *potassium salt* forms small, brownish plates, extremely soluble in water; the *ethyl salt*, $C_{12}H_6NO_3Et$, crystallises in orange-red needles melting at 225°. The acetyl-compound crystallises in long needles, melts at 223°, and has the formula given to it by Weselsky and Benedikt. Tetrabromoresorufin ("fluorescent blue") was prepared in a manner similar to tetrabromoresazurin; the *sodium salt*, $C_{12}H_2Br_4NO_3Na + 2H_2O$, crystallises in splendid, lustrous, green needles.

Hydroresorufin, the compound obtained by the action of zinc chloride on resorufin or on resazurin, has the formula $C_{12}H_9NO_3$. It crystallises in nearly colourless, wide needles, which soon become green when exposed to air. The *triacetyl-compound*, $C_{12}H_6NO_3Ac_3$, forms long, colourless, lustrous needles, melts at 216°, and is nearly insoluble in water, sparingly soluble in hot alcohol, and very soluble in hot glacial acetic acid. The molecular weight of the acetyl-derivative was determined by Raoult's method. When hydroresorufin is distilled with zinc-dust, diphenylamine is formed.

The paper concludes with remarks on the constitution of resorufin and resazurin.

N. H. M.

Dyes of the Benzeïn Group. By K. HEUMANN and H. REY (*Ber.*, **22**, 3001—3004).—*Tetramethylrosamine*, $C_{21}H_{23}N_2(OH)_3$ (?), is prepared by the action of benzotrichloride (1 mol.) on dimethylmetamidophenol (2 mols.) at 50—60°, using sand or benzene as a diluent to keep down the temperature; the reaction is completed by heating at 60° on a water bath. The product is steam-distilled, extracted with boiling water containing hydrochloric acid, and precipitated with sodium chloride. It is purified by dissolving in water, partially precipitating with sodium carbonate, filtering, and precipitating with sodium carbonate or ammonia. The *hydrochloride*, $C_{19}H_{11}Me_4N_2OCl$, forms black-red needles with steel-blue reflection; the *platinochloride* is a dark red precipitate soluble in water; the *oxalate* and *nitrate* form dark green and steel-blue needles respectively. The aqueous solutions of the salts have a splendid bluish-red colour with yellowish-red fluorescence. The solution in sulphuric acid is orange-yellow, the colour being changed to red by the addition of water. Silk and wool are coloured rose-colour to dark-red by a slightly acid bath of the dye. The colour on silk and jute shows a yellowish-red fluorescence, which is increased by sulphuric acid.

The rosamines are decolorised by zinc-dust in acid and alkaline solutions. Addition of soda does not produce an immediate precipitate in solutions of the dyes; a sodium salt seems to be formed. The alkaline solutions dye unmordanted wool an intense rose-colour, or even deep-red, but the colour is removed by boiling soap solution, or by prolonged boiling with water.

Tetrethylrosamine was also prepared from diethylmetamidophenol and benzotrichloride. The salts produce a bluer colour than those of the methyl-derivatives.

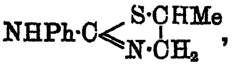
Diphenylrosamine, from metahydroxydiphenylamine, is a violet dye, readily soluble in alcohol, sparingly in water. N. H. M.

Action of Chlorocarbonylamide (Urea Chloride) on Aromatic Hydrocarbons in the Presence of Aluminium Chloride. By E. P. HARRIS (*Chem. Centr.*, 1889; ii. 285—286).—The following compounds are obtained by gently warming chlorocarbonylamide with the corresponding hydrocarbons and finely-powdered aluminium chloride. *Metaxylamide*, $C_6H_3Me_2\cdot CO\cdot NH_2$, forming lustrous needles melting at 180°, from which Fittig's xylic acid is obtained by saponifying with alcoholic potash. *Orthoxylamide*, crystallising in lustrous needles and melting at 136—137°, from which Fittig's paraxylic acid is obtained by hydrolysis. *β-Isodurylamide*, $C_6H_2Me_3\cdot CO\cdot NH_2$, forming lustrous plates melting at 184°. *Tetramethylbenzamide*, $C_6HMe_4\cdot CO\cdot NH_2$, crystallising in plates melting at 172—173°. *Acenapthenecarboxylamide*, $C_{13}H_{11}ON$, forming plates melting at 198°. *a-Ethylnaphthalenecarboxylamide*, $C_{10}H_6Et\cdot CO\cdot NH_2$, crystallising in colourless needles melting at 166°. All these amides are readily hydrolysed, the corresponding acids being formed. Alkaline potassium permanganate oxidises acenaphthenecarboxylic acid to naphthalenetricarboxylic acid. In the case of the homologues of benzene, the amidocarbonyl group enters in the para-position, unless this is already occupied, in which case it assumes the meta-position. In the case of the homologues of naphthalene only the α-derivatives react with chlorocarbonylamide. J. W. L.

Behaviour of Aniline towards Substitution-derivatives of Hydroxybenzoic Acids at High Temperatures. By H. LIMPRICHT (*Ber.*, 22, 2906—2912). The author, before examining the action of aniline on substituted hydroxybenzoic acids, repeated other experimenters' work on the action of aniline (14 grams) on the hydroxybenzoic acids (10 grams). With the ortho-acid, 1·5 grams of anilide were obtained, with the para-acid, 1 gram of anilide, whilst with the meta-acid apparently nearly all the hydroxy-acid was converted into the anilide. Contrary to Kupferberg's statement, the author finds that salicylanilide distils at a high temperature without decomposition. L. T. T.

Action of Aniline on Amidosalicylic Acid. By H. LIMPRICHT and v. RECHENBERG (*Ber.*, 2, 2908—2912).—Amidosalicylic acid [OH : COOH : NH_2 = 1 : 2 : 4] is best obtained by heating azobenzenesalicylic acid with stannous chloride. When amidosalicylic acid is heated with aniline hydrochloride at 160—210° for some hours, it yields *phenamidophenol*, $NHPh\cdot C_6H_4\cdot OH$, and *diphenamidophenylene*, $C_6H_4(NHPh)_2$. The former is soluble in cold alcohol, the latter only in boiling alcohol. Phenamidophenol crystallises from water in large, flat, colourless prisms, which turn brown on exposure to the air. It melts at 70°, and distils almost without decomposition. It is soluble in soda, and is coloured blue by strong nitric acid. With ethyl iodide and alcohol, it yields a derivative which was not, however, obtained in a pure state. With excess of acetic anhydride, it yields *diacetylphenamidophenol*, $OAc{\cdot}C_6H_4{\cdot}NPhAc$, which forms white crystals soluble in alcohol, ether, and benzene, and melts at 119°. *Phenamidophenolsulphonic acid*, $SO_3H{\cdot}C_6H_3(OH){\cdot}NHPh$, obtained by heating the phenol with strong sulphuric acid, crystallises from boiling water in small, grey prisms, which are still solid at 260°. It is easily soluble in alcohol, sparingly so in ether and benzene. The barium salt is crystalline. Diphenamidophenylene, obtained as above, forms grey or brownish needles, easily soluble in ether, chloroform, acetone, benzene, carbon bisulphide, acetic acid, and boiling alcohol, insoluble in water, and melts at 141°. Nitric acid gives first a blue and then a blood-red coloration, concentrated sulphuric acid dissolves the crystals to a blue solution; hydrochloric acid has no action, but if sodium nitrite is added to the mixture, an unstable *nitroso*-derivative is formed. Diphenamidophenylene is not formed by the action of pure aniline on phenamidophenol, but only when hydrochloric acid or aniline hydrochloride is present. Both the phenol and phenylene are *para*-compounds, and they can also be similarly prepared from the [1 : 3 : 4] amidosalicylic acid. L. T. T.

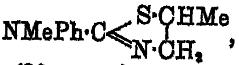
Aromatic Substituted Pseudothiocarbamides. By B. PRAGER (*Ber.*, **22**, 2991—3001).—*Phenylpropylene-ψ-thiocarbamide*,



$$\mathrm{NHPh{\cdot}C}<\begin{array}{l}\mathrm{S{\cdot}CHMe}\\ \quad|\\ \mathrm{N{\cdot}CH_2}\end{array},$$

is prepared by heating allylphenylthiocarbamide (m. p. 95°, 50 grams) with crude hydrochloric acid (100 c.c.) for two hours at 100°. The product is evaporated down, diluted with water, and saturated with ammonia. It melts at 117°, and dissolves readily in chloroform, alcohol, ether, and benzene. The *picrate* crystallises in yellow needles melting at 154°; the *platinochloride*, $(C_{10}H_{12}N_2S)_2,H_2PtCl_6$, forms microscopic, yellow crystals.

Phenyl-β-methyltaurocarbamic anhydride, $C_{10}H_{12}N_2SO_3$, is formed when the above base is oxidised with potassium chlorate and hydrochloric acid (Andreasch, Abstr., 1883, 664). It melts at 192°, dissolves in alcohol and glacial acetic acid, sparingly in hot water, and is indifferent to acids and alkalis. When heated with hydrochloric acid at 230° for five hours it is converted into β-methyltaurine (Gabriel, Abstr., 1889, 848) and aniline.



Phenylmethylpropylene-ψ-thiocarbamide, $\mathrm{NMePh{\cdot}C}<\begin{array}{l}\mathrm{S{\cdot}CHMe}\\ \quad|\\ \mathrm{N{\cdot}CH_2}\end{array}$, is obtained when a mixture of methylaniline (30 grams) and allylthiocarbamide (30 grams) is heated for a short time, then left for some hours, and finally heated with hydrochloric acid (120 c.c.) at 100° for two hours (compare Gebhardt, Abstr., 1885, 383). The base was not obtained pure by this method, but salts were prepared. The base was also prepared by the action of an excess of methyl iodide on phenylpropylenethiocarbamide. It distils at about 300° without decomposition. The *picrate* crystallises from boiling water in yellow needles melting at 125°; the *platinochloride* separates from the dilute hydrochloric acid solution in orange-red crystals melting at 183—184° with decomposition.

When phenylmethylpropylenethiocarbamide is oxidised with potassium chlorate and hydrochloric acid and the product heated with hydrochloric acid at 150—160°, β-methyltaurine and methylaniline are formed.

Allylorthotolylthiocarbamide, $C_{11}H_{14}N_2S$, is prepared by heating a mixture of orthotoluidine (25 grams) dissolved in alcohol (20 c.c.) and allylthiocarbamide (25 grams) and evaporating the product on a water-bath. It forms lustrous crystals, melts at 98°, dissolves readily in glacial acetic acid, chloroform, alcohol, and benzene, is less soluble in alcohol, and insoluble in water.

Orthotolylpropylene-ψ-thiocarbamide,  $C_7H_7\cdot NH<\begin{matrix}S\cdot CHMe\\ | \\ N\cdot CH_2\end{matrix}$, obtained from the above compound by the action of hydrochloric acid, crystallises in small, rhombic plates, melts at 126°, dissolves readily in the usual organic solvents, and in mineral acids, sparingly in hot water. The *picrate* melts at 175—176°; the *platinochloride* forms orange-red crystals melting at 177—178°.

Orthotolylmethylpropylene-ψ-thiocarbamide,  $C_7H_7\cdot NMe<\begin{matrix}S\cdot CHMe\\ | \\ N\cdot CH_2\end{matrix}$, formed by the action of methyl iodide on orthotolylpropylenethiocarbamide, boils at about 295°. The *hydriodide* crystallises in long hexagons melting at 165—166°; the *picrate* forms yellow prisms melting at 137—138°; the *platinochloride* decomposes at above 200°. When the base is oxidised and the product heated with hydrochloric acid, β-methyltaurine is formed.

α-Naphthylpropylene-ψ-thiocarbamide, $C_{14}H_{14}N_2S$, obtained from allyl-α-naphthylthiocarbamide (m. p. 145°, not 130°; Zinin, *Annalen*, **34**, 346), crystallises in rhombic plates, melts at 134°, dissolves readily in chloroform, alcohol, and benzene, is less soluble in ether, and insoluble in light petroleum and water. The *picrate* crystallises in long, rectangular prisms melting at 192°; the *platinochloride* is an orange-coloured, crystalline salt which melts at 205—206° with effervescence.

N. H. M.

Piaselenoles and Piazothioles. By O. Hinsberg (*Ber.*, **22**, 2895—2902).—Continuing his previous work (Abstr., 1889, 785), the author finds that selenious anhydride or acid reacts with aromatic orthodiamines to form piaselenoles, but that no similar derivatives are formed from aromatic meta- or para-diamines or from fatty diamines. Sulphurous anhydride forms a similar series of *piazothioles* with aromatic ortho-diamines, but phosphorous, boric, and tellurous anhydrides, phosphorous chloride, phosphoric oxychloride, and arsenious chloride do not yield any analogous compounds. The piaselenoles and piazothioles closely resemble many of the substituted quinoxalines.

Piaselenole, $C_6H_4{:}N_2{:}Se$, prepared from orthophenylenediamine, forms colourless needles easily soluble in alcohol, ether, and benzene, sparingly so in water; when heated it melts at 76° and emits an odour resembling that of quinoxaline. Its salts are yellow in colour and are decomposed by excess of water. Sodium yields a characteristic green periodide. *Ethoxypiaselenole*, $OEt\cdot C_6H_3{:}N_2{:}Se$, prepared from ethoxyphenylenediamine, crystallises in pale, yellowish needles, soluble in alcohol, and melting at 103—104°. With concentrated sulphuric acid it yields an intensely yellow solution; with stannous chloride and potassium periodide it behaves like the other piaselenoles. *Amidopiaselenole*, $NH_2\cdot C_6H_3{:}N_2{:}Se$, unlike the other piaselenoles, is only formed when selenious acid and triamidobenzene (1 : 2 : 4) solutions are mixed in the cold; at higher temperatures, the triamidobenzene acts as a reducing agent towards the selenious acid. It crystallises in brownish-red needles, soluble in alcohol, benzene, and ether, sparingly so in water, and melting at 149—150°. Its salts are dark-brown and crystalline, but are rather unstable. Concentrated sulphuric acid dissolves it, forming an almost colourless solution, with a reddish fluorescence, but it becomes intensely brown on dilution.

Piazothiole, $C_6H_4{:}N_2{:}S$, is formed when orthophenylenediamine is heated with concentrated aqueous sulphurous acid (or sodium hydrogen sulphite) for five or six hours at 180—200°. It is also formed when a stream of sulphurous anhydride is passed into the boiling diamine, but its formation is then generally accompanied by that of resinous bye-products. It forms colourless crystals having a strong odour resembling that of quinoxaline, melts at 44°, boils at 206° (uncorr.), distils in a current of steam, is sparingly soluble in boiling water, easily so in organic solvents, and is only feebly basic in character, its solutions in strong mineral acids being precipitated on the addition of water. Piazothiole is a very stable substance, and very resistent to oxidation; strong reducing agents convert it into phenylenediamine and hydrogen sulphide. *Methylpiazothiole*, $C_6H_3Me{:}N_2{:}S$, from metaparatoluylenediamine resembles piazothiole in character, melts at 34°, and boils at 233—234° (uncorr.). Determination of its molecular weight by Raoult's method gave 143, the formula $C_7H_6N_2S$ requiring 150. Its salts are colourless and are decomposed by water. The *platinochloride*, $(C_7H_6N_2S)_2,H_2PtCl_6$, forms reddish-yellow crystals; the periodide is also crystalline. When methylpiazothiole is dissolved in strong sulphuric acid and strong nitric acid then added in excess, *nitromethylpiazothiole*, $NO_2\cdot C_6H_2Me{:}N_2{:}S$, is obtained. It forms colourless crystals, soluble in alcohol and glacial acetic acid, and melting at 154—156°. *Bromomethylpiazothiole*, $C_6H_2MeBr{:}N_3{:}S$, formed by the addition of bromine to a cold chloroform or hot acetic acid solution of methylpiazothiole, forms white needles melting at 98°. It is volatile in steam and is very stable, the bromine-atom not being removed by boiling with potash.

L. T. T.

Derivatives of Paranitrocinnamaldehyde. By A. EINHORN and C. GEHRENBECK (*Annalen*, **253**, 348—376; compare Abstr., 1889, 396).—*Paranitrocinnamaldoxime*, $NO_2\cdot C_6H_4\cdot C_3H_3{:}N\cdot OH$, prepared by boiling the aldehyde with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution, is a yellow, crystalline compound melting at 178—179°. The *anilide*, $C_{15}H_{12}N_2O_2$, crystallises from alcohol in yellow needles melting at 132—133°.

Paranitro-α-bromocinnamaldehyde (m. p. 136°), identical with the compound obtained by Zincke and Hagen (Abstr., 1884, 1343), by nitrating α-bromocinnamaldehyde, is formed when nitrocinnamaldehyde is treated with bromine in glacial acetic acid solution; the dibromide could not be obtained in a pure condition.

Paranitrophenylbutine methyl ketone,

$$NO_2{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH{:}CH{\cdot}COMe,$$

is obtained, together with paradinitrodiphenyldibutine ketone, when paranitrocinnamaldehyde is treated with acetone in alcoholic soda solution; the filtrate from the paradinitro-compound is poured into acidified water, the precipitate digested with dilute sodium carbonate solution to free it from paranitrocinnamic acid and recrystallised. It separates from water in colourless needles, melts at 132°, and is readily soluble in the ordinary solvents. The *hydrazone*, $C_{18}H_{17}N_3O_2$, separates from alcohol in ruby-red crystals melting at 209—210°.

Paradinitrodiphenyldibutine ketone, $CO(CH{:}CH{\cdot}CH{:}CH{\cdot}C_6H_4{\cdot}NO_2)_2$, crystallises from acetic anhydride in pale yellow needles, melts at 216—218°, and is readily soluble in glacial acetic acid but insoluble in water, ether, chloroform, and alcohol.

Paranitrophenylbutinecarboxylic acid (compare Einhorn and Gehrenbeck, *loc. cit.*) can be prepared by gradually adding an alcoholic solution of paranitrophenylbutine methyl ketone to a boiling, concentrated solution of sodium hypochlorite. The *ethyl* salt, $C_{13}H_{13}NO_4$, crystallises from alcohol in yellowish plates, melting at 118°. The *copper* salt, $C_{22}H_{16}N_2O_8Cu$ is crystalline, the *silver* salt, $C_{11}H_8NO_4Ag$, amorphous; the alkaline salts are very readily soluble in water.

Paranitrophenylbutine-ω-dicarboxylic acid (m. p. 208°) is readily soluble in alcohol, hot water, and glacial acetic acid, but sparingly in benzene, ether, and chloroform. The *ethyl* salt, $C_{16}H_{17}NO_6$, crystallises from dilute alcohol in colourless needles melting at 104—105°. The *copper* salt, $C_{12}H_7NO_6Cu$, is crystalline, the *silver* salt. $C_{12}H_7NO_6Ag_2$, amorphous, and the alkaline salts are very readily soluble in water.

Paranitrophenyl-γδ-dibromethyl-β-bromacrylic acid is readily soluble in ether, ethyl acetate, and alcohol, but only sparingly in chloroform and benzene; when oxidised with 3 per cent. potassium permanganate, it yields paranitrobenzoic acid. The *ethyl* salt $C_{13}H_{12}NBr_3O_4$, crystallises from alcohol in colourless plates melting at 124°. The *sodium* salt crystallises with 2 mols. H_2O. F. S. K.

Constitution of Filicic Acid. By H. Schiff (*Annalen*, **253**, 336—342).—The author discusses the results obtained by Grabowski (*Annalen*, **143**, 279), Luck (Abstr., 1889, 276), and Daccomo (*ibid.*, 54) in their investigations of filicic acid, and comes to the conclusion that filicic acid is a butyrophloroglucyl allyl ketone of the constitution 
$$\begin{array}{l} C(OH){:}CH{\cdot}C{\cdot}O{\cdot}CH_2{\cdot}CHMe_2 \\ | \qquad\qquad\quad \| \\ CH{:}C(OH){\cdot}C{\cdot}CO{\cdot}CH_2{\cdot}CH{:}CH_2 \end{array}$$

. The criticisms of Paterno (Abstr., 1889, 615) on the experimental results of Daccomo (*loc. cit.*)

would seem, according to the author, to be to a great extent ungrounded. F. S. K.

Carbothionylic Acids of Resorcinol and Pyrogallol. By E. LIPPMANN (*Monatsh.*, **10**, 617—623; compare Abstr., 1888, 1092).—*Dihydroxydithiobenzoic acid*, $C_6H_3(OH)_2 \cdot CSSH$, is obtained in 60 per cent. of the theoretical yield by heating in a closed flask for 12 hours at 100° a mixture of resorcinol (50 grams) and potassium xanthate (80 grams). On heating the acid (50 grams) at 130—140° with potash (250 grams) dissolved in a little water, it is converted into β-resorcylic acid and consequently must be regarded as a metacarbothionylic acid.

Pyrogallolcarbothionylic acid, $C_6H_2(OH)_3 \cdot CSSH + H_2O$, is prepared in a manner precisely similar to that used in the case of dihydroxydithiobenzoic acid. It crystallises unchanged from dilute alcohol in the form of beautiful, glistening, golden scales, which become anhydrous at 70° and melt at 154°. On heating it with five times its weight of potash and a little water at 120—130°, it gives the pyrogallolcarboxylic acid of Senhofer and Brunner, and consequently has the constitution $CSSH : (OH)_3 = 1 : 2 : 3 : 4$. G. T. M.

Action of Orthonitrocinnamaldehyde on Malonic Acid. By A. EINHORN and C. GEHRENBECK (*Annalen*, **253**, 374—376).—*Orthonitrophenylbutine-ω-dicarboxylic acid*, $C_{12}H_9NO_6$, prepared by heating orthonitrocinnamaldehyde with malonic acid for six hours in glacial acetic acid solution, crystallises from glacial acetic acid in yellowish needles, melts at 212—213°, and is sparingly soluble in benzene, ether, and chloroform, but readily in alcohol and hot water. The *silver* salt, $C_{12}H_7NO_6Ag_2$, crystallises in yellowish plates; the copper salt, $C_{12}H_7NO_6Cu$, is a yellowish-green, crystalline compound.

Orthonitrophenylbutene-α-hydroxy-ω-dicarboxylic acid,

$$NO_2 \cdot C_6H_4 \cdot CH\vdots CH \cdot CH(OH) \cdot CH(COOH)_2,$$

is the first product of the action of malonic acid on orthonitrocinnamaldehyde; it crystallises from alcohol, in which it is only sparingly soluble, in colourless needles, melts at 269°, explodes when heated strongly, and is insoluble in benzene and light petroleum, and only sparingly soluble in ether, chloroform, and glacial acetic acid, but readily in hot water. F. S. K.

Benzoyltannin. By C. BÖTTINGER (*Ber.*, **22**, 2706—2709).—*Benzoyltannin* can be obtained by shaking an aqueous solution of tannin with soda and benzoic chloride; the dirty-white precipitate which is produced is boiled with ether to free it from benzoic acid, and the residue is warmed to expel the ether, washed with water, and dried. It is a pale yellow, crystalline powder, insoluble in boiling water, and almost insoluble in boiling alcohol. It is not acted on by ammonia, and it is only very slowly dissolved and decomposed by cold dilute soda. When heated with water at 150°, it liquefies completely, but it is only partially decomposed even after heating for two hours at 165°. It dissolves in hot aniline with formation of benzanilide, and is soluble in hot dimethylaniline. It is decomposed by warm, concentrated sulphuric acid or when heated alone. It dissolves in warm phenylhydrazine with slight evolution of gas, yielding a yellow substance and a crystalline compound which is soluble in ether and in boiling soda.

Other naturally occurring tannic acids give similar benzoyl-derivatives.

Tannin dissolves in warm, concentrated sulphuric acid, and is thereby converted into gallic acid.

The benzoyl-derivative of tannic acid (from oak bark) dissolves in warm phenylhydrazine with evolution of gas, yielding a yellowish-brown substance which is soluble in soda. F. S. K.

Tannins. By C. Etti (*Monatsh.*, **10**, 647—664).—Investigation of the tannins of the formulæ $C_{17}H_{16}O_9$ and $C_{20}H_{20}O_9$ (compare Abstr., 1881, 277; 1883, 994) has proved that they are not glucosides, but are to be regarded as derivatives of a ketonic acid,

$$C_6H_2(OH)_3\cdot CO\cdot C_6H(OH)_3\cdot COOH.$$

The author has now isolated a new tannin, which resembles those above mentioned in its general chemical and physical properties, appearing from its behaviour with phenylhydrazine and hydroxylamine to be also a ketonic compound. It has the formula $C_{16}H_{14}O_9$, and is obtained as a red powder from the diluted extract of the wood of the common Slavonian oak by careful precipitation with hydrochloric acid (excess of acid must be avoided, as it diminishes the yield). The precipitate is allowed to remain for several days, then collected, well washed with water, air dried, and, lastly, fractionally dissolved by alcoholic solutions of different strengths and precipitated with water. The pure substance, which is brownish-red, is made up of microscopic, warty, spherical masses (recrystallised from alcohol), insoluble in water and ether, but readily soluble in acetone, and has been shown by Fuchs (*Monatsh.*, 9, 1132—1142) to be a monobasic acid. With phenylhydrazine, it gives a yellow, amorphous compound, $C_{22}H_{20}N_2O_8$, forms a brown amorphous oxime, $C_{16}H_{15}NO_9$, and when heated with dilute sulphuric acid (1 : 10) for six hours in a sealed tube at 120—130°, yields, together with an insoluble anhydride, a red solution, from which, by extraction with ether, a red, crystalline mass may be obtained. On pressing this and recrystallising from water, it becomes colourless, and is identical with gallic acid (m. p. 238—240°). On treatment with magnesia, the tannin, $C_{16}H_{14}O_9$, gives the following salts:—$(C_{16}H_{13}O_9)_2Mg$, a brownish-yellow, amorphous mass; $(C_{16}H_{10}O_9)_2Mg_4$ and $(C_{14}H_{11}O_9)_2Mg_3$, both bright-yellow powders scarcely soluble in water; $(C_{16}H_{13}O_9)_2Mg + 2C_{16}H_{14}O_9$, of a brownish-yellow colour and very soluble in water. In all probability, the extract furnishing the tannin contains it as a soluble normal magnesium salt.

The tannin, $C_{16}H_{14}O_9$, when heated alone at 130—135°, or in closed tubes with water at 100°, loses water, forming anhydrides, from which the acid cannot be again regenerated, and which yield methyl iodide on boiling with hydriodic acid. On boiling the tannin with dilute sulphuric acid in an open vessel, an acid of the formula $C_{32}H_{24}O_{16} = 2C_{16}H_{14}O_9 - 2H_2O$ is formed as a reddish, insoluble mass, whilst, on heating in a closed tube, two anhydrides are formed, of which one, $C_{32}H_{20}O_{14}$, of a dark-red colour, is soluble in 95 per cent. alcohol, and, according to Fuchs (*loc. cit.*), is of an acid nature, whilst the other, $C_{32}H_{18}O_{13}$, which is blackish, is insoluble, and shows no acid reaction. The tannin, $C_{16}H_{14}O_9$, on long heating with hydrochloric acid at 100°, loses a methoxyl-group, and is converted into an acid, $C_{15}H_{12}O_9$, of a yellow colour, which still contains a methoxyl-group; so that the tannin itself contains two methoxyl-groups.

G. T. M.

Dibromosulphanilic Acid and its Derivatives. By O. HEINICHEN (*Annalen*, **253**, 267—288).—Dibromosulphanilic acid can be conveniently prepared by gradually adding a freshly prepared solution of bromine (10 c.c.) and soda (16 grams) in water (150 c.c.) to a hot, aqueous (500 c.c.) solution of sulphanilic acid (17·3 grams) and 35 per cent. hydrochloric acid (21 grams); the yield of the barium salt is 39·9 grams, or 95 per cent. of the theoretical. It can also be prepared by gradually adding a solution of potassium bromate (11·1 grams) in water (250 c.c.) to a hot, aqueous solution (500 c.c.) of sulphanilic acid (17·3 grams) and 43 per cent. hydrobromic acid (37·6 grams); the yield of the barium salt is 38 grams, or 90 per cent. of the theoretical, and no tribromaniline is formed in the reaction.

Sulphanilic acid is converted into aniline, but only very slowly, when it is heated at 200—220° with dilute sulphuric acid (b. p. 160°) in a current of steam. Dibromosulphanilic acid, at a temperature of about 170—178°, other conditions remaining the same, is readily converted into dibromaniline (m. p. 83—84°); the yield is 83 per cent. of the theoretical.

Dibromaniline [$Br_2 : NH_2 = 1 : 3 : 2$] crystallises from hot, dilute alcohol in long, colourless needles, melts at 83—84°, sublimes at 262—264°, and is readily soluble in alcohol, ether, benzene, and chloroform. The *hydrochloride*, prepared by passing hydrogen chloride into a benzene solution of the base, melts at 126°, and is decomposed by alcohol and by water, or by exposure to the air. The *platinochloride*, $(C_6H_3Br_2\cdot NH_2)_2,H_2PtCl_6$, crystallises in golden plates and is decomposed by water.

Diazodibromobenzene sulphate, $C_6H_3Br_2N_2,HSO_4$, prepared by treating dibromaniline with sulphuric acid and ethyl nitrite in well-cooled alcoholic solution, crystallises in colourless needles, and is, relatively, very stable; when boiled with water under reduced pressure, it yields an oil, probably metadibromobenzene, but when heated with sulphuric acid (b. p. 150°), it is converted into dibromophenol (m. p. 55—56°).

Metadibromoquinone [$O_2 : Br_2 = 1 : 4 : 2 : 6$] is obtained when dibromosulphanilic acid is oxidised with potassium chromate and sulphuric acid in the cold. It crystallises from hot alcohol in golden, iridescent plates, melts at 131°, and is readily soluble in alcohol, ether, chloroform, and benzene, but only very sparingly in cold water. The same compound is obtained by oxidising dibromoparamidophenol; this quinone is probably identical with the dibromoquinone obtained by Levy and Schultz (Abstr., 1882, 509) by oxidising tribromophenol with fuming nitric acid. F. S. K.

Tin Tetraphenyl. By A. Polis (*Ber.*, **22**, 2915—2918).—500 grams of a tin-sodium alloy (25 per cent. of sodium and 75 per cent. of tin), 600 grams of bromobenzene, and 25 c.c. of ethyl acetate were heated together at incipient boiling for about 30 hours. The product was a syrupy, brown mass, the solution of which in boiling benzene deposited crystals of *tin tetraphenyl*, $SnPh_4$, on cooling This substance when pure forms thin, colourless prisms belonging to the tetragonal system, $a : c = 1 : 0\cdot3893$; $111 : 110 = 70° 35'$. It is thus isomorphous with silicon tetraphenyl and lead tetraphenyl, the axial ratios following the order corresponding with the positions of the metals in the periodic system. It melts at 225—226°, volatilises unchanged, and boils above 420°.

It resembles the corresponding silicon and lead compounds in solubility, dissolving readily in boiling benzene, glacial acetic acid, chloroform, and carbon bisulphide; very sparingly in alcohol and ether. It inflames spontaneously when exposed to air. When treated with bromine (2 mols.), bromobenzene and tin diphenyl dibromide are formed. The author finds that under 42 mm. pressure the latter compound distils at 230° without decomposition. Chlorine is similar in its action to bromine, whilst iodine is without action.

L. T. T.

Derivatives of Diphenyline. By J. Reuland (*Ber.*, **22**, 3011—3019).—*Dibenzylidenediphenyline*, $C_{12}H_8(N{:}CHPh)_2$, is prepared by heating a mixture of diphenyline (1 mol.) and benzaldehyde (2 mols.) on a water-bath for several hours until clear, dissolving the product in ether and precipitating with light petroleum. It crystallises from alcohol and benzene in lustrous, yellow plates, melts at 232—233°, and is sparingly soluble in alcohol and ether. It was not analysed.

Dimetanitrobenzylidenediphenyline, $C_{12}H_8(N{:}CH\cdot C_6H_4\cdot NO_2)_2$, prepared by heating diphenyline (1 mol.) dissolved in a little alcohol with metanitrobenzaldehyde (2 mols.) for some time on a water-bath, crystallises from a mixture of benzene and alcohol as a fine, yellow, crystalline powder. It melts at 184—185°, and is readily soluble in benzene, less so in alcohol. The *diparanitro-derivative*, $C_{26}H_{18}N_4O_4$, is a yellowish-red powder, melting at 208°.

Diorthohydroxybenzylidinediphenyline, $C_{12}H_8(N{:}CH\cdot C_6H_4\cdot OH)_2$, prepared from diphenyline and salicylaldehyde, crystallises from alcohol in yellow plates, melting at 145°.

Difurfuraldiphenyline, $C_{12}H_8(N{:}C_5H_4O)_2$, is formed when furfuraldehyde (3 grams) is added to a solution of diphenyline (3 grams) in absolute alcohol (100 grams) and kept for 24 hours. It crystallises in lustrous, yellow plates, and melts at 137°. When the alcoholic solution is treated with mineral acids, splendid, red compounds are formed.

Phthalodiphenyline,  $C_{12}H_8\left(N{:}C{<}\begin{matrix}C_6H_4\\O\,\text{—}\end{matrix}{>}CO\right)_2$, obtained by heating diphenyline with phthalic anhydride (2 mols.) for two hours at 115—120°, crystallises from glacial acetic acid in lustrous, white plates, melting at 255—257°.

Thiocarbodiphenyline, $CS{<}\begin{matrix}NH\cdot C_6H_4\\ |\\ NH\cdot C_6H_4\end{matrix}$, is prepared by heating diphenyline (5 grams) with absolute alcohol (15 grams) and carbon bisulphide (15 grams) for 18—20 hours in a reflux apparatus on a water-bath, distilling off the alcohol and carbon bisulphide, and extracting the residue several times with hot alcohol and ether. It melts at 238° and does not give an odour of thiocarbimide when heated with strong hydrochloric acid.

Diphenylenebisazo-β-naphthol, $C_{12}H_8(N{:}N\cdot C_{10}H_6\cdot OH)_2$, is obtained when diphenyline is dissolved in hydrochloric acid (4 mols.), well cooled, and treated with the calculated amount of sodium nitrite. The tetrazo-compound is filtered and added to a filtered solution of β-naphthol in just sufficient potash. It is crystallised from benzene. It melts at 243—245° and dissolves in strong sulphuric acid with red colour.

Diphenylenebisazoresorcinol, $C_{12}H_8(N{:}N\cdot C_6H_5O_2)_2$, prepared in a manner similar to the above compound, is a reddish-brown powder.

Diphenylenebisazodimethylaniline, $C_{12}H_8(N{:}N\cdot C_6H_4\cdot NMe_2)_2$, is formed as a red precipitate of a metallic lustre by the action of the tetrazo-compound of diphenyline on methylaniline.

Tetramethyldiphenyline, $NMe_2\cdot C_6H_4\cdot C_6H_4\cdot NMe_2$, is obtained by heating dry diphenyline hydrochloride (1 mol.) with methyl alcohol (4 mols.) at 180° for two hours. The product is poured into hydrochloric acid, treated with potash, and extracted with ether; the ether is distilled off, the residue boiled with acetic anhydride and fractionally distilled. The oil, which distils over at 333—345°, solidifies in a short time. It crystallises from absolute alcohol in monoclinic prisms, which are phosphorescent when rubbed together; it melts at 51—52°. It gives a blue coloration with chloranil. The *picrate* crystallises from alcohol in long, red needles, resembling chromic acid, melts at 199—200°, and decomposes at 204°. The *methiodide* forms slightly rose-coloured needles, melts at 184°, and is readily soluble in alcohol and water, almost insoluble in ether. The *dimethiodide* melts at 196° and is readily soluble in water and alcohol.

Diphenylorthoparadicyanide, $C_{12}H_8(CN)_2$ [= 2 : 4′], is prepared by Sandmeyer's method for displacing amido-groups by cyanogen, following exactly the instructions given for benzonitrile (Abstr., 1885, 149). It crystallises in slightly yellowish plates, and melts at 152—153°.

Diphenylorthoparadicarboxylic acid, $C_{12}H_8(COOH)_2$ [= 2 : 4′], obtained by the hydrolysis of the above dicyanide crystallises in colourless plates melting at 251—225°. The *silver salt* is a white powder, melting at 235—237°, readily soluble in ammonia; the *copper salt* is a sparingly soluble, bluish-green, crystalline powder N. H. M.

Oxidation of Triphenylmethane. By M. HANRIOT and O. SAINT-PIERRE (*Bull. Soc. Chim.* [3], 1, 773—774).—Triphenylmethane, suspected by the authors to contain a higher homologue derived from toluene, was oxidised with chromic mixture; in addition to triphenylcarbinol (20 per cent.) and benzophenone (40 per cent.), small quantities of orthobenzoylbenzoic acid, and of anthraquinone resulting from the dehydration of this acid, were obtained. Pure triphenylmethane yielded neither of the latter substances on oxidation.
T. G. N.

Paramethylbenzil and Benzilparacarboxylic Acid. By E. BUCHER (*Ber.*, **22**, 2819—2820).—Paramethyldeoxybenzoïn yields the following bromo-substitution-products:—
$CHPhBr\cdot CO\cdot C_6H_4Me$, $CBr_2Ph\cdot CO\cdot C_6H_4Me$, $CBr_2Ph\cdot CO\cdot C_6H_4\cdot CHBr_2$, and $CBr_2Ph\cdot CO\cdot C_6H_4\cdot CBr_3$, from which *paramethylbenzil*, *dibromodeoxybenzoïnparacarboxylic acid*, $CBr_2Ph\cdot CO\cdot C_6H_4\cdot COOH$, and *benzilparacarboxylic acid* can be obtained.

Paramethylbenzil, $COPh\cdot CO\cdot C_6H_4Me$, is formed when dibromodeoxybenzoïn is heated with water at 180°; it is a yellowish oil.

Benzilparacarboxylic acid, $COPh\cdot CO\cdot C_6H_4\cdot COOH$, is obtained by heating the pentabromide with water at 160°; it crystallises in colourless plates and decomposes at 280—300° without melting.

The acid, $CBr_2Ph\cdot CO\cdot C_6H_4\cdot COOH$, is formed when methyldeoxybenzoïn is heated with bromine (5 mols.) at 160°, or when dibromoparamethyldeoxybenzoïn is heated with bromine (3 mols.) and water at 160°; it crystallises in yellow needles, melts at 218° and is partially converted into benzilcarboxylic acid when heated with magnesia at 190°.
F. S. K.

1.4′-Iodonaphthalenesulphonic Acid. By R. MAUZELIUS (*Ber.*, **22**, 2820—2823).—*1.4′-Iodonaphthalenesulphonic* acid, $C_{10}H_6I\cdot SO_3H$, can be prepared by treating α-diazonaphthalenesulphonic acid with warm 40 per cent. hydriodic acid; it is purified by converting it into the chloride (see below) and decomposing the latter with water at 150°. It crystallises in almost colourless plates with 2 mols. H_2O, melts at 129°, and is readily soluble in water. The *potassium* salt,

$$C_{10}H_6I\cdot SO_3K + H_2O,$$

ammonium salt, *sodium* salt, with 1 mol. H_2O, *silver* salt, *copper* salt, with $2H_2O$, and a number of other salts were prepared; they are mostly crystalline and sparingly soluble in water. The *methyl*-salt, $C_{10}H_6I\cdot SO_3Me$, crystallises from alcohol in prisms, melts at 59—60°, and is readily soluble in chloroform and ether, but only sparingly in cold alcohol. The *ethyl*-salt crystallises from alcohol in hexagonal plates, melts at 74° and is readily soluble in chloroform, ether, and benzene. The normal *propyl* salt crystallises in plates and melts at 67°, the *isopropyl* salt in long prisms melting at 90°. The *chloride*, $C_{10}H_6I\cdot SO_2Cl$, crystallises from chloroform in large, monoclinic prisms, melts at 114°, and is readily soluble in hot glacial acetic acid, chloroform, and benzene, but only sparingly in light petroleum. The *bromide* crystallises from benzene and chloroform in short prisms melting at 153°. The *amide*, $C_{10}H_6I{\cdot}SO_2{\cdot}NH_2$, crystallises from alcohol in small scales melting at 239°. F. S. K.

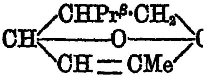
Specific Volumes of Camphor and Borneol. By M. KUHARA (*Chem. News*, **60**, 114).—The camphor employed melted at 177·7° (corr.) and boiled at 205·3° (corr.), the borneol boiled at 209·7° (corr.). Numerous determinations of the specific gravities of these two substances were made, by filling small glass cylinders with them at their respective boiling points and weighing when cold. The sp. gr. of the camphor was found to be 0·8110 at 205·3°, and its sp. vol. 187·42; whilst the mean sp. gr. of the borneol is 0·8083 at 209·7°, and its sp. vol. 190·5. D. A. L.

An Isomeride of Camphor. By O. WALLACH and A. OTTO (*Annalen*, **253**, 249—267; compare this Jour., 1889, 1069, 1071, and 1072).—In preparing pinene nitrosochloride by the method already described (Abstr., 1888, 1098), oily bye-products are formed in considerable quantity, and can be isolated by distilling them with steam in small quantities at a time. The same oily compounds are obtained when ethyl nitrite is used in the place of amyl nitrite; experiments showed that under certain conditions the former can be advantageously employed instead of amyl nitrite in the preparation of nitrosochlorides.

The crude bye-product distils completely between 160 and 190°, the principal portion boiling at 182—188°; it is most probably a mixture of cymene and a compound of the composition $C_{10}H_{16}O$, which the author names *pinole*, as will be shown below.

Pinole dibromide, $C_{10}H_{16}OBr_2$, is obtained in crystals when the fraction boiling at 182—188° is treated with bromine in glacial acetic solution until a permanent coloration is produced and the solution then allowed to evaporate slowly. The mother-liquors from the dibromide contain cymene, which can be isolated by distillation with steam. The dibromide separates from ethyl acetate or alcoholic ether in rhombic crystals, $a : b : c = 0·57 : 1 : 1·5553$, melts at 94°, boils at 143—144° (11 mm.), and is moderately easily volatile with steam. It is insoluble in water, but readily soluble in alcohol, ether, chloroform, and ethyl acetate. When boiled with alcoholic potash, it is decomposed, yielding an oil which is readily volatile with steam and very easily soluble in dilute alcohol. This oil can be separated into two principal fractions boiling at 183–184° and at about 210° respectively.

The fraction boiling at 183—184° consists of almost pure *pinole*, $C_{10}H_{16}O$. It has an odour hardly distinguishable from that of cineole, a sp. gr. of 0·953 at 20°, and a refractive power $[\alpha]_D = 1·46949$ at 20°. It combines energetically with bromine, yielding a dibromide (m. p. 94°), also with halogen acids and with nitrosyl chloride, but it does not react with acid chlorides, hydroxylamine, phenylhydrazine, or hydrogen sulphide. It is readily oxidised by warm dilute potassium permanganate solution, yielding carbonic anhydride, oxalic acid, and terebic acid (m. p. 175—176°); nitric acid (1 : 1) converts it into terebic acid and resinous products. The dibromide gives the same oxidation-products as pinole itself but it is only very slowly acted on by both the reagents. The constitutional formula,



is in accordance with the observed properties of pinole.

The fraction boiling at about 210° consists of impure *pinoleglycol ethyl ether*, $C_{10}H_{16}O(OEt)_2$. This compound can be obtained in colourless, compact needles by fractionating under reduced pressure, cooling the portion boiling at 110—120° (14 mm.) in a freezing mixture, and spreading the crystals on well-cooled porous plates; it is then dissolved in a little glacial acetic acid, the solution poured into water, and the precipitated oil brought into contact with a crystal of the substance.

Pinole nitrosochloride, $C_{10}H_{16}O,NOCl$, is a, relatively, very stable compound melting at 103°; it is readily converted into nitrolamines which generally crystallise well, and thus serve as a means of distinguishing this compound from other nitrosochlorides.

Pinolenitrolamine hydrochloride, $NOH{:}C_{10}H_{15}O{\cdot}NH_2,HCl$, separates after some time in crystals when the nitrosochloride is treated with excess of alcoholic ammonia; it crystallises well from water and dilute alcohol. The alcoholic mother-liquors from the hydrochloride contain the free *base*, which can be isolated by evaporating under reduced pressure, extracting the residue with chloroform, and distilling the extract under reduced pressure; it is a yellowish liquid, boiling at about 129—130° (14 mm.) with slight decomposition.

Pinolenitrolpiperidine, $NOH{:}C_{10}H_{15}O{\cdot}C_5NH_{10}$, separates from alcohol in crystals, melts at 154°, and is insoluble in water. The *hydrochloride*, $C_{15}H_{26}O_2N_2,HCl$, is a colourless, crystalline powder very readily soluble in water.

Pinolenitrolbenzylamine, $NOH{:}C_{10}H_{15}O{\cdot}NH{\cdot}C_7H_7$, is best obtained in a pure state by decomposing the hydrochloride, as it seems to crystallise from alcohol with 1 mol. of alcohol. It crystallises from ether in transparent prisms, melts at 135—136°, and soon becomes opaque on keeping, but without change in melting point or composition. The *hydrochloride*, $C_{17}H_{24}O_2N_2,HCl$, is crystalline and readily soluble in water.

Pinolenitrolaniline, $NOH{:}C_{10}H_{15}O{\cdot}NHPh$, crystallises in yellowish plates, melts at 174—175°, and is readily soluble in alcohol and ether. The *hydrochloride*, $C_{16}H_{22}N_2O_2,HCl$, is crystalline and decomposes on exposure to the air.

Pinolenitrol-β-naphthylamine, $NOH{:}C_{10}H_{15}O{\cdot}NH{\cdot}C_{10}H_7$, crystallises from alcoholic ether, melts at 194—195°, and is insoluble in water and only sparingly soluble in alcohol; solutions of the base and its salts are highly fluorescent. This compound is isomeric with camphor.

F. S. K.

Preparation of Aloin. By T. WOODRUFF (*Pharm. J. Trans.* [3], 19, 773—775).—The aloes are exhausted with amyl alcohol at the temperature of a water-bath, when most of the resinous matters remain in the residue. The liquid is filtered and evaporated and the aloin is obtained as a crystalline mass, contaminated, however, with a small deposit of resinous matters. This product is then exhausted with cold water, the solution is filtered, and the filtrate allowed to evaporate spontaneously, when the crystals are obtained quite pure. R. R.

Cephalanthin, a Bitter. By E. CLAASEN (*Chem. Centr.*, 1889; ii, 258, from *Pharm. Zeit.*, **34**, 384).—The bark of *Cephalanthus occidentalis* ("button bush" or "swamp dogwood"), a bush belonging to the Cinchoneæ, contains a saponin-like substance having a bitter taste and tanning properties. For its separation, the bark is digested with lime, the filtrate treated with carbonic anhydride, and the cephalanthin precipitated from the solution by hydrochloric acid and purified by treatment with alcohol and ether. It is amorphous, sparingly soluble in cold and hot water, readily soluble in alcohol and ether, and has the properties of an acid. When warmed with nitric acid, it gives a yellow coloration, and with concentrated sulphuric acid an orange coloration changing to reddish-brown. Dilute sulphuric acid seems to split up cephalanthin with formation of sugar. J. W. L.

Digitalin and Tanghinin. By ARNAUD (*Compt. rend.*, **109**, 701—703).—If digitalin is heated in sealed tubes at 180° with water and barium hydroxide, it yields a crystalline compound, which is insoluble in hot water, but somewhat soluble in boiling alcohol. It melts at 305—310° with rapid decomposition. It has the composition $(C_{31}H_{51}O_{11})_2Ba$, and is the barium-derivative of a compound $C_{31}H_{52}O_{11}$, formed from digitalin by the assimilation of water. It follows that the molecule of digitalin is represented by the formula $C_{31}H_{50}O_{10}$.

Tanghinin under similar conditions yields a barium-derivative of the compound $C_{27}H_{44}O_{10}$, which is formed by the assimilation of 2 mols. H_2O by the tanghinin. The molecule of tanghinin is, therefore, represented by the formula $C_{27}H_{40}O_8$. (Comp. Abstr., 1889, 900, and this vol., p. 65.) C. H. B.

Colouring Matters of Chlorophyll. By A. HANSEN (*Ann. Agronom.*, **15**, 428—429; from *Bot. Centr.*, **38**, 632).—The author prepares the yellow and the green constituents of chlorophyll in what he believes to be a pure condition by the following process:—Some leaves of grass are boiled in water for 15—30 minutes, then washed many times with water and dried in the dark. The dry matter is extracted with boiling alcohol, and the solution saponified by boiling three hours with a slight excess of aqueous soda; a current of carbonic anhydride is then passed through the solution, which is afterwards evaporated to dryness on the water-bath. Ether extracts from this soap the yellow colouring matter only, which is purified by evaporating down and crystallising from a mixture of equal parts of ether and light petroleum. The soap, after extraction with ether, is extracted with a mixture of alcohol and ether, which dissolves only traces of the combination of the green colouring matter with soda. On adding another quantity of alcohol-ether and also phosphoric acid, the green matter is liberated and passes at once into solution, from which it is obtained by evaporation in the form of a brilliant, fragile, greenish-black solid, insoluble in water, benzene, and carbon bisulphide, sparingly soluble in pure ether, very soluble in alcohol with strong red fluorescence. The crystals of yellow colouring matter form orange-red plates insoluble in water, soluble in alcohol, ether, chloroform, and benzene to a deep-yellow colour, and in carbon bisulphide to a brick-red. These crystals are transformed in the light into cholesterin. The author considers this yellow substance to be identical with the yellow colouring matter of flowers and fruits in general, including that of the carrot.

J. M. H. M.

Dibromoquinolines. By A. CLAUS and C. GEISLER (*J. pr. Chem.* [2], **40**, 375—382).—1 : 4-Dibromoquinoline has been obtained by Metzger (Abstr., 1884, 757), who asserts that it is identical with La Coste's dibromoquinoline (Abstr., 1881, 74; 1882, 980). When oxidised by potassium permanganate, it yields only pyridinedicarboxylic acid, which is converted into nicotinic acid (m. p. 229°) at 180°. It yields no methiodide, and only one nitro-compound.

Nitro-1 : 4-*dibromoquinoline*, obtained by nitrating the above compound with a cold mixture of two parts of nitric acid (sp. gr. 1·52) and four parts of water, forms colourless, silky needles melting at 155° (uncorr.), and sparingly soluble in water and cold alcohol, but freely in other solvents. The *hydrochloride* forms small, yellowish crystals melting at 228° (uncorr.) when sharply heated. The *platinochloride* is described.

Amido-1 : 4-*dibromoquinoline*, $C_9NH_4Br_2\cdot NH_2$, formed by reducing the nitro-compound with stannous chloride and hydrochloric acid in alcohol, distils with steam as small, colourless needles melting at 165° (uncorr.). Bromine converts it into a tribromoquinoline melting at 174° (uncorr.), perhaps identical with Lubavin's (m. p. 173—175°). By directly brominating 1 : 4-dibromoquinoline a tribromide of melting point 115° (uncorr.) and another substance are obtained.

1 : 3-Dibromoquinoline (La Coste, Abstr., 1882, 978) forms no methiodide and only one nitro-compound.

4-*Nitro*-1 : 3-*dibromoquinoline* crystallises in lustrous leaflets which have a greenish shimmer and melt at 162° (uncorr.); it forms well-crystallised, unstable salts. The *platinochloride* is described.

4-*Amido*-1 : 3-*dibromoquinoline* crystallises in needles melting at 184° (uncorr.).

2 : 4-*Dibromoquinoline*, obtained from symmetrical dibromaniline, crystallises in beautiful white, lustrous needles melting at 110° (uncorr.), and freely soluble in the usual solvents except water. The *hydrochloride* forms small, colourless needles melting at 158°. The *platinochloride* is described.

When 2 : 3-dibromaniline is quinolised, two dibromoquinolines are produced, and are separated by crystallising from ether and sorting the crystals.

2 : 3-*Dibromoquinoline* forms prisms which melt at 95° uncorr.; its *hydrochloride* melts at 144° (uncorr.).

3 : 4-*Dibromoquinoline* crystallises in slender needles melting at 124° (uncorr.); its *hydrochloride* and *platinochloride* are described.

A. G. B.

1 : 2-Dibromoquinoline, and Derivatives of 2-Bromoquinoline and 4-Bromoquinoline. By A. Claus and G. N. Vis (*J. pr. Chem.* [2], **40**, 382—387).—1-*Nitro-2-bromoquinoline* and 1-*amido-2-bromoquinoline* have been already described as α-nitrometabromoquinoline and α-amidometabromoquinoline, respectively (Abstr., 1889, 281). The 1 : 2 :-amidobromoquinoline *platinochloride* is here described.

1 : 2-*Dibromoquinoline*, obtained by diazotising 1-amidobromoquinoline and treating the diazo-compound with cuprous bromide, crystallises in beautiful, white needles melting at 112° (uncorr.).

4-Bromoquinoline melts at 52°, not 48° (*loc. cit.*); it is best obtained as follows:—The mixture of bromoquinolines prepared from metabromaniline (70 grams) is dissolved in warm dilute nitric acid (1 litre), when 2-bromoquinoline nitrate separates; the mother-liquor is mixed with potash, the precipitated oil dissolved in alcohol (100 c.c.), and a solution of oxalic acid (15 grams) in alcohol (25 c.c.) added; 4-bromoquinoline *oxalate* (m. p. 143°, uncorr.) crystallises out, and is saponified with ammonia to obtain the pure base.

The nitro-4-bromoquinoline melting at 146° (Abstr., 1889, 281) is 3 : 4-*nitrobromoquinoline;* its basic properties are very feeble, so that it is only soluble in concentrated acids, and forms no methiodide. 3 : 4-*Amidobromoquinoline* forms small, yellowish crystals melting at 105° (uncorr.), sparingly soluble in water, and dissolving in dilute acids with an intensely red colour; it gives the carbylamine reaction with alcoholic potash. Its *platinochloride* is described. A. G. B.

Bromine-derivatives of Quinoline. By A. Claus and A. Welter (*J. pr. Chem.* [2], **40**, 387—395).—The authors point out that La Coste's bromoquinoline (Abstr., 1881, 741) is not 3-bromoquinoline but 4′-bromoquinoline, and that the dibromoquinoline obtained from it is not identical with 1 : 4-dibromoquinoline, already described (above abstract); the former dibromoquinoline can also be obtained by brominating 4′-bromoquinoline, and is therefore 3 : 4′-bromoquinoline. A *tribromoquinoline* melting at 169° (uncorr.) is obtained at the same time.

3 : 4′-*Dibromoquinoline* crystallises from alcohol in lustrous, silky needles melting at 130° (uncorr.). The *hydrochloride* forms colourless, four-sided prisms melting at 185°, and easily decomposed by water, alcohol, or dilute acids. The *nitrate* forms colourless needles and prisms which melt at 158°. The *platinochloride* and the *methiodide* are described.

Generally speaking, whenever a bromoquinoline, with the bromine in the benzene-ring, is brominated, the new bromine-atom enters into the 4′-position; this is the case with anabromoquinoline, the 4 : 4′-dibromoquinoline, previously described by Claus and Decker (Abstr., 1889, 729), being obtained. 4 : 4′-Dibromoquinoline hydrochloride forms lustrous, rhombic tables melting at 183° (uncorr) and decomposed by water; the nitrate crystallises in colourless, four-sided tables melting at 147° (uncorr.). The *sulphate*, the *methiodide*, and the *methochloride* and its *platinochloride* are described.

2 : 4′-*Dibromoquinoline*, obtained by heating metabromoquinoline dibromide hydrobromide, crystallises from alcohol in beautiful, thick, colourless rhombohedra which are strongly refractive whilst immersed in the liquid. It melts at 126—127° (uncorr.). The *hydrochloride* is very sparingly soluble; the *nitrate* forms colourless prisms melting at 178°; the *platinochloride* is described; the *methiodide* forms microscopic needles melting at 271° (uncorr.).

1 : 4′-bromoquinoline has been described by Claus and Tornier (Abstr., 1888, 164). A. G. B.

Kynurin. By Z. H. Skraup (*Monatsh.*, 10, 726—731).—Kynurin, an oxidation-product of cinchonine and of cinchonidine, but not of quinine, is obtained to the extent of about 10 per cent. of the weight of the cinchonic acid taken, when the latter (50 grams) is oxidised with a mixture of chromic acid (20 grams) and sulphuric acid (30 grams) dissolved in water (200 grams). The kynurin (hydroxyquinoline) thus prepared melts at 201°, and has all the properties of the compound obtained by the direct oxidation of cinchonine. On heating at 100—110° with $1\frac{1}{2}$ times its weight of phosphorus pentachloride, it is converted into a chloroquinoline, which melts at 34°, and is reconverted into kynurin by heating with acidified water at 120°; consequently it cannot be α-chloroquinoline, since that compound melts at 38°, and is converted into carbostyril on heating with water. G. T. M.

Alkyl-derivatives of 1-Hydroxyquinoline. By E. Lippmann and F. Fleissner (*Monatsh.*, 10, 665, 672).—A molecular compound of methoxyquinoline hydriodide and hydroxyquinoline methiodide, $C_9NH_6{\cdot}OMe,HI + C_9NH_6{\cdot}OH,MeI + 2H_2O$ [$OH = 1$; $OMe = 1$], is obtained by heating together in sealed tubes at 100° for several hours a mixture of 1-hydroxyquinoline and methyl iodide in molecular proportion, with methyl alcohol. It is insoluble in ether, but soluble in alcohol and water, crystallising from the former in yellow, triclinic plates, decomposes at 143°, gives a hydrochloride, $C_9NH_6MeO,HCl + C_9NH_7O,MeCl + 5H_2O$, forming minute, red crystals easily soluble in water, and a platinochloride, $C_{20}H_{18}N_2O_2,H_2PtCl_6 + 2H_2O$, crystallising in orange-red prisms which decompose at 248°.

Methoxyquinoline-hydroxyquinoline methiodide, $C_{20}H_{19}N_2O_2I$, may be prepared by treating the above compound with ammonia or soda. It crystallises from hot alcohol in orange-red needles, and combines with methyl iodide to form the compound $C_{21}H_{22}N_2O_2I_2 + 2H_2O$, which crystallises in yellow needles and is converted by silver oxide into the deliquescent compound $C_{20}H_{20}N_2O_3$. The iodide, $C_{20}H_{19}N_2O_2I$, on reduction with tin and hydrochloric acid, was expected to yield kairin and tetrahydroxymethoxyquinoline, but only the formation of the former of these compounds could be ascertained. The ethyl-compound, $C_{22}H_{23}N_2O_2I$, is prepared by a method similar to that used in the case of the methyl-compound above described. It crystallises in red needles which melt at 202°, and furnishes a platinochloride which crystallises with 2 mols. H_2O. G. T. M.

Quinolineparamethenylamidoxime and its Derivatives. By J. Biedermann (*Ber.*, **22**, 2761—2767).—*Quinolineparamethenylamidoxime*, $C_9NH_6\cdot C(NH_2){:}NOH$, is formed when paracyanoquinoline (m. p. 135°), prepared from paraquinolinesulphonic acid by Fischer and Willmack's method (Abstr., 1884, 1051), is treated with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution. It crystallises from boiling alcohol in yellowish needles, melts at 105°, and is readily soluble in alcohol and ether, more sparingly in benzene, chloroform, and hot water, and almost insoluble in light petroleum. It dissolves freely in acids, but is only sparingly soluble in alkalis; it gives a greyish-green precipitate with Fehling's solution, and a deep-red coloration with ferric chloride. In aqueous solutions, silver nitrate produces a colourless, crystalline precipitate which darkens after some time with separation of silver. The *hydrochloride*, $C_{10}H_9N_3O,HCl$, crystallises in colourless needles, and is readily soluble in alcohol and water, but insoluble in ether, benzene, light petroleum, and chloroform. The *platinochloride*,

$$(C_{10}H_9N_3O)_2,H_2PtCl_6,$$

crystallises in well-defined prisms. The *ethyl*-derivative, $C_{12}H_{13}N_3O$, crystallises from dilute alcohol in colourless needles, melts at 85°, and is readily soluble in alcohol, ether, chloroform, benzene, and hot water, but almost insoluble in cold water. The *acetyl*-derivative, $C_{12}H_{11}N_3O_2$, prepared by treating the amidoxime with acetic chloride in ethereal solution, crystallises from hot benzene in colourless needles, melts at 115°, and is sparingly soluble in alcohol, ether, chloroform, and benzene, and almost insoluble in cold water.

Quinolineparamethenylethenylazoxime, $C_9NH_6\cdot C\left\langle\begin{smallmatrix}N\cdot O\\ N\end{smallmatrix}\right\rangle CMe$, prepared by dissolving the amidoxime in hot acetic anhydride, or by digesting the acetyl-derivative with alkalis or water, crystallises from dilute alcohol in slender needles, melts at 175°, and is soluble in alcohol, ether, benzene, and chloroform, but almost insoluble in water. It gives with ferric chloride a bluish-violet coloration, and mercuric chloride and auric chloride produce precipitates in a hydrochloric acid solution.

Ethyl quinolineparamethenylamidoximecarboxylate,

$$C_9NH_6\cdot C(NH_2){:}NO\cdot COOEt,$$

is formed when the amidoxime is treated with ethyl chlorocarbonate in chloroform solution. It crystallises from boiling alcohol in colourless needles, melts at 97°, and is soluble in ether, chloroform, benzene, and acids, but almost insoluble in light petroleum and cold water, and insoluble in alkalis.

Quinolineparamethenylcarbonylamidoxime, $C_9NH_6\cdot C\left\langle\begin{smallmatrix}N\cdot O\\ NH\end{smallmatrix}\right\rangle CO$, prepared by boiling the preceding compound with alkalis, or by digesting the amidoxime with excess of ethyl chlorocarbonate, crystallises from

boiling benzene in colourless needles, melts at 155°, and is soluble in alcohol, ether, chloroform, and alkalis, but almost insoluble in cold water. In aqueous solutions of the ammonium-derivative, copper sulphate produces a green, lead acetate and silver nitrate a colourless, crystalline precipitate.

Quinolineparamethenyluramidoxime, $C_9NH_6\cdot C(NOH)\cdot NH\cdot CONH_2$, separates in colourless crystals when a concentrated, aqueous solution of the amidoxime hydrochloride is treated with potassium cyanate; it crystallises from boiling water in small, colourless needles, melts at 164·5°, and is only sparingly soluble in cold water and acids, but more readily in hot water, alcohol, ether, benzene, light petroleum, and alkalis.

Quinolineparamethenylbenzenylazoximeparacarboxylic acid,

$$C_9NH_6\cdot C{<}^{N\cdot O}_{\text{—}N}{>}C\cdot C_6H_4\cdot COOH,$$

prepared by melting the amidoxime with phthalic anhydride, crystallises from hot alcohol in colourless needles, melts at 203°, and is soluble in ether and chloroform, but only sparingly in benzene and water, and almost insoluble in light petroleum. F. S. K.

α-Cinnamenylcinchonic Acid and 2:4-Quinolinedicarboxylic Acid. By O. Doebner and J. Peters (*Ber.*, 22, 3006—3011).—*α-Cinnamenylcinchonic acid*,  $CHPh{:}CH\cdot C{<}^{N—C_6H_4}_{CH:\dot{C}\cdot COOH}$, is prepared by gradually adding from a dropping funnel an alcoholic solution of aniline (52 grams) to a solution of cinnamaldehyde (75 grams) and pyruvic acid (50 grams) in absolute alcohol. The whole is boiled in a reflux apparatus on a water-bath for four to five hours; the liquid is then concentrated, and the crystals which separate washed with ether and crystallised from hot alcohol. The yield is 10 grams. The acid crystallises in yellow needles, melts at 295° with evolution of carbonic anhydride, is insoluble in water, sparingly soluble in ether, benzene, and chloroform, more soluble in hot alcohol, especially if a few drops of hydrochloric acid are added. The acid solution has a green fluorescence. The *potassium*, *sodium*, and *ammonium salts* are readily soluble; the *magnesium salt*, $(C_{18}H_{12}NO_2)_2Mg$, crystallises in concentrically-grouped, lustrous, yellow needles; the *silver salt* is a flaky precipitate; the *nickel* and *copper salts* are yellowish-green, and the *zinc* and *lead* salts yellow. When the acid is distilled, it decomposes into benzylidenequinaldine (Jacobsen and Reimen, Abstr., 1884, 335) and carbonic anhydride.

Cinnamenylcinchonic acid is also formed by heating α-methylcinchonic acid with benzaldehyde and zinc chloride, and by the action of aniline on pyruvic acid and cinnamaldehyde at the ordinary temperature. In the latter case an indifferent compound of the formula $C_{24}H_{20}N_2O$ is obtained, which crystallises from glacial acetic acid in yellowish needles melting at 194°.

2 : 4-*Quinolinedicarboxylic acid*, $C_9NH_5(COOH)_2$, is obtained by adding a solution of potassium permanganate (7·5 grams) in water (500 c.c.) to a solution of α-cinnamenylcinchonic acid in

soda diluted to 500 c.c. After 24 hours it is filtered, evaporated down to one-third of its bulk, treated with dilute hydrochloric acid, and allowed to cool. The acid separates in slender needles, and is crystallised from water. It melts at 246° with decomposition, is sparingly soluble in cold water, alcohol, and ether, insoluble in benzene and chloroform. The *calcium salt*, $C_{11}H_5NO_4Ca$, crystallises in slender, white, lustrous needles; the *barium salt* forms groups of long needles, the *copper salt* (with 1 mol. H_2O) is a sparingly soluble, bluish-green precipitate; the *silver salt* is a very gelatinous, white precipitate: other salts were prepared. When the acid is heated above its melting point, it partly sublimes, and is partly decomposed into quinoline and carbonic anhydride. N. H. M.

Hydroquinoline-derivatives. By O. Srpek (*Monatsh.*, **10**, 701—729).—A solution of the hydrochloride of quinic acid (20 grams) in concentrated hydrochloric acid (100 grams) was mixed with stannous chloride (10 grams), and then heated with metallic tin (28 grams). When the metal had dissolved, the solution was saturated with hydrogen sulphide to precipitate the tin, filtered, and concentrated in an atmosphere of carbonic anhydride, whereby the hydrochloride of *tetrahydroquininic acid*, $C_{11}H_{13}NO_3,HCl$, crystallising in small needles melting at 205—206° (uncorr.), separated out. The acid has probably all four, but certainly two, hydrogen-atoms attached to the pyridine nucleus, since it gives an acetyl-derivative, $C_{11}H_{12}AcNO_3$, melting at 240—241° (uncorr.), and, therefore, contains an imidogen-group. On treatment with bromine, the acid furnishes what is probably an additive product, which has a red colour, and on treating this with hot hydrochloric acid, washing with water, boiling with sodium hydrogen sulphite, and recrystallising from xylene, it gives tribromoquinanisoil, $C_{10}H_6Br_3NO$, a substance which crystallises in white needles, melts at 233°, and is identical with the compound obtained by Skraup from thalline; on heating it with concentrated hydrochloric acid, first at 150° and afterwards at 170°—180°, it gives a *tribromhydroxyquinoline*. This tribromhydroxyquinoline crystallises from acetic acid in needles melting at 218° (uncorr.), and is also produced, together with tribromoquinanisoil, on bromination of thalline hydrochloride.

Tribromoquinanisoil is oxidised by boiling concentrated nitric acid to a *bromopyridinecarboxylic acid* which melts at 182° (uncorr.), and proves to be identical with the bromonicotinic acid obtained by Claus and Collishonn (Abstr., 1887, 158). Tribromohydroxyquinoline is converted by potassium permanganate into a *bromoquinolinic acid*, $C_5H_2Br(COOH)_2 + H_2O$, which appears to be identical with the acid obtained by Claus and Collishonn (*loc. cit.*), and decomposes at 165° into carbonic anhydride and the above-mentioned bromonicotinic acid. On fusion with potash, these bromonicotinic acids furnish an acid free from bromine and 4′-hydroxypyridine. The tribromo-compounds must consequently be regarded as having one bromine-atom in the 4′-position of the pyridine nucleus, and the other two atoms in the benzene nucleus.

Tetrahydrobromhydroxyquinoline hydrochloride, $C_9NH_9Br{\cdot}OH,HCl$, which crystallises in needles melting at 238°, is obtained on reducing tribromohydroxyquinoline with tin and hydrochloric acid.

G. T. M.

Formation of Azines from Orthodiamines and Polyamines. By R. Nietzki (*Ber.*, **22**, 3039—3040).—A discussion of the bearing of recent work on this subject.

Derivatives of Orthamidobenzyl Alcohol. By H. G. Söderbaum and O. Widman (*Ber.*, **22**, 2933—2942).—The *platinochloride* of the benzophenyldihydroketometadiazine previously described (Abstr., 1889, 973) forms prismatic crystals melting with decomposition at 199°; the *aurochloride*, yellow needles melting at 170—172°.

Phenomethyldihydrothiometadiazine,  $C_6H_4<\begin{array}{l}CH_2\cdot NMe\\ NH\cdot CS\end{array}$, is formed by heating orthamidobenzyl alcohol with methyl thiocyanate in benzene solution. *Hydroxytolylmethylthiocarbamide* is first formed as a brown oil, which becomes thick on cooling but does not crystallise, and if this is heated with hydrochloric acid, it is converted into the diazine, which crystallises from methyl alcohol in long, glistening needles and melts at 139°. The *platinochloride* crystallises in four-sided plates melting with decomposition at 195°; the *aurochloride* forms yellow, microscopic needles melting at 151—153°.

ω-Hydroxytolylethylthiocarbamide, formed like its methyl analogue, is also an oil, and with hydrochloric acid yields *phenethyldihydrothiometadiazine*,  $C_6H_4<\begin{array}{l}CH_2\cdot NEt\\ NH\cdot CS\end{array}$, which crystallises from alcohol in long needles melting at 103°. The *platinochloride* is a pale-yellow powder melting at 208°; the *aurochloride* forms crystals melting at 118°.

When the methylthiocarbamide is heated with mercuric oxide, it yields *phenomethyldihydroketometadiazine*,  $C_6H_4<\begin{array}{l}CH_2\cdot NMe\\ NH\cdot CO\end{array}$. This is easily soluble in organic solvents, sparingly so in water. The *platinochloride*, $(C_9H_{10}N_2O)_2,H_2PtCl_6$, crystallises in needles or plates melting at 202—203°, the aurochloride, $(C_9H_{10}N_2O),HAuCl_4$, in yellow, glistening prisms melting at 185°. The ethylthiocarbamide in like manner yields *phenethyldihydroketometadiazine*, which crystallises from alcohol in flat, colourless needles and melts at 94—95°. The *platinochloride* crystallises in yellow needles melting with decomposition at 205°; the *aurochloride* forms golden-yellow scales melting at 116—118°.

Phenallyldihydroketometadiazine,  $C_6H_4<\begin{array}{l}CH_2\cdot N\cdot C_3H_5\\ NH\cdot CO\end{array}$, prepared from the allylthiocarbamide, is very soluble in alcohol, crystallises in microscopic prisms, and melts at 77—78°. The *platinochloride* crystallises in needles and melts at 169—171°.

Benzophenodihydroketometadiazine,  $C_6H_4<\begin{array}{l}CH_2\cdot NPh\\ NH\cdot CO\end{array}$, prepared from the benzothiocarbamide, crystallises from alcohol in needles or prisms melting at 145—146°. It forms a crystalline platinochloride and aurochloride. All attempts to obtain phenodihydrothiodiazine proved futile. The author points out the regularity of the melting points in these thio- and oxy-series.

When oxidised with chromic acid in acetic acid solution, phenodihydroketometadiazine yields benzoylencarbamide,  $C_6H_4<\begin{matrix}CO.NH\\ |\\ NH\cdot CO\end{matrix}$, described by Griess and by Abt.

The formation of these two groups of compounds appears at first sight to be analogous to that of the pseudo-carbamides lately described by Gabriel (Abstr., 1889, 848). But after a careful examination of the evidence the author concludes that the formulæ ascribed by him to the diazine is correct, and that his and Gabriel's compounds are not strictly analogous. L. T. T.

Codeïne Methiodide. By Z. H. SKRAUP and D. WIEGMANN (*Monatsh.*, 10, 732—733). It has been previously shown (Abstr., 1889, 1018) that in all probability the nitrogen-atom in morphine has both a methyl- and an ethyl-group directly attached to it. If this view is a correct one, codeine methiodide, which on heating with alkalis is converted into methylmorphomethine, should give rise to ethyldimethylamine when treated with alcoholic potash, and not to dimethylamine (the product said to be obtained by Knorr, Abstr , 1889, 417). On repeating Knorr's experiments, the authors find that ethyldimethylamine, together with a small quantity of trimethylamine, is really produced, and furnishes a characteristic platinochloride, which is sparingly soluble with alcohol, and crystallises from water in octahedra melting at 193°. G. T. M.

Oxidation-products of Quinoidine. By H. STRACHE (*Monatsh.*, 10, 642—646; compare Abstr., 1889, 1016).—When quinoidine (800 grams) is oxidised by boiling with commercial nitric acid (about 26 kilos.), added a little at a time until the solution is no longer rendered turbid by ammonia, a mixture of α-pyridinetricarboxylic acid (73 grams), cinchomeronic acid (48 grams of the hydrochloride), and cinchonic acid (34 grams) is obtained. At the same time a hydrochloride of a nitroquinolinecarboxylic acid is formed, which on sublimation gives a nitroquinoline crystallising in needles melting at 153—154°. The properties of this base agree with those of La Coste's 4-nitroquinoline. G. T. M.

Action of Potash on Alkyl Halogen-derivatives of Papaverine. By G. GOLDSCHMIEDT (*Monatsh.*, 10, 673—691).—The author defends the views of Stransky (Abstr., 1889, 166) against those of Claus and Edinger (*ibid.*, 415), and has made the following observations on repeating Stransky's experiments. According to Claus, the bases obtained on treating the alkyl halogen additive products of papaverine with silver oxide and with potash respectively, differ considerably, for whereas the hydrochloride and alkyl chlorides of the former give a platinochloride which is crystalline, anhydrous, and may be crystallised from hot water, the hydrochloride of the latter gives a platinochloride containing water of crystallisation, and which readily decomposes when attempts are made to recrystallise it from boiling water. Claus and Edinger obtained from the methyl base an uncrystallisable platinochloride, containing 1 mol. H_2O, and Hütlein found that the ethyl base gave a crystalline platinochloride, also containing 1 mol. H_2O. The author shows that the platinochloride of ethylpapaverinium oxide $(C_{20}H_{21}NO_4Et)_2PtCl_6 + 3\frac{1}{2}H_2O$, prepared by means of potash, and the corresponding methyl-compound,

$$(C_{20}H_{21}NO_4Me)_2PtCl_6 + 3H_2O,$$

similarly prepared, are both stable in presence of boiling water, whilst the methyl-compound, obtained by means of silver oxide, is an anhydrous salt. On the other hand, the hydrobromide obtained by Stransky from ethylpapaverinium oxide and hydrobromic acid is crystallographically identical with the papaverine ethyl bromide previously described by the author. Of these apparently contradictory facts no explanation can at present be offered.

Claus and Hütlein have expressed the opinion that during the action of potash on the alkyl halogen-derivatives of papaverine, the alkyl-groups swing from the nitrogen- to a carbon-atom; the author, however, finds that ethylamine is formed by boiling papaverine ethyl bromide with potash; at the same time, a compound melting at 240°, and also one melting at 186—187°, crystallising from alcohol in white needles, having the formula $C_{19}H_{20}O_5$ or $C_{19}H_{18}O_5$, and containing four methoxyl-groups, are formed. G. T. M.

Papaverinic and Pyropapaverinic Acids. By G. GOLDSCHMIEDT and H. STRACHE (*Monatsh.*, **10**, 692—700; compare Abstr., 1888, 302).—Correcting a previous communication (Abstr., 1886, 479), the authors state that papaverinic acid (Abstr., 1885, 1080), $C_{16}H_{13}NO_7$, crystallises with 1 mol. H_2O, and furnishes a ketoxime, $C_{16}H_{14}N_2O_7$, which crystallises from alcohol in small needles melting at 154—157°.

Ammonium pyropapaverinate gives precipitates with many metallic salts, and may be used to prepare the undermentioned compounds: Calcium pyropapaverinate, $(C_{15}H_{12}NO_5)_2Ca + 4H_2O$, crystallises in groups of needles; barium pyropapaverinate, $(C_{15}H_{12}NO_5)_2Ba + 4H_2O$, in plates; the hydrochloride, $C_{15}H_{13}NO_5,HCl + H_2O$, crystallises in orange-red needles; the phenylhydrazone, $C_{15}H_{13}NO_4{:}N_2HPh$, crystallises from alcohol in yellow prisms, softens and turns red at 210°, melts with decomposition at 223°, and forms a hydrochloride,

$$C_{15}H_{13}NO_4{:}N_2HPh,HCl,$$

a vermilion-coloured powder. The ketoxime of pyropapaverinic acid, $C_{15}H_{14}N_2O_5$, crystallises from alcohol in needles melting at 226°, its hydrochloride, $C_{15}H_{14}N_2O_5,HCl + H_2O$, crystallises in lemon-yellow needles, which lose HCl and H_2O when heated at 105°, and are slowly decomposed on boiling with water. G. T. M.

Ulexine. By A. W. GERRARD and W. H. SYMONS (*Pharm. J. Trans.* [3], **19**, 1029—1030).—Ulexine, $C_{11}H_{14}N_2O$, the alkaloïd previously obtained by the authors from the seeds of the common furze, *Ulex Europœus* (Abstr., 1886, 1048), forms colourless, odourless, deliquescent crystals, freely soluble in chloroform, but insoluble in absolute ether. The substance fuses at 151°, and begins to char at 175°. It cannot be sublimed without decomposition. It is a strong base, for it precipitates quinine, cocaïne, and strychnine, and also liberates ammonia from its compounds. The platinochloride,

$$(C_{11}H_{14}N_2O)_2,H_2PtCl_6,$$

forms lustrous, crystalline plates; the aurochloride, $C_{11}H_{14}N_2O,HAuCl_4$, was also analysed.

When ulexine is treated with alkaline permanganate, it gives off two-thirds of its nitrogen as ammonia. Ulexine has a powerful physiological action, and one-tenth of a grain has been found to produce toxic effects. It raises arterial tension, produces diuresis, and acts as a nerve and muscle poison, affecting the respiratory organs especially.

A second base seems also to occur in the seeds, but has not yet been obtained in quantity sufficient for examination. R. R.

Bile-Pigments. By J. B. HAYCRAFT and H. SCOFIELD (*Zeit. physiol. Chem.*, 14, 173—181).—When bilirubin is oxidised, biliverdin is formed; if the oxidation be carried further, as by nitric acid, a blue pigment, bilicyanin, is formed, then a violet (perhaps a mixture of the blue and red), then a red, and lastly a yellow pigment (choletelin) are formed. There have been, however, very few experiments recorded in which by means of reducing agents the lower terms of the series have been obtained from the higher. Lauder Brunton (*Handb. of Physiol. Lab.*, p. 498) alone mentions that sulphuric acid colours an alkaline solution of biliverdin yellow, and that if this yellow solution is then treated with nitric acid, a solution of bilirubin is obtained.

In the present research it was noticed that ox bile, on being allowed to remain for some hours, changed in colour from green to orange-brown. This is regarded as reduction, for if nitric acid be added to it, bilirubin is first obtained, and then the usual series of green, blue, violet, red, and yellow pigments. It was also noticed that the bile in the gall-bladder was yellowish where it came in contact with the wall of that viscus; this is an instance of reduction brought about by living tissues. Another instance of reduction is the presence of gall-stones, coloured by bilirubin in the bile of the ox, of which the natural pigment is biliverdin.

Experiments were then carefully performed in which bile was observed under different conditions in the air, in closed sterilised tubes, mixed with pieces of mucous membrane and so forth, from which the following conclusions are drawn:—That biliverdin parts with its oxygen as easily as oxyhæmoglobin; in sterilised vessels the reduction stops at bilirubin; the reduction is hastened by exposure to light, putrefaction, and admixture with mucus or mucous membrane, but hindered by darkness and drying the bile. When putrefaction occurs, reduction goes on to the formation of a brownish pigment, which gives no play of colours with Gmelin's test, but which differs from hydrobilirubin by being insoluble in ether, and easily soluble in alcohol. It moreover shows no absorption-bands. Copeman and Winston (Abstr., 1889, 792) have observed that human bile is olive-green; probably this undergoes reduction after death; hence the pigment usually described in human bile is bilirubin.

The play of colours can be obtained at the positive pole of a battery (4 Grove cells) placed in the bile, indicating successive stages of oxidation; if the negative pole be then placed in the bile, the series is reversed, indicating reduction. W. D. H.

Preparation of Crystalline Egg-albumin. By F. HOFMEISTER (*Zeit. physiol. Chem.*, 14, 165—172).—Fresh white of egg freed from membranes was mixed with an equal volume of saturated solution of ammonium sulphate to precipitate the globulin, and the filtrate allowed to evaporate in flat dishes at the ordinary temperature. In a few days a deposit of granules or scaly aggregations of granules was observed, and later needles or stellate collections of needles were mixed with these. Whether these are pure egg-albumin or a compound of egg-albumin with ammonium sulphate, and whether other animal proteids act similarly, are questions which have still to be investigated. Remarks on the differences between colloids and crystalloïds, and the necessity of modifying our ideas concerning this difference, conclude the paper. W. D. H.

Peptone and Similar Substances. By J. SEBELIEN (*Bied. Centr.*, 1889, 717—718).—Pure milk casein was digested with peptone and hydrochloric acid, the nucleïn filtered off, all albumoses separated by ammonium sulphate, and the resulting filtrate mixed with tannin. The precipitate thus obtained was decomposed by baryta-water, and then the barium removed. A solution of pure peptone was thus obtained, and was only precipitated by alcohol, phosphotungstic acid, and tannin, and was redissolved by excess of the latter. Optical estimation of the amount of peptone present indicated a percentage of only 1·2—2·7 per cent., which was obviously too low; hence it was concluded that the compound was almost, or even quite, inactive. E. W. P.

Physiological Chemistry.

Calorimetric Investigations on Heat Production in Animals. By J. ROSENTHAL (*Arch. Anat. Physiol., physiol. Abth.*, 1889, 1—53). —A long account of investigations relating chiefly to the influence of body weight and food on the production of heat, together with full descriptions of the methods employed, including that of the air-calorimeter. W. D. H.

Conditions of Absorption of various Hæmoglobins. By S. JOLIN (*Arch. Anat. Physiol., physiol. Abth.*, 1889, 265—288).—Böhr (*Ludwig's Festschrift*, 1886) has shown in experiments with the hæmoglobin of the dog, by the use of a new absorptiometric method, how the dissociable unions of hæmoglobin with oxygen and with carbonic anhydride vary with differences of pressure. This is not strictly proportional to the pressure, but falls at first slowly, but with low pressures (below 20 or 30 mm. of mercury) very quickly. This can be represented graphically by a curve constructed from abscissæ representing the pressure, and ordinates representing the amount of gas absorbed by 1 gram of hæmoglobin; the curve so obtained with oxygen is quite different from that obtained with carbonic anhydride.

In the present research, the same methods were applied first to guinea-pig's hæmoglobin, which crystallises in rhombic tetrahedra, not in prisms, as dog's hæmoglobin does; and secondly with goose's hæmoglobin, as an instance of blood pigment occurring in nucleated red corpuscles. In the first case, the results obtained were practically the same as in Böhr's researches, the difference of crystalline form causing no difference in the type of the curves produced, the general conclusion being that there are two possible compounds of each of the gases with the hæmoglobin. With regard to the second series of experiments, those with birds' hæmoglobin, the curves are in respect to both gases of a character different from those obtained with mammalian blood pigment. The curves are flatter, and show that the quantity of gas absorbed in the first place is less, and in the second place does not increase with the pressure beyond a certain point, namely, 95 mm. in the case of oxygen, 65 mm. in that of carbonic anhydride.

W. D. H.

Gases in the Swimming-bladder of Fishes. By M. Traube-Mengarini (*Arch. Anat. Physiol., physiol. Abth.*, 1889, 54—63).—If fish are placed in water containing hydrogen in solution, the swimming-bladder, whether it be of the open or closed variety, becomes in a few hours filled or partially so with the gas. This fact shows that the gases of the swimming-bladder are more or less directly obtained from water in which the fish is living. W. D. H.

Digestion in the Pig. By Ellenberger and Hofmeister (*Arch. Anat. Physiol., physiol. Abth.*, 1889, 137—153).—This is an account of experiments on the pig carried out on the same lines as previous experiments by the same authors on other animals. The anatomy of the stomach, the process of digestion with different foods in different parts of the alimentary canal, and the process of absorption are described. With regard to gastric digestion, an important point made out is that the proteolytic period is preceded by a period in which no secretion of acid takes place, and when amylolytic action proceeds freely. W. D. H.

Absorption of Fat in the Intestine. By A. Gruenhagen and Krohn (*Bied. Centr.*, 18, 617—619; from *Arch. Phys.*, **24**, 535—545).—The author showed some time ago that the epithelium cells of the intestine cut out of a frog, as well as those in the living organism, are capable of taking up drops of fat from the intestinal tube filled with fat or emulsion.

The experiments were made with frogs which had not been fed for some time, so that the intestine should be free from food constituents. The substances employed were milk, olive oil, lanolin emulsion, and, to determine whether the epithelium absorption is confined to fatty substances (Funke's view), a solution (?) of the finest Chinese ink. The results of the experiments show that the assumption of a mechanical activity of the epithelium of the intestines in taking up of fat is inadmissible, inasmuch as only fat and not even the finest grains of other substances enter into the protoplasma of the border cells. It is also established that the intestinal epithelium of hibernating frogs forms a store place for excess of fat, and will retain fatty substances enclosed in it with great tenacity. N. H. M.

Origin of Urea in the Animal Economy. By F. Coppola (*Chem. Centr.*, 1889, ii, 375; from *Rend. Acad. dei Lincei* [4], 5, 1).—A dog was fed with an insufficient amount of bread for a month, at the end of which time its weight remained constant. The urea and acidity were determined in the voidings for five days, and then varying quantities of cyanuric acid were administered in addition to the daily ration of bread, the urea and acidity being still determined. The administration of the cyanuric acid had no influence on the weight of the animal. Up to 1 gram of administered cyanuric acid, the amount of urea increased; an excess of this amount had no further influence on the quantity of urea formed. Some of the cyanuric acid passed away with the excreta, and the total acidity increased with the amount of cyanuric acid administered. The author concludes that one part of the cyanuric acid is changed into carbimide, which is further decomposed into water and carbonic anhydride, the ammonia then combining with a second portion of cyanuric acid, with formation of urea. J. W. L.

Origin of Uric Acid in Mammals. By J. Horbaczewski (*Monatsh.*, **10**, 624—641).—Since uric acid is a derivative of acrylic acid, and is produced in abnormally large quantities when glycerol is taken internally, it was thought probable that it might be built up synthetically in mammals from acrylic acid, and some nitrogenous compound, such as urea. In order to ascertain whether this was the case, sodium acrylate was mixed with the food of a strictly dieted subject, but no increase in the quantity of uric acid formed could be observed. The urine, however, showed indications of becoming alkaline, a result probably due to the formation of sodium carbonate from the sodium acrylate.

Minkovski has suggested (*Arch. exper. Path. Pharm.*, **21**) that in birds the formation ot uric acid is probably due to some function of the liver, whereby the acid is built up from lactic acid and ammonia, but the author now shows that in the case of men whose death results from *cirrhosis hepatis*, the amount of uric acid formed does not vary with the progress of the disease, and that mixtures of fresh spleenic juice and defibrinated blood, obtained from recently-killed calves, through which, at 37—40°, a slow stream of air is passed, give rise to very considerable quantities of uric acid. This result is not produced by the blood alone, and must be regarded as due to a function of the spleen, which perhaps under some circumstances brings about the degradation of the white corpuscles of the blood. G. T. M.

Changes in the Glycogen, Sugar, and Lactic Acid of the Muscle while performing Work. By A. Molinari (*Chem. Centr*, 1889, ii, 372—373, from *Ann. Chim Farm.*, 9, 351—366).—The muscles of two dogs, one of which had rested and weighed 20·5 kilos., whilst the other had run 92 kilometres (57 miles) and weighed 25·5 kilos, were analysed, and the respective amounts of glycogen, sugar, and lactic acid determined. The glycogen was estimated by Windgradoff's method.

In the filtrate from the precipitated glycogen, the sugar was determined by Fehling's solution. The lactic acid was estimated by two methods. By the first, 350 grams of muscle is extracted with water, concentrated somewhat, 99 per cent. alcohol added, the filtrate distilled and concentrated, and the residual alcohol-free liquid diluted with a little water. A slight excess of lead acetate is added, the filtrate and washing concentrated in order to allow the creatine to crystallise out, the mother-liquor acidified and extracted with ether, the ether distilled off, the residue dissolved in a little water, powdered zinc oxide added, the filtrate again concentrated, and treated with four or five volumes of 99 per cent. alcohol, and the precipitate filtered off, dried, and weighed. In the second method, baryta is used to remove the phosphates. The results obtained by the two different methods did not agree very closely, and the author recommends the former as the more exact.

In the muscles of the tired dog, less glycogen and lactic acid but more sugar was found, showing that the lactic acid is not formed from the glycogen. J. W. L.

Diastatic Ferment of the Liver. By Kaufmann (*Compt. rend. Soc. Biol.* [9], 1, 600—603).—Bernard first advanced the doctrine that the hepatic glycogen is transformed into sugar by a ferment which is separable from the liver substance. Recent observations by Dastre (and others not quoted) have thrown doubt on the existence of such a special ferment. In the present research, it was sought to further elucidate the question by examining the secretion of the liver, not the liver substance itself. Dog's bile was found to be free from a saccharifying ferment. Cat's bile was feebly saccharifying. The bile of the pig, sheep, and ox was found to be powerful in converting starch into sugar. These facts are considered as additional evidence that a diastatic ferment is formed by the liver; the dog, however, is supposed to transform its glycogen into sugar by some other means. W. D. H.

Quantity of Iron in the Spleen and Liver of Young Animals. By L. Lapicque (*Compt. rend. Soc. Biol.* [9], 1, 510—512). —The spleen of young animals is poor in iron. Four rabbits born at the same time were taken. Intravenous injection of distilled water was performed on two of these in order to destroy some of their red-blood corpuscles; their spleens contained respectively 0 24 and 0·26 parts of iron per 1000; the amount of iron in the spleens of the other two animals, which served as control specimens, was 0·44 and 0·19 per 1000 respectively. The result is thus an uncertain one.

Estimations were then made to determine if the quantity of iron in the liver varies with age. The organs were in each case freed from blood, and the results were as follows :—

Age of rabbit.	Weight in kilos.	Parts of iron per 1000.	
		In blood.	In liver.
8 days	0·120	0·45	1·00
11 days	0·137	0·40	0·20
21 days	0·320	0·41	0·14
3 months	1·170	—	0·043
3 months	1·350	0·42	0·035
3 months	1·360	0·36	0·040

The quantity of iron thus diminishes with the age of the animal.

W. D. H.

The Physiological Rôle of Lactose. By A. DASTRE (*Compt. rend. Soc. Biol.* [9], 1, 145—149).—Although lactose is so important as a food, it is stated that very little is known of the part it plays in the organism. The present communication relates to the question whether lactose is itself assimilable. The conclusion arrived at is that which others have found before, that lactose is not directly assimilable, but is first inverted in the alimentary canal. What agent accomplishes this change is still uncertain. After injecting into the circulation a mixture of galactose and glucose, a small quantity of the sugar which is not utilised passes into the urine. This sugar is a reducing one, but does not undergo the alcoholic fermentation. Its nature is, however, uncertain. W. D. H.

Physiology of the Tannins. By F. REINITZER (*Chem. Centr.*, 1889, ii, 292—293, from *Ber. deut. bot. Gesell.*, 7, 187—196).—The author contends that the assertion of Kraus (Abstr., 1889, 917), that the tannins of various origins are physiologically alike, is not correct, and that the methods at present employed for the determination of tannin are not suitable for physiological investigation, however useful they may be for the practical valuation by the tanner.

J. W L.

Volatile Fatty Acids of Butter. By P. SPALLANZANI (*Chem. Centr.*, 1889, ii, 339—341, from *Staz. sperem. agric. ital.*, 16, 277—293).—The author has carried out an investigation into the cause of butter fat containing so variable a quantity of volatile fatty acids. Four different breeds of cows, namely, that of the Province Reggio d'Emilia, Dutch, Schwitz, and Simmenthal, were employed and fed exactly in the same way. The cream of the milk of the several different breeds was separately churned, as was also cream which was 12 hours, and that which was 36 hours old. Further, the influence of length of time from calving, the sudden changing of food, and the age of the butter, with regard to the quantity of volatile fatty acids in the butter, was investigated.

The amount of volatile fatty acids, expressed in terms of c.c. of decinormal alkali per 5 grams of butter fat, varied from 20·63 to 30·60. Nor could any regularity in the quality of butter obtained from the different sources be observed. The butter from cows stationed at high lying places contained usually more volatile fatty acids than that from low lying stations. Of the different breeds that of Schwitz gave butter containing most fatty acids, then followed the breeds Simmenthal and Reggio, alike in this respect, and last the Dutch. Lastly, with regard to the influence of length of time since calving, the percentage of fatty acids declined as this period advanced.

J. W. L.

Urobilin in the Bile. By J. Winter (*Compt. rend. Soc. Biol.* [9], 1, 139).—In reference to the method adopted by Engel and Kiener (Abstr., 1889, 637) for the separation of urobilin, it is pointed out that the precipitates of the biliary constituents produced by adding calcium salts, especially the phosphate, carry urobilin down with them. The final filtrate, even in urines rich in urobilin, is always colourless. The conclusion drawn by Engel and Kiener, that urobilin is absent from the bile, is therefore not proved, as their method was one unsuited for discovering small quantities of that pigment. W. D. H.

The Behaviour of Tyrosine Ethyl Ether in Animal Metabolism. By R. Cohn (*Zeit. physiol. Chem.*, **14**, 189—202).—Considering the amount of proteïd daily ingested by an animal, the amount of tyrosine formed cannot be inconsiderable. Blendermann (Abstr., 1883, 876) and Jaffe (*Zeit. physiol. Chem.*, **7**) by feeding animals with tyrosine could, however, find no increase in the aromatic substances in the urine, nor indeed any constant relation between tyrosine or any urinary constituent. Baas (Abstr., 1887, 1133) found no increase in the hippuric acid secreted in similar experiments. In the present experiments on dogs and rabbits, the tyrosine ethyl ether hydrochloride was injected both subcutaneously and intravenously. Large doses acted fatally: but no tyrosine was ever found in the urine or bile; nor was there an increase in aromatic hydroxy-acids, phenol, or hippuric acid. It is thus probable that tyrosine undergoes complete destruction in the organism. W. D. H.

Determination of Potassium in Urine as Potassium Hydrogen Tartrate. By A. Robin (*Compt. rend. Soc. Biol.* [9], 1, 356—363).—When the potassium in urine is estimated by the weight of the precipitate obtained by adding tartaric acid to concentrated urine, the results obtained as compared with those obtained from the platinic chloride method are found to be from 9 to 70 per cent. too high. All conclusions drawn from such estimations are therefore null. Roger and Gaume have stated that the output of potassium salts is increased in ague and certain other diseases; their conclusions regarding this subject, and also regarding the toxicity of urine from the presence in it of potassium salts, rest on experiments performed by the tartaric acid method. The precipitate produced by tartaric acid in urine carries down with it uric acid, hippuric acid, albumin, and other organic substances. W. D. H.

Reducing Substances in Urine. By GAUBE (*Compt. rend. Soc. Biol.* [9], 1, 383—390).—Various urines were examined with regard to the substances in them that reduce alkaline solutions of cupric hydroxide. In one case, that of an emaciated child, the reducing substance is stated to have been aldehyde. The following statements are also made:—In acetonæmia and acetonuria, lactic acid exists in the urine, in combination conjointly with phosphoric acid, producing acid salts, principally of potassium, to which the acidity of the urine in these cases is chiefly due. Lactose is said to be met with in the urine of cases of what the author terms oxycrasia. W. D. H.

Benzamide in Urine after Administration of Benzaldehyde. By R. COHN (*Zeit. physiol. Chem.*, **14**, 203—208).—After feeding dogs on benzaldehyde (10 grams per diem), the urine was collected, extracted with hot alcohol, the extracts evaporated, and the deposit dissolved in water strongly acidified with sulphuric acid. This was shaken with ether; the ethereal extracts concentrated, and the hippuric acid so deposited filtered off. The ether was distilled off, and the small crystalline residue was dissolved in a concentrated solution of sodium carbonate, and again shaken with ether; the ether was again evaporated, and the crystalline residue was recrystallised from hot water, animal charcoal being used to decolorise it. The crystals were right-angled plates soluble in water, giving a neutral reaction, sparingly soluble in cold ether and light petroleum, easily in hot ether, in alcohol, and in hot benzene. They melted easily (127—128° uncor.), sublimed without decomposing, and contained no water of crystallisation, and proved to be benzamide; about 4 grams of it were obtained in the urine for every 100 grams of benzaldehyde given to the animal.

In the rabbit no benzamide was found in the urine, even after subcutaneous injection of ammonium benzoate; probably in this animal the ammonia derived from the benzoate is completely used in building up urea. W. D. H.

Uroleucic Acid and Alcaptonuria. By R. KIRK (*Brit. Med. J.*, 2, 1889, 1149—1150).—Prof. Huppert, in a private communication to the author, regards the uroleucic acid ($C_9H_{10}O_5$) previously described by him (Abstr., 1888, 1121) in the urine of cases of alcaptonuria as a homologue of gallic acid and probably pyrogallolpropionic acid, or at least a trihydroxyphenylpropionic acid, $C_6H_2(HO)_3\cdot CH_2\cdot CH_2\cdot COOH$. It does not give the genuine Millon's reaction, and therefore contains either no hydroxyl-group in the benzene nucleus, or more than one; it is optically inactive, and therefore contains no asymmetrical carbon-atom.

Uroleucic acid was found to have considerable antiseptic power. It is entirely absent in normal urine. The substance previously described as uroxanthic acid, which accompanies uroleucic acid in these peculiar urines, has been more fully investigated, and found to consist simply of uroleucic acid mixed with hippuric acid as an impurity.

W. D. H.

Cystinuria. By B. MESTER (*Zeit. physiol. Chem.*, **14**, 109—150). —This paper relates to the examination of the urine of patients suffering from cystinuria, and many of the considerations introduced are of clinical, therapeutical, historical, and theoretical interest. The chief points of chemical importance relate to:—

(1.) The solubility of cystin in urine; it appears that even in acid urine as much as 0·5 gram of cystin will dissolve per litre.

(2.) The sulphur in cystin is doubtless combined in a non-oxidised form; numerous analyses in this direction are tabulated; and the average result of estimations on the urine from nine individuals shows that the non-oxidised sulphur forms 18·1 per cent. of the total sulphur; from these numbers a method is devised for estimating the amount of cystin in urine.

(3.) Different kinds of diet, and the use of alcohol, appeared to be without influence on the amount of cystin excreted.

(4.) By administering sulphur and also salol as drugs, the amount of unoxidised sulphur in the urine was practically unchanged.

Chemistry of Vegetable Physiology and Agriculture.

Colouring Matters and Aromatic Products from the Bacillus Pyocyanicus. By A. BABÈS (*Compt. rend. Soc. Biol.* [9], 1, 438—440). —A pure culture of the *B. pyocyanicus* β (Ernst) in neutralised peptonised gelatin gave rise to other colouring matters than those named pyocyanin and pyoxanthin by Fordos. Certain aromatic substances are simultaneously formed. The cultivation was greenish-blue, and its odour that of limes. The following are the substances which were separated:—

1. An azure-blue pigment turned red by acids, and as sensitive as litmus. It dissolves in chloroform, from which it crystallises in the rhombic system. The absorption spectrum of the blue (alkaline) pigment shows two bands, (1) λ30—66, (2) λ150—ultra-violet. The absorption spectrum of the red (acid) pigment shows also two bands, (1) ultra-red—λ26, (2) λ40—ultra-violet. This substance is doubtless pyocyanin.

2. Pyocyanin being separated, the cultures remain coloured reddish-brown by reflected, emerald-green by transmitted light; when acidified the liquid loses its dichroism, which, however, returns when it is made alkaline once more. The colouring matter is a mixture of two pigments: one, soluble in alcohol, of a green colour by reflected, and blue by transmitted light; the other, insoluble in alcohol, is orange-red by reflected, greenish-blue by transmitted light. Neither of these corresponds with pyoxanthin, which is apparently not formed by the β bacillus.

3. The aromatic substances are not yet identified, a further communication on this part of the subject is promised; the methods adopted for their separation are briefly described. W. D. H.

Relation between the Assimilation and Transpiration produced by Chlorophyll. By H. JUMELLE (*Compt. rend. Soc Biol.* [9], 1, 9—10).—In sunlight, chlorophyll is stated to have two functions, that of assimilation of carbon from carbonic anhydride, and that of vaporising the water contained in the plant (transpiration) In order to investigate the relationship between these two phenomena, a certain number of plants were placed in air containing carbonic anhydride, and another number of similar plants in air free from carbonic anhydride; otherwise, the two sets of plants were under the same conditions. It was found that those in air free from carbonic anhydride, that is, those in which no assimilation was taking place, gave out more water than the other set. It thus appears that when assimilation is in abeyance, the greater part of the radiant energy absorbed from the light serves for the evaporation of water.

W. D. H.

Influence of Acids on the Evolution of Gases by Plants. By L. MANGIN (*Compt. rend.*, **109**, 716—719).—The researches of de Saussure, Mayer, and de Vries, have shown that Cactæ and Crassulaceæ, which contain a notable proportion of organic acids, have the power of evolving oxygen without absorbing carbonic anhydride when placed in sunlight, this change being accompanied by a reduction in the quantity of the organic acids.

The leaves of fusain, which contain practically no free acids, were injected with a dilute solution (2 to 3 per cent.) of some organic acid, and exposed to light. With malic, citric, and tartaric acids, oxygen was evolved, but acetic, formic, oxalic, and succinic acids gave negative results, probably because they killed the protoplasm. The volume of oxygen liberated varied with the nature of the acid, but, other conditions being the same, it was greatest with malic, less with citric, and least with tartaric acid. The volume of oxygen decreases with the concentration of the acid injected, because of the destructive action of the acid on the protoplasm.

The respiration of plants in the dark is also affected by the presence of free acid, the volume of oxygen absorbed, and the volume of carbonic anhydride liberated, being largely increased. Moreover, in normal leaves, the ratio CO_2/O is less than or at most equal to unity, whilst in presence of acids it is always greater than unity, and in some cases considerably greater.

The presence of certain organic acids in plants exerts a double influence. In the dark, it causes the evolution of a volume of carbonic anhydride greater than that of the oxygen absorbed, and, in light, the evolution of oxygen without a correlated absorption of carbonic anhydride. The cause of these disturbances is in the leaves themselves; the chlorophyll simply reduces, under the influence of light, the excess of carbonic anhydride which is exhaled by the tissues under the influence of the acids. C. H. B.

Formation of Calcium Oxalate in Plants. By KOHL (*Ann. Agronom.*, 15, 418—420, from *Bot. Centr.*, 38, 471).—The author's view is that asparagine and other amides are built up into albuminoïds with the aid of carbon and hydrogen derived from the carbohydrates. The oxygen liberated goes to form organic acids, especially oxalic, and this acid combines with the lime which is distributed through the tissues in combination with sugar and other soluble carbohydrates. The building up of the albuminoïds can only take place in the cells exposed to light; therefore the amides accumulate in any organ kept in the dark, and but little acid is found in these parts. In the parts exposed to light, acid is, on the contrary, abundant. When starch is stored up in roots, rhizomes, bulbs, seeds, &c., the lime which held the carbohydrate in solution is set free, and it is in these places that most calcium oxalate is found. In the Gramineæ much of the calcium oxalate is replaced by potassium oxalate.

J. M. H. M.

Calcium Oxalate in the Leaves of Alnus glutinosa, Symphoricarpus racemosa, and Cratægus oxyacantha. By C. WEHMER (*Ann. Agronom.*, 15, 420—421, from *Bot. Zeit.*, 1889, 141, 165).—By comparing corresponding leaves in shoots of different age, the author concludes that there is no solution and migration of the calcium oxalate at first formed, as contended by Schimper, but that the deposits of oxalate increase at different rates in tissues of different age.

J. M. H. M.

Occurrence of Scatole in the Vegetable Kingdom. By W. R. DUNSTAN (*Pharm. J. Trans.* [3], 19, 1010; and *Proc. Roy. Soc.*, 46, 211).—From the wood of *Celtis reticulosa*, a tree which grows in Java, Ceylon, and Eastern India, and which when freshly cut has a very disgusting odour, the author has obtained a substance of the composition of scatole (3′-methylindole.) This corresponds in all its properties with synthetical scatole from propylidene phenylhydrazide. Indole is found with scatole in human fæces, but none was detected in the wood of *Celtis reticulosa*.

R. R.

Inulin in the Capitula of Composites. By L. DANIEL (*Compt. rend. Soc. Biol.* [9], 1, 182—184).—Inulin has been found in the roots of a large number of composites, but has not been before noted in the capitules. It is, however, present in large quantities in the bracts, the receptacle, and even the seeds in course of development, especially in the Cynarocephala. It is always absent in parts exposed to light, and darkness appears to be favourable or perhaps essential for its elaboration.

The flowers were examined in different stages of development, and the conclusion drawn from these observations is that inulin is a reserve material, lasting, however, only a short time, and used up entirely in the development of the ovary and embryo.

Chemical Examination of Moorland and Peat Soils. By C. G. Eggertz and L. F. Nilson (*Bied. Centr.*, 1889, 664—668).—Various soils in Sweden were examined as to their volume-weight, percentage of organic matter and nitrogen, as well as of silicic acid, &c. The mineral constituents were dissolved out by a 2 per cent. solution of hydrochloric acid, and this strength of acid was found to be amply sufficient for the removal of all plant-food, and to render the soil sterile for barley; but to sterilise the fertile soils for oats, a 4 per cent. solution was requisite. These two solutions removed about equal quantities of silicic acid, which amounted to 0·1 per cent. of the dry soil. If the soil was exhausted with the acid, both directly and after ignition, then a very considerable difference in the quantities of sulphuric acid removed was noted, namely, 0·4 per cent. in the first case, and 0·96 in the second; also there was a great difference in the quantities of sulphates found, depending on the source of the soil, and the authors consider that, as the sulphates were not found in the hydrochloric extract, but only after ignition, the sulphur must be in many cases present as an organic compound. Only in 5 out of 32 cases did the sulphuric acid exceed 0·1 per cent., and it never amounted to 0·2 of the dried soil. The phosphoric acid estimations were of a similar kind, so that this element (phosphorus) must be considered as also being present in organic compounds, which are only rendered soluble by ignition; hence the advantage of burning a moorland soil without further addition of phosphatic manures.

In most cases the ignited soil yielded the most lime to dilute hydrochloric acid, the excess being 0·5—1·0 per cent. more than that found in the natural soil; but the opposite was found to be the case with the Gotland samples. A soil derived from Sphagnum, which contained only 0·22 per cent. of CaO, was completely sterile for oats, even after a heavy manuring with basic slag, potassium sulphate, and nitre, but 4,000 kilos of chalk per hectare rendered it fertile. Concerning magnesium nothing remarkable was noticed; neither was much difference noticed in the case of potassium, except in those soils where potassium silicates were present in large quantities; these, being readily acted on by hot lime, naturally yielded after ignition a larger quantity of potassium to the acid.

The percentages of nitrogen varied from 1·38 to 4·57.

Analytical Chemistry.

Filter Holder for Drying and Weighing. By C. REINHARDT (*Zeit. ang. Chem.*, 1889, 61).—This is a glass box, in shape like a funnel, with a short, wide neck, and having a light ground cover. The filter, whether full or empty, is dried in it whilst retaining its conical form, whereby not only is drying accelerated, but any subsequent treatment of the precipitate is much facilitated.

M. J. S.

Estimation of Sulphur in Burnt Pyrites. By G. LUNGE (*Zeit. ang. Chem.*, 1889, 239—240).—Of methods depending on the neutralisation of an alkali by the conversion of the sulphur into a sulphate in the dry way, that of Watson (Abstr., 1889, 306) is the only accurate, as well as the simplest and most expeditious one.

M. J. S.

Estimation of Nitrites. By W. R. DUNSTAN and T. S. DYMOND (*Pharm. J. Trans.* [3], 19, 741—743).—The authors have devised an apparatus for titrating, in an air-free space, the iodine liberated by nitrites from an acid solution of potassium iodide. All sources of error are thus eliminated, and the process has distinct advantages over the gasometric methods, especially in the case of organic nitrites. A stout glass flask of about 100 c.c. capacity is fitted with an india-rubber stopper, through which passes a short glass tube connected with a small tube-funnel by means of a short piece of thick india-rubber tubing carrying a steel screw clamp. 5 c.c. of 10 per cent. potassium iodide solution, 5 c.c. of 10 per cent. sulphuric acid, and 40 c.c. of water are introduced, and the mixture boiled in the flask with the tubes open until all the air and iodine that may have been liberated have been expelled; when the steam is escaping freely from the funnel, the clip is closed tightly at the same moment that the source of heat is withdrawn. Then the flask is cooled. A known quantity of the nitrite solution, equivalent to about 0·1 gram of nitrous acid, is placed in the funnel and cautiously drawn into the flask by unscrewing the clip, recently boiled water being used for washing it down. The iodine liberated is estimated by a decinormal sodium thiosulphate solution, gradually introduced into the flask with due precautions for the exclusion of air. The colour of the dissolved iodine is a sufficient indicator, but starch may be used. Many test determinations of volatile organic nitrites are given, with the figures controlled by other methods. The results are very accordant, and speak well for the accuracy of the process.

R. R.

Estimation of Arsenic in Iron. By M. A. v. Reis (*Chem. Centr.*, 1889, ii, 379; from *Stahl. u. Eisen*, 9, 720—723).—10 grams of pig iron is dissolved with 100 c.c. of water and 20 c.c. of concentrated sulphuric acid. The insoluble residue, consisting of those metals precipitable by hydrogen sulphide in acid solution, especially arsenic and copper, is collected, and dissolved with hydrochloric acid and potassium chlorate. The chlorine is expelled, the ferric chloride reduced by sodium hypophosphite, and the arsenic and copper precipitated by ammonium thiocarbamate, filtered, washed with dilute hydrochloric acid and water, then oxidised with concentrated nitric acid, filtered and the arsenic precipitated with magnesia mixture. The precipitate is washed into a platinum crucible with nitric acid, evaporated to dryness, and weighed after driving off the ammonium salts by ignition.

J. W. L.

Carbonic Oxide Detector. By Racine (*Bull. Soc Chim.* [3], 1, 555—558).—To indicate the presence of deleterious quantities of carbonic oxide in dwelling rooms, an apparatus is described in which the fact, that guncotton dusted with platinum black fires in air containing 2·5 per 1,000 of carbonic oxide, is made use of to determine the closure of an electric circuit containing an alarum.

T. G. N

Improvement in the Method of Estimating Carbonic Anhydride by Volume. By F. Fuchs (*Monatsh.*, 10, 602—604).—The acid solution used to decompose the carbonate is previously saturated with and is kept in an atmosphere of carbonic anhydride, whereby the usual error due to the retention of the gas in the acid is avoided.

G. T. M.

Estimation of Silica and Analysis of Siliceous Material. By G. Craig (*Chem. News*, 60, 227).—Taking into consideration the errors and difficulties attached to the estimation of silica by the method of fusion with alkaline carbonates, the author prefers to drive off the silica by means of hydrofluoric and sulphuric acids, and to estimate other substances in the residue. About 1·5 gram of finely-powdered substance is treated with sulphuric acid diluted with an equal volume of water, about 4 grams of pure hydrofluoric acid added, the whole mixed well by shaking gently, and heated over a small flame until almost dry; the operation is repeated, and the heating continued until sulphuric acid vapour is evolved in order to be sure that all the fluorides are decomposed. The residue is subsequently dissolved in hydrochloric acid and examined in the usual manner.

D. A. L.

Analysis of Sodium Sulphate. By Isbert and Venator (*Zeit ang. Chem.*, 1889, 66—67).—For many purposes a rapid and fairly

accurate estimation of the sodium sulphate in the commercial article is required. About 2 grams of the sample is dissolved in a little hot water, ammonia and ammonium carbonate are added, and the mixture is filtered; the precipitate is dissolved off the filter by hydrochloric acid, again precipitated as before, and then collected and thoroughly washed. A little sulphuric acid is added to the filtrates and washings, which are then evaporated in a platinum basin and ignited. From the weight of the residue is deducted the sodium sulphate corresponding to the sodium chloride in the original substance, as estimated by titration for chlorine. The remainder is the sodium sulphate in the substance taken.
M. J. S.

Chromium and Barium in Foods. By L. DE KONINGH (*Arch. Pharm.* [3], **27**, 944; from *Ned. Tij. Pharm. Chem. Tox.*, 1889, 257).—At least 25 grams of the substance is burnt in a platinum dish, and the ash is weighed. To the ash is added four times its weight of potassium sodium carbonate and the same amount of potassium nitrate, and the whole is fused for 15 minutes. After boiling with water and filtering, the liquid is yellow if chromium is present; but the presence of manganese may produce a greenish colour, which is removed by boiling for a few minutes with a little alcohol. The liquid is then concentrated to 20 c.c., filtered into a test-tube, and compared with water to which potassium chromate solution is added until the two tints are of the same intensity. To prove that the colour is due to chromium, acidify with acetic acid and add lead acetate. If lead is present in the original substance, a yellow precipitate is obtained before the acetate is added. The portion of ash insoluble in water is dissolved in hydrochloric acid, and if lead is to be sought for, this is carefully neutralised before hydrogen sulphide is added. To detect barium carbonate, the strongly acid solution of the ash is treated with a large excess of calcium sulphate solution, by which the barium is quickly precipitated as sulphate free from lead, as the latter is readily soluble in the strong acid.
J. T.

Magnesium as a Reagent. By H. N. WARREN (*Chem. News*, **60**, 187—188).—It is pointed out that magnesium, on account of its purity and activity, is an excellent reducing agent. In the dry way it reduces most metals, and even silica and boric anhydride when intensely heated in closed vessels with them. It does not reduce the alkalis and alkaline earths, but is attacked by molybdic anhydride with explosive violence. Being free from arsenic, it is well suited for use in Marsh's test, and as it contains neither iron, phosphorus, nor sulphur, scarcely reacts with potassium ferricyanide, and is more active than zinc, it may be used with advantage for reducing ferric to ferrous salts. If a solution of zinc acetate is boiled with magnesium, the whole of the zinc is precipitated, even though the solution also contains metals of the fourth group.

Iron may be separated from chromium in the following manner: the acid solution of iron and chromium is precipitated with sodium carbonate, the precipitate dissolved in acetic acid and magnesium added. The reducing action is at first violent and then ceases, but on applying heat, the colour of the solution changes from green through pink, red, violet back to green, the iron in the meantime being precipitated on the magnesium. D. A. L.

Volumetric Estimation of Zinc. By A. VOIGT (*Zeit. ang. Chem.*, 1889, 307—308).—The solution of the substance in hydrochloric acid is oxidised with nitric acid and diluted to about 100 c.c. Sufficient potassium tartrate to keep the iron in solution is added, and then ammonia to feeble alkalinity, and the liquid is further diluted to about 250 c.c. Standard solution of potassium ferrocyanide is then run in, until a drop of the mixture brought in contact with strong acetic acid develops a permanent blue. The ferrocyanide is of suitable strength if 1 c.c. is equal to 0·01 gram of zinc. About 46 grams of the salt is dissolved to a litre, and the solution is standardised against one of zinc made by dissolving 12·461 grams of zinc oxide in hydrochloric acid and diluting to a litre; 10 c.c. of this solution is mixed with 5 grams of potassium tartrate, a few drops of ferric chloride, ammonia, and water to 250 c.c., and should require 10 c.c. of the ferrocyanide. An essential condition is that the excess of ammonia should be as small as possible. Incorrect results are obtained when much manganese is present; lead is not injurious. The process is more rapid than Schaffner's. M. J. S.

Standardisation of Permanganate. By R. JAHODA (*Zeit. ang. Chem.*, 1889, 87).—In dissolving iron wire for the above purpose, the flask is fitted with a cork and a bent tube which dips into a beaker containing solution of sodium hydrogen carbonate. Any of this solution drawn in during the cooling of the iron solution produces an evolution of carbonic anhydride in the flask. M. J. S.

Incineration of Vegetable Matter. By G. LECHARTIER (*Compt. rend.*, 109, 727—731).—When vegetable matter is incinerated with free exposure to air or in a current of oxygen, there is always volatilisation of a portion of the sulphur, which may be absorbed by conducting the operation in a retort and passing the products of decomposition through a tube containing sodium carbonate.

Phosphorus, however, is not volatilised, if the matter is first carefully carbonised and then incinerated in presence of air or oxygen.

Incineration is best conducted in a platinum dish with a glass funnel supported a short distance above it. The temperature is raised very gradually, and when thoroughly carbonised the residue is extracted with warm water, washed, and the insoluble portion moistened thoroughly with milk of lime, dried, and heated until all carbonaceous matter is burnt away. The phosphoric acid in the aqueous solution and the final residue is estimated in the usual way. C. H. B.

Water Analysis. (*Chem. News*, **60**, 203—204.) *Report of the Committee appointed by the British Association to confer with the Committee of the American Association with a view of forming a uniform system of recording results of Water Analysis;* B. A. Meeting, 1889.—The committee recommend a system of statement for a complete analysis of which the following is an epitome. Results to be expressed in parts per 100,000. In a potable water, the numbers to be given in the following order:—Total solid matters, (*a*) in suspension, (*b*) in solution; organic carbon; organic nitrogen; oxygen consumed, as indicated by decoloration of permanganate; ammonia expelled on boiling with sodium carbonate; ammonia expelled on boiling with alkaline permanganate; nitrogen as nitrates and nitrites; chlorine; hardness—temporary, permanent, total; in a mineral water—carbonate of lime; carbonate of magnesia; carbonate of soda (calculated from residual alkalinity after boiling and filtering off precipitated $CaCO_3$ and $MgCO_3$); total of each of the following elements—calcium, magnesium, potassium, sodium, iron (ferrous), iron (ferric), and each of the following radicles—sulphuric (SO_4), nitric (NO_3), nitrous (NO_2), phosphoric (PO_4), silicic (SiO_3); then each of the elements—chlorine, bromine, and iodine, and of sulphur as sulphide. *Dissolved gases;* c.c. at 0° C. and 760 mm. in 1 litre of water. Carbonic anhydride (CO_2); oxygen; nitrogen; sulphuretted hydrogen.

They consider that this uniform method should be adopted in all cases where communications come before learned bodies and whenever possible in professional practice; that the decimal numerical notation is to be preferred; that the different scales for potable and mineral waters suggested by the American Committee are undesirable; that all results obtained by calculation should be sharply distinguished from those obtained by direct determination; that a statement of mineral constituents combined as *salts* is not to be approved of unless the analytical data upon which it is based are clearly stated; that the American Committee's suggestion of recording the proportion of each element of binary compounds, and recording all the oxygen in oxy-compounds in combination with the negative element, as indicated above, is the most convenient for all purposes of calculation, although the want of a name for these negative groups and the custom of quoting metallic elements as bases are objections to this system; finally, that volumes of dissolved gases may be given as above or in volumes of gas per 100 volumes of water. D. A. L.

Estimation of Carbonic Acid in Potable Waters containing Magnesia. By H. Trillich (*Zeit. ang. Chem.*, 1889, 337).—100 c.c. of the water is mixed in a stoppered cylinder with 5 c.c. of barium chloride solution (1 : 10) and 45 c.c. of titrated baryta-water (7 grams of barium hydroxide and 0·2 gram of chloride per litre) and allowed to subside for 12 hours. Two quantities of 50 c.c. each are then removed without disturbing the sediment and are titrated with hydrochloric acid, of which 1 c.c. equals 1 mg. of carbonic anhydride (using phenolphthalein). The magnesia is determined gravimetrically. Putting a for the number of c.c. of acid required by 45 c.c. of the baryta, b for the acid required by 50 c.c. of the clarified mixture, and m for the number of milligrams of magnesia in 100 c.c., then $10(a - 3b - 1{\cdot}1m)$ gives the number of milligrams of free and loosely-combined carbonic anhydride per litre. The remaining 50 c.c. in the settling vessel with the precipitate is titrated with the same acid (using cochineal). If d is the number of c.c. used, $10(d - b - 1{\cdot}1m)$ is the total carbonic anhydride in milligrams per litre. M. J. S.

Standard Solution for Clark's Soap-test. By F. E. Nelson (*Chem. News*, **60**, 132).—The author suggests the following mode of preparing a standard soap solution of constant composition :—A gram of pure palmitic acid is dissolved in a little pure spirit, neutralised with 4 c.c. of normal soda solution and diluted to 200 c.c. with so much aqueous spirit as to retain 35 per cent. of alcohol in the standard solution. Fatty acids separated from ordinary tallow may be used instead of palmitic acid. D. A. L.

Detection of Mercuric Cyanide in Toxicological Investigations. By D. Vitali (*Chem. Centr.*, 1889, ii, 391—392; from *L'Orosi*, **12**, 181—196).—The author recommends the following modification of Selmi's method for the detection of mercuric cyanide in toxicological investigations.

The substance is acidified with tartaric acid, neutralised again with precipitated calcium carbonate, a slight excess of aqueous hydrogen sulphide solution added, the flask closed and allowed to remain at rest for 24 hours in the cold, then a further quantity of hydrogen sulphide water is added and a current of hydrogen passed through the liquid. The gases are passed first through a solution of bismuth nitrate in dilute nitric acid to absorb the hydrogen sulphide, and secondly through aqueous potash for absorption of hydrogen cyanide; in the latter solution, the usual tests for hydrogen cyanide may be made.

J. W. L.

Reaction of Sodium Nitroprusside with Alkaline and Alkaline Earthy Hydroxides. By H. Brunner (*Chem. News*, **60**, 168). —Sodium nitroprusside produces an intensely yellow coloration with sodium, potassium, barium, or calcium hydroxide, but does not react with the soluble carbonates or hydrogen carbonates.

By adding aqueous sodium nitroprusside to sodium hydroxide until an orange-colour appears, shaking with alcohol and allowing to settle, a deep-yellow oil separates, which ultimately solidifies to orange-coloured crystals. An aqueous solution of this salt gives coloured precipitates with metallic salts; moreover, with acids it gives a green colour, becoming violet on exposure to the air, finally giving a green precipitate. D. A. L.

Estimation of Glycerol by Oxidation with Permanganate in Acid Solution. By H. Grünwald (*Zeit. ang. Chem.*, 1889, 34—35). —Planchon's method (Abstr., 1888, 1345) affords very serviceable results; in 12 determinations, the mean error of a single result was 1·81 per cent. Potash in Liebig's bulbs is, however, more suitable than soda-lime for absorbing the carbonic anhydride.

M. J. S.

Copper Solution for the Estimation of Glucose. By E. Soldaini (*Chem. Centr.*, 1889, ii, 389—390; from *L'Orosi*, **12**, 196—198).—The author recommends a more dilute solution of cupric sulphate in potassium hydrogen carbonate than that generally described under the name of "Soldaini's solution" (compare Abstr., 1889, 313). 3·464 grams of cupric sulphate (5 aq.) and 297 grams of potassium hydrogen carbonate are dissolved in 1 litre.

This solution will detect 0·0005 gram of glucose in 10 c.c. of water by boiling with the reagent for 10 minutes. For quantitative purposes it is applied as when using Fehling's reagent, approximate tests being first made, and finally the quantity thus found added all at once to the copper solution and boiled for five minutes, when an excess of neither copper nor sugar should be present.

J. W. L.

Iodine Absorption of Essential Oils. By R. H. Davies (*Pharm. J. Trans.* [3], 19, 821—824).—This paper records the results of the application of Hübl's reagent to determine the "iodine absorption" of essential oils. A weighed quantity of the oil was allowed to remain all night with an excess of the iodine solution. The differences were greater than those found with fixed oils, as they ranged from 0 to nearly 400 per cent. A table of the results obtained with 64 essential oils and their derivatives shows the percentages obtained. Oil of almonds is *nil*, menthol 0·12, camphor 0·46 per cent. English and Japanese oil of peppermint 43·5 to 57·7 per cent.; but American, 121·8 to 132·2. Thymol and anethoïl 171·5 to 182·9 per cent.

R. R.

Testing Oil of Peppermint for Adulterants. By H. W. Snow (*Pharm. J. Trans.* [3], 19, 1056—1058).—The author gives the results of his trials of some tests which have been proposed for detecting the presence of certain adulterants in oil of peppermint. When 5 per cent. or more of alcohol has been added, the oil will be coloured distinctly red on agitating it for a few seconds with a little magenta, which is insoluble in the perfectly pure oil. Oil of camphor may be detected by agitating two drops of the sample with a little nitric acid (sp. gr. 1·42), when a reddish-brown colour may appear, even in the absence of oil of camphor, but this fades in two or three hours, while the distinct red colour due to the presence of this adulterant persists for two days. For detecting turpentine, the optical test is not conclusive, as French oil of turpentine has itself left-handed rotation. The non-solubility of turpentine in 80 per cent. alcohol fails to detect even 50 per cent. of it when mixed with oil of peppermint. Fractional distillation is useful, and when followed by determinations of the iodine absorption, trustworthy indications may be obtained in certain cases. Gold chloride in chloroform solution, boiled with a few drops of an essential oil, gives characteristic reactions. Oil of turpentine reduces the solution quickly with little or no colour; oil of camphor acts slowly with only a faint-blue colour; oil of copaiba gives a fine blue solution which gradually loses its colour; oil of peppermint quickly gives a brown, changing into violet-red. These reactions can, however, seldom be used with confidence, except under special circumstances. R. R.

Reactions of Essential Oils. By R. Williams (*Chem. News*, 60, 175—176).—The author has examined a great number of essential oils with regard to their potash and iodine absorption, noting also their boiling points and specific gravities; a table of results is given.

In his opinion concordant results have been obtained with oils of bergamot, caraway, cassia, cedar-wood, cinnamon, citron, citronelle, cloves, lemon, mace, nutmeg, orange, thyme, and verbena, and it is suggested that by examining these oils in this manner adulterations may be detected with certainty. Oils of aniseed, cajeput, eucalyptus, juniper, lavender (various), spike, lemon grass, pennyroyal, peppermint (various), rosemary, rue, sage, and sassafras, did not yield concordant results, for which various causes are assigned, such as adulteration, difference in age, and change in composition. Oil of spike has a lower boiling point and a lower potash absorption than the more expensive oil of lavender. Oil of cinnamon has a lower gravity, boiling point, and potash absorption, but a much higher iodine absorption than the cheaper oil of cassia. At least two, and in some cases more samples of each oil have been examined. D. A. L.

Reactions of Essential Oils. By R. A. CRIPPS (*Chem. News*, **60**, 236).—In reference to the iodine absorption of essential oils, attention is called to the importance of time and temperature in these reactions; the latter has already been recognised by both R. H. Davies and H. W. Snow (preceding page), but disregarded by R. Williams (preceding abstract). The author now compares the results obtained by Barenthin, Davies, Snow, and Williams; there are discrepancies which are probably due to want of uniformity as regards the two factors mentioned above. H. W. Snow, in a letter (*Chem. News*, **60**, 245), points out that he found the iodine absorption extremely useful in connection with the examination of oil of peppermint for adulteration with oil of turpentine; he also gives references his own contributions and to the work of others on the subject.

D. A. L.

Tests for Fixed Oils. By F. X. MŒRK (*Pharm. J. Trans.* [3], **19**, 785).—A reaction proposed by Hirschsohn (Abstr., 1889, 658) for the detection of cotton-seed in other fixed oils was to mix 5 c.c. of the oil with 10 drops of a chloroform solution of gold chloride (1 gram in 200 c.c.), and to heat to 100°. The red coloration produced in from three to five minutes is found by the author not to be characteristic of cotton-seed oil, for he has obtained the like result with the oils of arachis, ben, poppy, sesame, walnut-kernel, &c. The paper contains extended lists of the gold chloride, and also of the silver nitrate reactions with these and many other kinds of fixed oils—pure, doubtful, and commercial. R. R.

Estimation of Neutral Fats. By M. GRÖGER (*Zeit. ang. Chem.*, 1889, 61—62).—In the saponification of a neutral fat by alcoholic potash, it does not suffice to boil for half an hour with a bare excess of the alkali, but it is necessary that the excess should not be less than a certain amount. For 5 grams of fat, the residual alkali ought to consume at least 5 c.c. of semi-normal acid, otherwise saponification is very liable to be incomplete. This may account for many of the recorded variations in the saponification equivalents of fats.

General and Physical Chemistry.

Phosphorescence of Copper, Bismuth, and Manganese in the Sulphides of the Alkaline Earth Metals. By V. Klatt and P. Lenard (*Ann. Phys. Chem.* [2], 38, 90—107).—The difference in the colour of the light emitted by the phosphorescent sulphides of metals of the alkaline earths when prepared by different methods, has hitherto been attributed to a difference in physical structure. The authors find, however, that the difference is really a chemical one, the above sulphides being, when pure, practically without phosphorescence, and only exhibiting this phenomenon when containing traces of the sulphides of copper, bismuth, manganese, or some fourth metal not yet identified, the colour of the phosphorescence varying with the nature and proportions of the active sulphides present. The presence or absence of any of the above metals can readily be ascertained, as each gives rise to a characteristic band in the spectrum of the phosphorescent material, the position of which is always the same. The intensity of the phosphorescence increases with the amount of active sulphide present, up to a certain point, but, when a maximum is reached, any further addition causes a decrease in the intensity, and ultimately destroys the phosphorescence. The quantities of active sulphide necessary to produce the above maximum are very small. In order to produce the brightest phosphorescence, a third substance should be present in addition to the above. This consists of some colourless salt which is fusible at the temperature required for the preparation of the phosphorescent sulphides. It will therefore form a thin layer on the surface of the sulphide, to which the active metal imparts a faint coloration, essential to the production of phosphorescence. H. C.

Refractive Indices of Gases. By T. P. Dale (*Phil. Mag.* [5], 28, 268—271).—The author has observed certain empirical relations between the specific refractive energies of gaseous elements and between the logarithms of these values. Thus the logarithms of the specific refractive energies of nitrogen, chlorine, and phosphorus are identical, as also are those of sulphur and oxygen. The logarithms of the first three are double, and those of sulphur and oxygen 1½ times that of hydrogen. The logarithm of the specific refractive energy of mercury is 8 times, and that of arsenic 9 times this quantity. Again, the specific refractive energy of oxygen is nearly double that of hydrogen, that of mercury 4 times, of arsenic 8 times, of sulphur 12 times that of hydrogen. Amongst compounds, the log. specific refractive energy of nitrous oxide is half that of carbonic oxide, whilst that of cyanogen is 6 times that of hydrogen. The author is engaged on the relations between the molecular weight and refraction of gases. H. K. T.

Refractive Indices of Salt Solutions. By B. WALTER (*Ann. Phys. Chem.* [2], 38, 107—118).—The author finds from his own observations and those of others that the refraction of salt solutions is subject to laws similar to those for the reduction of the freezing point. Thus the index of refraction of a salt solution is proportional to the amount of salt dissolved. Solutions containing equal numbers of molecules of salts of monad metals with monobasic acids have the same refractive index, other similar solutions of salts of monad metals with bibasic acids have a refractive index which is practically double the above, and those of salts of diad metals have a refractive index which is three times that of the first. These laws hold even for concentrated solutions, and there is nothing to indicate the formation of hydrates in any of the solutions examined. The behaviour of cupric chloride in solutions containing more than 11 per cent. of the salt is abnormal, as the refraction of such solutions is greater than it should be according to the above rules, and points to the existence of molecules of greater complexity in the more concentrated solutions. This is supported by the well-known difference in colour of the concentrated and dilute solutions. A similar change is exhibited by potassium ferricyanide solutions at a concentration of 4 per cent. Fluorescein solutions were also examined up to a concentration of 40 per cent., in order to ascertain if any other molecular change, than that already recorded (Abstr., 1889, 553) at 2 per cent., could be detected, but with negative result. H. C.

A Standard Clark Cell. By H. S. CARHART (*Phil. Mag.* [5], 28, 420—423).—The author finds that local action takes place in Clark cells owing to contact between the zinc and the mercurous sulphate, the temperature coefficient being thereby altered. He has constructed a cell in which contact is prevented. The new cell has a temperature coefficient less than that of Lord Rayleigh's cell; moreover its temperature coefficient decreases with rise of temperature. The polarisation is negligible for external resistances greater than 10,000 ohms. H. K. T.

Electromotive Forces of Cells containing Mixed Salt Solutions. By G. F. R. BLOCHMANN (*Ann. Phys. Chem.* [2], 37, 564—575).—The E.M.F. of the standard Clark cell, Hg | Hg_2SO_4 | $ZnSO_4$ | Zn, decreases with rise of temperature, whereas that of the Helmholtz cell, Hg | Hg_2Cl_2 | $ZnCl_2$ | Zn, increases. By mixing the chlorides and sulphates of the metals, the author hoped to obtain a cell that would remain unaffected by change of temperature, but a cell containing mixtures in the proportions calculated to effect this result was found to differ but slightly from the chloride cell in its behaviour with respect to temperature. The author was therefore led to further investigate the E.M.F. of cells containing mixed salt solutions. Copper and zinc were selected as electrodes, the copper being immersed in a solution of two copper salts contained in a porous pot, surrounded by a solution of two similar zinc salts in which the zinc electrode is placed. The salts used were the sulphates, chlorides, and nitrates of the metals, in solutions containing 1 mol. of salt to 50 mols. of water, and the acetates dissolved in the proportion 1 to 250. The results obtained with the various mixtures are tabulated and given in curve form. Cells containing the sulphates and chlorides, sulphates and acetates, and the chlorides and acetates give electromotive forces which practically correspond with the mean of those of cells containing the unmixed solutions, taken in the ratio in which the salts are mixed. The E.M.F. of the other cells containing the nitrates is usually below that thus calculated; but in the case of mixtures of nitrates and acetates containing a large excess of nitrate, the E.M.F. is greater than the theoretical. The exceptions in these latter cases are probably due to the fact that the salts have some chemical action one on another, which may in some way be connected with the partial dissociation which such salts undergo in aqueous solution. H. C.

Specific Inductive Capacity of Water. By E. COHN (*Ann. Phys. Chem.* [2], **38**, 42—52).—The author confirms the former result obtained by himself and Arons (Abstr., 1888, 394) for the sp. ind. cap. of water, in this case using the method originally employed for liquids of low conductivity (*Ann. Phys. Chem.* [2], **28**, 454).

H. C.

Variations in the Electrical Resistance of Nitrogen Peroxide with a Rise of Temperature. By J. J. BOGUSKI (*Compt. rend.*, **109**, 804—806).—Nitrogen peroxide has a very high resistance, but the conductivity becomes recognisable and measurable in presence of 0·01 to 0·1 per cent. of water. No absolute measurements were made, but the relative resistances at different temperatures were determined. Concordant results were obtained with different methods of measurement.

The resistance increases as the temperature rises, and above 70° the peroxide is an almost perfect insulator. Abrupt variations are observed between 0° and 17°. Although a rise of temperature is accompanied by a definite and static increase in resistance, this is preceded by a temporary dynamic reduction of resistance, which is greater the more suddenly the compound is heated. This temporary variation is so considerable that it can readily be recognised if a lamp, or the body of the observer, is moved towards the tube containing the peroxide, provided that the latter is at a lower temperature.

The phenomena are doubtless connected with the dissociation of the peroxide. Neither NO_2 nor N_2O_4 is decomposed by an electric current, and hence they are insulators when separate and when mixed. The dissociation produced by heat sets up atomic movements favourable to the conduction of electricity by convection, and hence the resistance diminishes. These atomic motions soon cease, because the atoms form new molecules. A new condition of equilibrium is established, and the resistance acquires its normal static value.

If the peroxide is cooled suddenly, the variation of the resistance is always in the same direction, and no oscillations are observed similar to those produced by heating. C. H. B.

Change in Freshly-prepared Solutions. By E. PFEIFFER (*Ann. Phys. Chem.* [2], **37**, 539—563).—The author has noticed in former experiments (Abstr., 1886, 115) that if a solution is allowed to remain for some length of time, the electrical conductivity often undergoes a temporary decrease, and that this continues until a minimum is reached, from which it again increases. The author now finds that this occurs with water which is left freely exposed in the ordinary way, but not with water which has been kept out of contact with the atmosphere or only exposed to purified air. The phenomenon is, therefore, in some manner due to the impurities of the atmosphere. The change becomes more pronounced if the solution is acidified slightly, and the more so the greater the amount of acid added, whereas basic substances produce just the opposite effect, and neutral salts are practically without action. As carbonic acid is among the acids which have the above effect, and ammonium carbonate is a much better conductor than free ammonia in aqueous solution, the change is in all probability not due to the ammonia in the atmosphere. It might, however, be due to organic impurities. H. C.

Electrical Conductivity as a Means of Investigating the Interaction of Acids of Complex Function. By D. BERTHELOT (*Compt. rend.*, **109**, 801—804).—The author has utilised determinations of electrical conductivity in order to determine the conditions of equilibrium between dilute saline solutions and aspartic acid, which combines the functions of a base and an acid. Solutions were employed containing a gram-equivalent of the acid or salt in 100 litres. With this degree of dilution, variations in molecular conductivity with variations in the concentration of the solution, are sufficiently small to be negligible.

The conductivity of a mixture of aspartic acid and sodium chloride indicates decomposition to the extent of 4 per cent., and precisely the same final system is obtained by mixing sodium aspartate with hydrochloric acid, the decomposition in this case amounting to 96 per cent. In the first case, the addition of a second or third molecule of aspartic acid or sodium chloride has no appreciable effect. In the second case, if two molecular proportions of sodium aspartate are mixed with one molecular proportion of hydrochloric acid, the observed conductivity is lower than that calculated on the assumption of complete decomposition, a result due to interaction between sodium aspartate and aspartic acid, and, in a much lower degree, between sodium aspartate and sodium chloride. A third molecular proportion of sodium aspartate exerts a slight but distinct additional influence in the same direction. C. H. B.

Electrical Conductivities and Multiple Affinities of Aspartic Acid. By D. BERTHELOT (*Compt. rend.*, **109**, 864—867).—In this paper the author investigates the basic functions of aspartic acid, the methods of measurement being identical with those used in the investigation of its acid functions (preceding abstract). The addition of an equivalent proportion of hydrochloric acid to aspartic acid produces a very marked diminution in the electrical resistance; this indicates a reduction in the number of molecules, owing to combination between the two acids. A second equivalent of hydrochloric acid produces about one-fifth of the reduction produced by the first. A second equivalent of aspartic acid produces half the reduction of the first, and a third equivalent produces one-fourth of the original reduction.

The addition of aspartic acid to sodium aspartate increases the resistance, owing to the formation of a double salt, but the effect of successive quantities of aspartic acid gradually diminishes.

· The addition of an equivalent of sodium hydroxide to sodium aspartate is accompanied by a very considerable increase in resistance; a second equivalent of alkali produces an effect only one-third as great, and this is true also of a third equivalent. A second equivalent of aspartate has a comparatively small effect, and a third or fourth equivalent has still less.

Sodium chloride and sodium aspartate, in equivalent proportions, form a small quantity of a double salt, but a further quantity of either salt has but little influence on the result. C. H. B.

Correction of Thermometric Readings for the Column Outside the Heating Medium. By E. Rimbach (*Ber.*, **22**, 3072—3075).—The author has made a large number of observations with various thermometers of Jena glass, in order to determine the correction which must be made in the observed reading when only part of the mercurial column is surrounded by the heating vapour. The very numerous observations, which are given in tabular form, show that Kopp's (*Annalen*, **94**), Holtzmann's (*Handwörterbuch der Chemie*, **7**, 368), and Thorpe's (Trans., 1880, 160) corrections give results which are too low with long threads, and too high with short ones; the error in the case of long threads may be more than one degree when Holtzmann's or Thorpe's correction is employed.

Mousson's constant (*Ann. Phys. Chem.*, **133**, 311) has not a constant value in the case of high-registering thermometers, and the error in determining this constant, as recommended by Mousson, may amount to 0·7 degree. Wüllner's value for $\sqrt{h/\kappa}$ is also variable.

F. S. K.

Experimental Determination of the Ratio of the Specific Heats in Superheated Steam. By R. Cohen (*Ann. Phys. Chem.* [2], **37**, 628—633).—From the velocity of sound in superheated steam, the ratio of the specific heats k was determined by a method similar to that used by Strecker in the case of chlorine, bromine, and iodine. The mean value for k thus found was 1·287, the temperature varying from 144° to 300°; between these temperatures no change in the constancy of k being observed. From the equation of Clausius for the relation between volume, pressure, and temperature in any vapour, the values of k for other temperatures can be calculated, and such a calculation gives a value of 1·333 at 95°, agreeing with that found by Jaeger (Abstr., 1889, 460) and other observers. The author does not, however, place reliance in such a calculation, as the

Clausius equation is no longer truly applicable to superheated vapours.
H. C.

Animal Heat and the Heat of Formation and Combustion of Urea. By BERTHELOT and P. PETIT (*Compt. rend*, **109**, 759—764).—The combustion of urea was readily effected in the calorimetric bomb, the heat of combustion for 1 gram being 2530·1 Cals, or $CO(NH_2)_2 + O_3 = CO_2$ gas $+ N_2$ gas $+ 2H_2O$ liquid, develops +151·8 Cals. at constant volume, or +151·5 Cals. at constant pressure. The formation of solid urea from carbon (diamond) and its gaseous constituents liberates +80 8 Cals. The heat of dissolution at about 11° is —3 58 Cals., and hence the heat of formation in solution in water (or urine) is +77·2 Cals., and its heat of combustion +160·9 Cals.

The formation of solid urea and liquid water from carbonic anhydride and ammonia would liberate +31·1 Cals., and the formation of the dissolved compound from dissolved carbonic anhydride and dissolved ammonia, would liberate +4·3 Cals. The formation of urea from ammonium carbonate (both in solution) would absorb —6·4 to —8·0 Cals., and hence this change does not take place directly, but the reverse change liberates +6·4 to +8 0 Cals., and hence readily occurs under favourable conditions. The conversion of ammonium cyanate into urea liberates about +7·1 Cals. The complete combustion of urea liberates 11·8 Cals. less than the combustion of its constituents, if they were in the free state, but this complete oxidation only takes place under exceptional conditions. It seems, in fact, that nitrogen in the form of amido-compounds oxidises with much greater difficulty than carbon and hydrogen, is capable of being converted into ammonia, and when introduced into the organism in the form of food, is excreted again with a very small loss of its energy.
C. H. B.

Specific Gravity Apparatus. By BAILHACHE and COMMELIN (*Bull. Soc. Chim.* [3], 2, 196—198).—This apparatus is intended for the determination of the volume of vegetable products, such as fruits, roots, &c. By means of an iron plunger, the substance is kept immersed under the surface of mercury, contained in a vessel communicating by a U-tube with a cylinder containing the same metal above the surface of which is placed coloured alcohol; any displacement of mercury in the former vessel causes the alcohol to enter an upright narrow, calibrated tube, and thus the volume of the mercury displaced, and consequently that of the substance, is determinable.
T. G. N.

Dissociation of Salts containing Water, and the Constitution of the Combined Water. By W. MÜLLER-ERZBACH (*Ber.*, **22**, 3181—3182).—The author gives a list of salts containing water of crystallisation; those molecules of water which show a greater tension being placed in the table to the right and separated by a + sign.

$Na_2HPO_4 + 2H_2O + 5H_2O + 5H_2O$,
$Na_2CO_3 + H_2O + 9H_2O$,
$Na_2B_4O_7 + 5H_2O + 5H_2O$,
$Na_2SO_4 + 10H_2O$,
$MgSO_4 + H_2O + 5H_2O + H_2O$,
$NiSO_4 + H_2O + 5H_2O + H_2O$,
$CoSO_4 + H_2O + 5H_2O + H_2O$,
$FeSO_4 + H_2O + 3H_2O + 3H_2O$,
$ZnSO_4 + H_2O + H_2O + 5H_2O$,
$CuSO_4 + H_2O + H_2O + H_2O + 2H_2O$,
$MnSO_4 + H_2O + H_2O + 3H_2O$,
$CaCl_2 + H_2O + H_2O + 2H_2O + 2H_2O$,
$MgCl_2 + 4H_2O + 2H_2O$,*
$CoCl_2 + 2H_2O + 4H_2O$,
$NaBr + 4H_2O$,
$MnCl_2 + H_2O + H_2O$,
$BaCl_2 + H_2O + H_2O$,
$NaS_2O_3 + 2H_2O + 3H_2O$,
$PbC_4H_6O_4 + 3H_2O$,
$NaC_2H_3O_2 + 3H_2O$,
$CaN_2O_6 + 2H_2O + H_2O$ (?),
$CaN_2O_6 + 4H_2O$,
$CaN_2O_6 + 2H_2O + H_2O$,
$ZnN_2O_6 + 3H_2O + H_2O + H_2O$,
$AlK(SO_4)_2 + 3H_2O + 9H_2O$,
$Al(NH_4)(SO_4)_2 + 3H_2O + 9H_2O$,
$AlNa(SO_4)_2 + 6H_2O + 6H_2O$,
$CrK(SO_4)_2 + 6H_2O + 6H_2O$,
$BaH_2O_2 + H_2O + H_2O + 5H_2O + H_2O$,
$SrH_2O_2 + H_2O + 6H_2O + H_2O$.

* Only decomposed to $MgCl_2 + 4H_2O$.

In the case of copper sulphate, the second and third molecules of water cannot be separated in this way at temperatures above 40°.

F. S. K.

Osmosis with Living and Dead Membranes. By E. W. Reid (*Brit. Med. J.*, 1890, i, 165—167).—See this vol., p. 277.

Specific Volume of Aqueous Vapour. By C. Dieterici (*Ann. Phys. Chem.* [2], 38, 1—26).—This paper deals with the determination of the specific volume of water vapour saturated at 0°. The author has previously determined the heat of vaporisation of water at 0°, which is 596·8 cal. per gram, and now employs this quantity to determine the weight of water converted into vapour at 0°, and occupying a certain known volume. With the ice calorimeter, as small a quantity of heat as 0·03 cal. is still measurable, and therefore, although at 0° a volume of 5 litres would only contain 25 milligrams of saturated water vapour, this weight can be determined by the above method to within 0·2 per cent., the error of a direct weighing being about 4 per cent. The only other serious source of error is in the condensation which takes place on the surface of the glass, which is particularly marked if the vessel which is to contain the vapour is exhausted as far as possible. This error is very materially reduced by selecting a glass of as insoluble a variety as possible, boiling well with water to remove alkali, and allowing a small quantity of air to remain in the exhausted vessel.

The results show that water vapour saturated at 0° obeys Gay-Lussac's law for perfect gases down to the saturation point. The density of the vapour is 0·0048856 milligram / c.c., and therefore the specific volume at 0 °is 204·68 c.c. / milligram. Since water vapour saturated at 0° behaves like a perfect gas, the density corresponds with that which might be deduced from Avogadro's law. The pressure which it exercises may, therefore, be calculated, and is found to be 4·619 mm. The above numbers are correct to within 0·5 per cent.

H. C.

Molecular Constitution of Isomeric Solutions. By G. Gore (*Phil. Mag.* [5], 28, 289—303; compare Abstr., 1889, 90, 200, 201, 665, and 810).—The author examines by means of the voltaic balance the

distribution of base when equivalent quantities of sulphuric and nitric acids and sodium hydroxide are brought together. According to the researches of J. Thomsen, the final result is the same whether sodium sulphate is added to nitric acid or sodium nitrate to sulphuric acid, or sodium hydroxide to mixed nitric and sulphuric acids. The author has examined the voltaic energies of two mixtures, one A, consisting of $Na_2SO_4 + 2HNO_3$, the other B, consisting of $2NaNO_3 + H_2SO_4$. The general results of the investigation are that the solution B proceeds at once to the final distribution of soda between the acids ($\frac{2}{3}$rds of the soda to the nitric acid and $\frac{1}{3}$rd to the sulphuric acid), whilst the solution A, if very dilute or mixed at a low temperature, shows a voltaic energy approaching that of its separate constituents, and that it is only after a very considerable lapse of time or after a short ebullition that it approximates to the value found for B. Further, it has been found that a number of molecular compounds of the acids and salts with one another are formed when A is first prepared. Hence the order of mixing has a considerable influence on the voltaic energy of the freshly prepared solution. In the solution B, the evolved nitric acid probably unites with an equivalent quantity of the free sulphuric acid. Loss of voltaic energy does not necessarily involve loss of thermal energy, since the solution A absorbs heat when mixed, whilst B develops heat (Thomsen), both changes being accompanied by loss of voltaic energy.
H. K. T.

Inorganic Chemistry.

Density of Fluorine. By H. MOISSAN (*Compt. rend.*, **109**, 861—864).—Fluorine was obtained by electrolysis, as before, but a larger apparatus was used, and in order to purify the gas completely from hydrogen fluoride, it was passed through a platinum worm cooled to −50° by means of methyl chloride, and then through a platinum tube containing anhydrous sodium fluoride, which combines with hydrogen fluoride with great energy. The sodium salt is far preferable to the potassium salt, because it is not hygroscopic.

The pure fluorine was collected in platinum flasks of about 100 c.c. capacity, which had been previously filled with nitrogen. After being weighed, the fluorine was brought in contact with water, and the evolved gases were measured and analysed, a correction being made for any nitrogen which had not been displaced.

The mean sp. gr. found was 1·265, whilst the value calculated from F = 19 is 1·316.
C. H. B.

Autoxidation. By M. TRAUBE (*Ber.*, **22**, 3057—3062; compare Abstr., 1889, 937).—A reply to Hoppe-Seyler (Abstr., 1889, 1106). The author is satisfied that he has proved that nascent hydrogen in presence of oxygen molecules has not a powerful oxidising action, as stated by Hoppe-Seyler, and also that the oxidising action of palladium hydride cannot be attributed to nascent hydrogen. He criticises Hoppe-Seyler's remarks very severely, and concludes by expressing the hope that his part in the discussion on autoxidation with Hoppe-Seyler may be ended. F. S. K.

Hydrogen Arsenide and Antimonide. By O. BRUNN (*Ber.*, **22**, 3202—3207).—Hydrogen arsenide and hydrogen sulphide do not act on one another in absence of air at the ordinary temperature, either in the gaseous condition or in aqueous solution, even on exposure to direct sunlight. The admission of air quickly causes in both cases a precipitate of arsenious sulphide. It has been previously observed that hydrogen arsenide is itself acted on by air or oxygen, with formation of a black powder. An examination of this product has shown that its composition varies with the amount of air present, the gas being first oxidised to solid hydrogen arsenide, and then, if there be sufficient oxygen, to metallic arsenic. The above-mentioned formation of arsenious sulphide is, therefore, probably preceded by the formation of arsenic.

If the mixture of hydrogen arsenide and sulphide is heated, separation of arsenious sulphide commences at about 230°. Separate experiments with hydrogen arsenide show that the latter commences to dissociate at 230°, and that in this case also the formation of arsenious sulphide is a secondary reaction.

Hydrogen antimonide is at once decomposed by hydrogen sulphide, even in absence of air and light. On heating the former gas alone, dissociation commences at about 150°. The author proposes to make use of this fact for the detection of traces of antimony occurring together with arsenic, in other gases, such as hydrogen. For this purpose the gases are passed through a tube 0·8—1·0 metre in length, and heated by a liquid boiling at 208—210°. No arsenic whatever is deposited, and the antimony mirror may be further examined by the usual methods. H. G. C.

Combination of Sodium and Potassium with Ammonia. By A. JOANNIS (*Compt. rend.*, **109**, 900—902).—When one equivalent of the alkali metal is brought in contact with 20 equivalents of liquid ammonia, and the ammonia gas is afterwards removed, its pressure rapidly diminishes. At a certain point, the pressure becomes constant; in the case of sodium the pressure was 1700 mm. at 0°, and the composition of the mixture $Na + 5·3NH_3$. The exact composition varies with the temperature, notwithstanding the constancy of the pressure, and hence the product in the tube is not a definite compound. When a further quantity of the gas is removed, a solid substance with an intense copper-red colour is left, and the constant pressure observed may be regarded as the vapour pressure of liquid ammonia saturated with this solid. When only one molecule of ammonia is present for each atom of metal, no trace of liquid remains, and if still more ammonia is removed, the free sodium or potassium alone remains, and as this decomposition takes place at a constant pressure, it may be regarded as true dissociation. Careful experiments gave 0·99 equivalent as the inferior limit, and 1·1 equivalent as the superior limit of the quantity of ammonia combined with one atom of the alkali metal, and it may therefore be taken that the solid residue, which the author calls *potassammonium* or *sodammonium*, has the composition NH_3K or NH_3Na. C. H. B.

Thiosulphates. By A. Fock and K. Klüss (*Ber.*, **22**, 3096—3101). —Potassium thiosulphate, $3K_2S_2O_3 + H_2O$, separates in colourless, prismatic crystals when an aqueous solution of the salt is evaporated over sulphuric acid, and when the mother liquors are kept over sulphuric acid for some time longer the salt separates in large, rhombic crystals, with 5 mols. H_2O; these results agree with those previously obtained by Rammelsberg, Kessler, and Döpping.

Lithium thiosulphate, $Li_2S_2O_3 + 3H_2O$, crystallises in large, colourless, very deliquescent needles, and is soluble in alcohol; when heated, it is decomposed into lithium sulphate and lithium sulphide.

Ammonium thiosulphate, $(NH_4)_2S_2O_3$, separates in anhydrous, colourless plates when an aqueous solution of the salt is evaporated over sulphuric acid; Rammelsberg found that the salt crystallised with 1 mol. H_2O. F. S. K.

Allotropic Forms of Silver. By M. C. Lea (*Amer. J. Sci.* [3], **37**, 476—491; and **38**, 47—50, and 129).—The author considers that his own researches have established the existence of silver subchloride, although the experiments of Newbury, Muthmann, v. Pfordten, and others, have shown that there is at present no evidence of the existence of a silver sub-oxide, Ag_4O. He points out that the fact that a substance will not pass through a dialyser merely proves that it is colloïdal and not that it is not in solution. Further, many substances which undoubtedly form true solutions are carried down by gum when the latter is added to the liquid and then precipitated by addition of alcohol. The products described in these papers differ from those obtained by v. Pfordten in that they readily amalgamate with mercury and evolve no gas when treated with dilute sulphuric acid.

Silver can exist in three allotropic forms, or more probably in three modifications of the same form, the differences between the three being less than their differences from normal silver. They differ in colour and other physical properties, and in chemical activity; they probably represent an active condition of silver of which the ordinary metal is a polymeride. The three modifications are as follows:—

A. *Soluble allotropic silver*, which forms a deep-red solution, is matt black, blue, or green, when solid and moist, and brilliant metallic bluish-green when dry.

B. *Insoluble allotropic silver*, derived from the preceding modification, dark reddish-brown when moist, and brilliant metallic bluish-green, like A, when dry.

C. *Gold-like allotropic silver*, dark-bronze coloured when moist, but like burnished gold when dry. No soluble modification of this form seems to exist, but a copper-coloured variety is produced under certain conditions.

All three modifications have certain properties in common. When dry they are very friable and are readily reduced to an impalpable powder, differing markedly in this respect from normal silver. Their most striking property, however, is their power of drying with their particles in optical contact, and if spread while moist on paper or glass, they form mirrors of great perfection and beauty when dry. If these films are treated with solutions of the haloids, ferric chloride, or, best of all, sodium hypochlorite, very beautiful interference colours are obtained. The phenomena are quite different from those obtained with normal silver leaf under the same conditions. Very dilute mineral acids and moderately dilute acetic acid immediately convert allotropic silver into grey normal silver without the evolution of any trace of gas.

A. *Soluble allotropic silver* is obtained by the action of concentrated solutions of ferrous citrate or a mixture of ferrous sulphate and sodium citrate on a concentrated solution of a silver salt. If the solutions are not very concentrated, a deep-red liquid is formed which may remain transparent for some time or may gradually deposit a black precipitate. Concentrated solutions should be used, the following proportions being found to give the best results. A mixture of 200 c.c. of a 30 per cent. solution of ferrous sulphate and 280 c.c. of a 40 per cent. solution of sodium citrate was added at once to 200 c.c. of a 10 per cent. solution of silver nitrate. The liquid, which immediately becomes black, is vigorously agitated for several minutes, allowed to remain for 10 to 15 minutes, and the liquid then decanted. A large quantity of a lilac-coloured precipitate remains, but alters slowly even in contact with the mother liquor, and when it is drained the colour changes almost immediately to deep blue. It may be washed with a solution of sodium or ammonium citrate, sulphate, or nitrate, preferably ammonium nitrate, because, although completely soluble in pure water, it is quite insoluble in presence of 5 to 10 per cent. of these salts. A good plan is to add sufficient water to dissolve nearly the whole of the precipitate and then sufficient ammonium nitrate to reprecitate it. The substance gradually changes whilst being washed and becomes less and less soluble. After washing seven or eight times in the manner described, it was washed with alcohol of 95 per cent. to remove ammonium nitrate and then analysed: it contained 97·27 per cent. of silver and the filtrate from the silver chloride precipitate contained only ferric citrate. It retains water even after prolonged exposure in a dry vacuum, but becomes anhydrous at 100°; at low redness it gives off small quantities of carbonic anhydride, but no trace of either hydrogen or oxygen. These determinations were made after the substance had become insoluble, and hence it seemed possible that while in solution it might be combined with citric acid. Determinations of the silver and citric acid in a solution of the purified substance (which was proved by optical examination to form a true solution) gave the ratio of silver to citric acid in one case as 55·63 : 1 and in another 193·7 : 1, results which show that the proportion of citric acid is variable and is always very small. Some of the purified precipitate was dried at 100°, mixed with water, and again evaporated to dryness; all the silver separated as grey normal silver and the liquid was quite neutral. If a perfectly neutral iron solution is used in the preparation of the substance, the liquid after reduction is either neutral or very faintly acid. If a solution of the purified lilac precipitate is mixed with a neutral solution of magnesium sulphate, the insoluble form, which consists of almost pure silver, is thrown down, but the liquid remains quite neutral. Possibly the silver is in combination with some neutral substance derived from citric acid, but if so, it must be some entirely new compound. Ballo has observed that the action of ferrous salts on tartaric acid produces a neutral substance of the same composition as arabin, $C_6H_{10}O_5$. The change which the lilac precipitate undergoes during purification and washing is indicated by changes of colour, and the constitution of the lilac precipitate whilst under the mother liquor is still doubtful. If the precipitate is spread on paper, it is blood red while moist, blue with metallic lustre when half dry, and matt blue when quite dry. If dried in lumps, the colour and lustre vary considerably.

B. *Insoluble allotropic silver* is obtained from the preceding form by spontaneous change or by the action of certain salts. Alkaline sulphates, nitrates, and citrates precipitate soluble allotropic silver from its solutions, but it still remains soluble. Magnesium, copper, iron, and nickel sulphates, potassium dichromate, potassium ferrocyanide, barium nitrate, and silver nitrate all precipitate it in an insoluble form. The soluble precipitate is blue or bluish-black; the insoluble form is brown and continually darkens while being washed. Ammonia dissolves the insoluble modification; sodium borate and alkaline sulphates reconvert it into a soluble form, different however from the original. With a dilute solution of sodium borate, a brown solution is obtained; with sodium or potassium sulphate, a yellow-red solution; with ammonium sulphate, a red solution. If concentrated solutions of these salts are used, the change into the soluble form takes place, but the substance does not dissolve until the salt has been washed away by pure water. Sodium nitrite added to a solution of the soluble form partially converts it into normal silver and renders it quite insoluble even in ammonia. In one case the insoluble variety became spontaneously soluble and formed a rose-red solution. In another case it separated very slowly and spontaneously from a solution in the form of short, black needles and thin prisms, which lost their crystalline form in contact with pure water but did not dissolve; it dried with a green, metallic lustre. It seems that pure water tends to produce a colloïdal form, whether soluble or insoluble, whilst salts tend to produce a crystalline form.

Analysis showed that the insoluble allotropic silver contained 97·96 per cent. of the metal, the remainder being ferric citrate. It retains water in a vacuum but becomes anhydrous at 100°.

When spread in the moist state over paper, it forms a green film with a brilliant metallic lustre. The green is a mixture of blue and yellow, one or the other predominating according to the direction of the illumination. The yellow is polarised in the plane of incidence, and the blue in a direction normal to that plane. All the products were more or less yellow, but the proportion of blue light varied considerably and is less the more prolonged the washing of the precipitate. If some of the substance is precipitated by means of magnesium or aluminium sulphate and is spread on paper without washing, the dry film has the appearance of a highly lustrous, bright-blue metal. When the moist substance is spread on glass, it forms very perfect mirrors when dry.

C. *Gold-like allotropic silver* is obtained by the reduction of silver tartrate by ferrous tartrate in dilute solutions, but the permanency of the product depends on the details of the preparation and is greater the more completely air and light are excluded from the dry substance. The following method gives a permanent product:—a mixture of 107 c.c. of a 30 per cent. solution of ferrous sulphate, 200 c.c. of a 20 per cent. solution of sodium-potassium tartrate, and 800 c.c. of water is added gradually, and with constant stirring, to a mixture of 200 c c. of a 10 per cent. solution of silver nitrate, 200 c.c. of the solution of the alkaline tartrate, and 800 c.c. of water. The precipitate is at first red, but changes to black, and when washed on the filter becomes bronze-coloured. If dried in lumps or in films on paper or glass, it has the colour and lustre of burnished gold. On glass it forms very perfect mirrors. It is very permanent when dry, but more liable to change while moist, and forms a copper-coloured variety, which however is still bright and permanent. While washing, it is important to keep the filter full of water. This modification contains 97·8 to 98·75 per cent. of silver, the remainder being ferric tartrate.

The specific gravities of B and C were determined after they had been left under water in a vacuum for a long time; sp. gr. of insoluble allotropic silver = 9 58; sp. gr. of gold-like allotropic silver = 8·51. The sp. gr. of normal silver is 10·5, and that of finely divided precipitated silver 10·62.

At 100°, a bluish-green film of B acquired a superficial bright-yellow colour, and a film of C under the same conditions became superficially blue, but these changes were confined to the surfaces.

All three modifications are affected by light; A and B become brown after some hours, and the coppery modification of C becomes bright-yellow. A very bright bluish-green modification of B obtained by rapid and short washing acquired the colour of gold after one day's exposure to sunlight; samples which have been well washed yield a matt film on paper and become brown when exposed to light.

The gold-like modification acquires a somewhat purer yellow colour when exposed to light in absence of moisture, but in presence of moisture 3 or 4 days exposure to sunlight changes it into white normal silver of great beauty. Moisture alone tends to darken its colour. It is interesting to note that organic compounds of silver always yield grey or black, lustreless products when exposed to light.

The modifications A and B are obtained by the reduction of silver citrate by ferrous citrate, and C by the reduction of silver tartrate by ferrous tartrate. No similar results are obtained by the action of ferrous oxalate on silver oxalate. C. H. B.

Action of Light on Silver Chloride. By R. HITCHCOCK (*Amer. Chem. J.*, 11, 474—480).—Finely divided precipitated silver chloride was allowed to settle on microscopic cover glasses, carefully washed, and dried in a desiccator. In this way the thin glass slips are obtained covered with a very thin, semi-transparent layer of silver chloride. They were then weighed, placed in a tube through which a current of pure hydrogen was passing, and exposed to sunlight, the chlorine which was liberated being absorbed in silver nitrate solution and afterwards weighed. The glass slips with the silver chloride were weighed after the experiment. The loss of weight varied from 0·042 to 0·049 gram per gram of silver chloride; the chlorine absorbed by the silver nitrate was very slightly smaller in quantity than the loss in weight of the silver chloride. In one case the product gave up a considerable proportion of silver when heated with dilute nitric acid, and hence it would seem that decomposition had gone so far that the protective action of the unaltered silver chloride had to a great extent been eliminated. C. H. B.

Zinc Hydrosulphide. By V. v. ZOTTA (*Monatsh.*, **10**, 807—812). —The author finds, contrary to the statement of Thomsen (Abstr., 1879, 206), that when equivalent quantities of zinc sulphate and an alkaline hydrosulphide are mixed, the precipitate obtained has not the formula $Zn(SH)_2$, but must be regarded as having the composition $Zn_3H_2S_4, = Zn(SH)_2,2ZnS$. The production of this compound explains the evolution of hydrogen sulphide which takes place on adding an alkaline hydrosulphide to zinc sulphate; for the compound $Zn_3H_2S_4$ may be regarded as being formed from 3 mols. of the hydrosulphide by loss of 2 mols. of hydrogen sulphide. Thomsen further says (*loc. cit.*) that if zinc sulphate is treated with two equivalents of sodium hydrosulphide, no precipitate is produced, but the resulting solution is slightly opalescent; and concludes that sodium hydrosulphide behaves towards zinc sulphate in precisely the same way as sodium hydroxide. The author in repeating this experiment finds that about 20 per cent. of the sulphur present is evolved as hydrogen sulphide, but that long continued boiling does not cause the formation of a precipitate. If, however, a mixture of zinc sulphate with four times its equivalent of sodium hydrosulphide is made, the slightly opalescent solution obtained is rendered turbid on boiling for a few minutes, or on treatment with acids, alkalis, or certain salts, and the precipitate is identical with the sulphide $Zn_3H_2S_4$, mentioned above. G. T. M.

Crystalline Anhydrous Zinc Phosphate and Zinc Arsenate. By A. DE SCHULTEN (*Bull. Soc. Chim.* [3], **2**, 300—302).—Zinc chlorophosphate did not separate from the solution of normal tetrahydrated zinc phosphate in fused zinc chloride, but rhombic prisms of anhydrous zinc phosphate were obtained from the melt; these have a sp. gr. of 3·998 at 15°, and melt at a red heat. The same substance is produced by heating the hydrated salt with a concentrated solution of zinc chloride in sealed tubes at 250°.

On evaporating to dryness arsenic acid solution containing excess of zinc chloride, and subsequently fusing the product, prismatic crystals of anhydrous zinc arsenate were obtained having a sp. gr. of 4·913 at 15°.

Hence, zinc differs from magnesium and cadmium in not forming chlorophosphates and chlorarsenates (compare Abstr., 1890, 11).

T. G. N.

Egyptian Blue. By O. MÜHLHÄUSER (*Dingl. polyt. J.*, **272**, 144). —This blue pigment was used by the Romans in the first few centuries of the Christian era. It is said to have been discovered by Vitruvius in Alexandria, who prepared it by intimately mixing finely divided sand with sodium carbonate, adding copper filings to the mixture, moistening with water, moulding into balls, drying, and heating in clay pots until the blue colour was produced.

Fouqué has recently examined this colouring matter, and finds that its composition is that of a double silicate of calcium and copper, $CaO,CuO,4SiO_2$. It has a sp. gr. of 3·04, and crystallises in laminæ belonging to the dimetric system. The crystals exhibit dichroism, showing a pale-red colour when viewed by reflected light, and a blue colour when the light is transmitted. The blue substance resists the action of most chemical agents, and this fact explains the perfect state of its preservation in the wall paintings executed about 1900 years ago. According to Fouqué, its preparation may be effected at a bright red heat from materials devoid even of traces of alkali. At a higher temperature the blue is decomposed into cuprous oxide, wollastonite and a light-green, vitreous mass; the higher the temperature, the more of the latter is formed, until eventually wollastonite disappears entirely. The same author finds the method described by Vitruvius applicable, but prefers the use of potassium sulphate as flux.

The brightness and fastness of this pigment, the fact that it resists atmospheric influences and is not affected by most chemical agents, as well as the facility and cheapness of production, render it desirable that its manufacture should be again taken up. D. B.

Nature of Steel. By KOSMANN (*Dingl. polyt. J.*, **270**, 190—192). The author reviews the theories of Rinman, Osmond and Werth, Müller, Ledebur, and Baedeker, respecting the state in which carbon exists in steel. He does not agree with the assumption that carbon exists evenly alloyed with iron only in hardened steel, whilst in slowly-cooled steel it is dissolved by the iron in the form of the compound Fe_3C, but considers that in rapidly-cooled steel the carbon is also chemically combined with the iron. D. B.

Synthesis of Double Sulphides of the Alkali Metals and the Heavy Metals. By H. BRUNNER (*Chem. Centr.*, 1889, ii, 554—555; from *Arch. sci. phys. nat. Genève*, **22**, 68—69).—The author has succeeded in preparing the double sulphides of sodium and the metals of the iron-group by heating the oxalate of the heavy metal with sodium thiosulphate. *Sodium iron sulphide* crystallises in beautiful, bronze-red prisms; *chromium sodium sulphide* is a reddish-brown mass; whilst *manganese sodium*, *cobalt sodium*, and *nickel sodium sulphides* form lustrous, yellow, crystalline masses, readily oxidised on exposure to the air. These double sulphides are also formed when the alkaline carbonates are calcined with sulphur and the oxalate of the heavy metal. The chromium sodium sulphide is also obtained by heating the double oxalate with sulphur. J. W. L.

Nickeloxydiamine Nitrite. By L. SORET and F. ROBINEAU (*Bull. Soc. Chim.* [3], **2**, 138).—To prepare this salt, ammonia solution of sp. gr. 0·924 (3 kilos.) and sodium nitrite (1 kilo.) are added to nickel sulphate (1 kilo.) dissolved in boiling distilled water (1 litre); the mixture is placed aside for 4—5 days, and the resulting crop of crystals, after washing, is recrystallised from a hot ammoniacal solution. Although the nickel salt used contained 3 per cent. of cobalt, the crystals of nickeloxydiamine nitrite produced were absolutely pure. T. G. N.

Double Fluorides of Antimony. By G. STEIN (*Chem. Zeit.*, **13**, 357).—By evaporating solutions of antimonious fluoride with lithium chloride or fluoride, the respective double salts $SbF_3,LiCl$ or SbF_3,LiF are obtained; they crystallise in hexagonal tables; both are readily soluble in water without decomposition, the former being the more soluble; the solutions have a slightly acid reaction. Ammonia precipitates flocculent, gelatinous antimonious oxide from those solutions; whereas the known double fluorides of antimony yield heavy precipitates.

In mordanting experiments with tannin-aniline colours, 100 grams of potassium antimony tartrate, or 60 grams of lithium antimony fluoride, or 65 grams of lithium antimony chloride were employed, and the results obtained as regards the purity and beauty of colour were of equal value.

Antimony fluoride does not form any useful double salts with potassium, sodium, or ammonium thiocyanate; in fact, the thiocyanate decomposes, and especially with ammonium thiocyanate the solution of the double salt, when strongly evaporated, gives a precipitate of antimony sulphide. D. A. L.

Antimonates. By F. EBEL (*Ber*, **22**, 3044—3045).—The author has prepared the following compounds by adding excess of a concentrated solution of the metallic salt to a boiling aqueous solution of sodium antimonate ($NaH_4Sb_2O_7 + 7H_2O$):—Barium antimonate, $BaSb_2O_6 + 5H_2O$; Beryllium antimonate, $BeSb_2O_6 + 6H_2O$; silver antimonate, $Ag_2Sb_2O_6 + 3H_2O$; copper antimonate, $CuSb_2O_6 + 5H_2O$; cadmium antimonate, $CdSb_2O_6 + 6H_2O$; lead antimonate, $PbSb_2O_6 + 5H_2O$; zinc antimonate, $ZnSb_2O_6 + 5H_2O$; manganese antimonate, $MnSb_2O_6 + 5H_2O$; amorphous cobalt antimonate, $CoSb_2O_6 + 6H_2O$; the crystalline salt, $CoSb_2O_6 + 12H_2O$; amorphous nickel antimonate, $NiSb_2O_6 + 6H_2O$; the crystalline salt, $NiSb_2O_6 + 12H_2O$; the ferric salt, $Fe_2O_3,Sb_2O_5 + 7H_2O$; and the aluminium salt, $Al_2O_3,Sb_2O_5 + 9H_2O$. F. S. K.

Behaviour of Bismuth with Sulphur and Selenium. By P. A. v. SCHERPENBERG (*Chem. Centr.*, 1889, ii, 643—644; from *Mitt. pharm. Inst. Erlangen*, 2 Heft, 1—12).—The author has not succeeded in preparing a higher sulphide of bismuth than the trisulphide, although an oxysulphide, Bi_2O_3S, is formed when bismuth pentoxide, suspended in boiling benzene, is treated with dry hydrogen sulphide.

Attempts to prepare double sulphides, similar to those described by Schneider (*Ann. Phys. Chem.*, **91**, 404), but with a larger proportion of sulphur, by heating the pentoxide with concentrated potassium hydrosulphide solution in a sealed tube, only resulted in the formation of the lower oxide. If, however, the pentoxide is fused with potassium polysulphide, the compound $Bi\,S_3.K_2S$ remains as a crystalline mass.

With selenium, the double salt Bi_2Se_3,K_2Se may be prepared in like manner.

J. W. L.

Platinum Tetrafluoride. By H. Moissan (*Compt. rend.*, **109**, 807—809).—Fluorine, free from hydrogen fluoride, does not attack platinum below 100°, and combination does not take place readily below 500—600°. In presence of hydrogen fluoride, the reaction takes place far more easily, even in the case of liquid hydrogen fluoride saturated with fluorine. Platinum tetrafluoride is obtained by heating a bundle of platinum wire to dull redness in a thick platinum tube or a fluor-spar tube through which a current of fluorine is passed. As soon as combination is complete, the product is transferred to a perfectly dry tube. It forms a deep-red, fused mass or chamois-yellow crystals resembling anhydrous platinum tetrachloride, is extremely hygroscopic, and cannot be kept for a long time even in a well-corked and carefully-dried tube. When thrown into a small quantity of water, a tawny coloration is first produced, then heat is rapidly developed, and decomposition takes place with formation of hydrogen fluoride and hydrated platinum dioxide. Very dilute solutions are more stable, but the same change takes place immediately if the liquid is heated. This reaction explains Fremy's failure to obtain platinum tetrafluoride by the action of hydrofluoric acid on hydrated platinum dioxide.

When platinum fluoride is heated, it yields fluorine and metallic platinum, the latter being left in a crystalline form, a result which supports Daubrée's views on the mineralising effect of fluorine.

C. H. B.

Mineralogical Chemistry.

Composition of Roumanian Rock-salt. By Istrati (*Bull. Soc. Chim.* [3], **2**, 4—8).—This mineral, which is mined in the Carpathians, contains 98—99·8 per cent. of sodium chloride. Some varieties have a definite odour of petroleum, which in some cases is contained in the mineral to such an extent that explosions have occurred. The variety known as "puturosa" contains as much as 117 c.c of gases per kilo.; the gas obtained from Dolftana salt yielded on analysis 25 per cent of unsaturated hydrocarbons and 19·6 per cent. of oxygen, but no carbonic anhydride.

T. G. N.

Kobellite from Colorado. By H. F. KELLER (*Zeit. Kryst. Min.*, 17, 67—72).—This mineral, from the Silver Bell mine, Ouray, is fine-grained, somewhat fibrous, and exhibits no crystalline form. It has a sp. gr. of 6·334. The analyses lead to the formula $2(PbAg_2Cu_2)S,(SbBi)_2S_4$. This does not agree with Rammelsberg's formula, Pb_3BiSbS_6. The mean of four analyses was as follows:—

S.	Bi.	Sb.	Pb.	Ag.	Cu.	Fe.	Zn.	Gangue.	Total.
18·39	28·40	7·55	36·16	3·31	2·59	1·50	0·39	0·45	98·74

B. H. B.

Aurichalcite. By A. BELAR (*Zeit. Kryst. Min.*, 17, 113—127).—In the aurichalcite of Temperino, Delesse detected the presence of calcium. Other chemists regard this as merely a mechanical impurity in the material analysed, and believe that aurichalcite is nothing more than a compound of copper and zinc hydrated carbonates. Analyses were made of aurichalcite (1 and 2) from Moravicza, (3) from Campiglia, and (4) from Sardina, with the following results:—

	CuO.	ZnO.	Fe_2O_3.	H_2O.	CO_2.
1	20·39	54·70	—	13·53	11·38
2	21·43	53·57	—	26·78	
3	20·20	55·51	—	26·50	
4	15·58	58·72	2·17	22·97	

All four analyses lead to the formula $CuCO_3 + 3Zn(HO)_2$.

In conclusion, the author gives the results of experiments made with the view of preparing aurichalcite artificially. He finds that the statement of Delesse, that aurichalcite re-crystallises out from solutions of the mineral in ammonium carbonate, is not correct.

B. H. B.

Messelite, a New Mineral. By W. MUTHMANN (*Zeit. Kryst. Min.*, 17, 93—94).—This mineral forms radiated masses of brown or colourless tablets in a bituminous shale embedded in the lignite of the Messel mine in Hesse-Darmstadt. The crystals were found optically to be triclinic. Analysis gave the following results:—

P_2O_5.	CaO.	FeO.	MgO.	MnO.	H_2O.	Insol.	Total.
37·72	31·11	15·63	1·45	trace	12·15	1·40	99·46

These results correspond with the formula $(CaFeMg)_3(PO_4)_2 + 2\frac{1}{2}H_2O$. Messelite differs from fairfieldite by the absence of manganese and by the different proportion of water. B. H. B.

Mazapilite, Anhydrite, Eleonorite, &c., from North America. By G. A. KÖNIG (*Zeit. Kryst. Min.*, 17, 84—92).—1. *Mazapilite* is the name given by the author to an extremely rare mineral from the Jesus Maria Mine, Mazapil, Mexico. The crystals belong to the rhombic system, the axial ratio being $a : b : c = 0·8616 : 1 : 9·9969$. Analysis gave—

As_2O_5.	Sb_2O_5.	P_2O_5.	Fe_2O_3.	CaO.	H_2O.	Total.	Sp. gr.
43·60	0·25	0·14	30·53	14·82	9·83	99·17	3·582

Formula: $Ca_3Fe_2(AsO_4)_4(OFe\cdot OH)_2 + 5H_2O$.

2. *Anhydrite.*—This mineral was found at the Darby tunnel, seven miles from Philadelphia, in the unusual form of crusts consisting of parallel prisms on the plagioclase and augite of a diabase. The silicates of the rock exhibited no trace of decomposition.

3. *Eleonorite from Arkansas.*—A strongly dichroic crystal in a geode of dufrenite, from Sevier Co., Arkansas, was identified by the author as Streng's eleonorite. As all the water was driven off at 280°, Streng's formula, $Fe_6P_4O_{19} + 8H_2O$, is preferable to that of Groth, $Fe_2(OH)_3(PO_4)_2 + 2\frac{1}{2}H_2O$.

4. *Minerals from Franklin, New Jersey.*—At this well-known locality the following minerals have recently been met with:—Chloanthite, arsenic-nickel, fluorspar, apatite, and hydrated nickel silicate; the latter on analysis gave—

SiO_2.	NiO.	CaO.	MgO.	ZnO.	FeO.	H_2O.	As_2O_5.	Total.
31·02	38·22	0·70	0·42	4·00	2·25	16·58	4·77	97·96

B. H. B.

Pseudobrookite, from Havredal, Norway. By A. CEDERSTRÖM (*Zeit. Kryst. Min.*, **17**, 133—136).—This mineral was first analysed by Koch and Lattermann. Owing to want of material, the analysis could not be made with accuracy. The discovery of large crystals at Havredal has enabled the author to make an analysis of carefully selected material, the results being as follows:—

	Author.	Koch.	Lattermann.	Calculated.
Ignition....	—	0·69	—	—
Fe_2O_3.....	56·42	42·29	48·64	56·54
TiO_2.....	44·26	52·74	46·79	43·46
MgO	—	4·28	4·53	—
Total	100·68	100·00	99·96	100·00

The last column gives the percentage composition calculated from the formula $Fe_4(TiO_4)_3$.

B. H. B.

Chemical-mineralogical Theories. By V. GOLDSCHMIDT (*Zeit. Kryst. Min.*, **17**, 25—66).—This memoir is divided into three sections: (1) on the varieties of isomorphism, (2) on symbols and formulæ, and (3) on the formulæ of the silicates. The two first sections serve as an introduction to the views propounded in the third. By the introduction of letters, the author endeavours to simplify the formulæ of silicates. Thus he employs the symbols—

E for R'_4O_2 or R''_2O_2, representing SiO_2,
A for $R'_2R^{vi}_6O_4$, representing Si_2O_4,
R_2 for $R^{vi}_2O_6$, representing Si_3O_6,
Si for SiO_2,
Si_2 for Si_2O_4, &c.,

so that, for example, $\begin{matrix}\mathrm{ASi_2}\\ \mathrm{Si_4}\end{matrix}$ would be the abbreviated formula for albite. Further, he employs symbols for the silicate molecules of more frequent occurrence; thus the hornblende molecule is $\mathrm{H} = \mathrm{ASi} = \left.\begin{matrix}\mathrm{R'_2R}\\ \mathrm{Si}\end{matrix}\right\}\mathrm{O_6}$, and the nepheline molecule $\mathrm{N} = \mathrm{ASi_2}$.

B. H. B.

Artificial Preparation of Wollastonite. By E. Hussak (*Zeit. Kryst. Min.*, 17, 101).—In these experiments, a glass composed of $3(\mathrm{Na_2O,SiO_2}) + 2(\mathrm{CaO,B_2O_3})$ was melted, and, on cooling, was found to be free from bubbles, crystals, and crystallites. Mixed with $\mathrm{CaSiO_3}$ (1 mol.), the mass on cooling was found to be full of bubbles and fissures, and on the sides of the crucible there were a few imperfect, columnar, colourless, minute crystals. When more $\mathrm{CaSiO_3}$ (2 mols.) was added, the colourless columns increased in number, and formed into a radiated globule. The mixture of the glass and 3 mols. of $\mathrm{CaSiO_3}$ on cooling became completely crystalline. A number of hexagonal tablets were present, but the minute columns still predominated. The tablets belong to the hexagonal, optically positive calcium silicate, whilst the columns are crystals of wollastonite extended in the direction of the axis of symmetry. B. H. B.

Leucitophyre from Persia. By V. Steinecke (*Zeit. Kryst. Min.*, 17, 110—111; from *Zeit. Naturwiss.*, 60, 4).—At Koschkserai Maraud, in a magma of orthoclase, plagioclase, nepheline, augite, leucite, and magnetite, there are found crystals of leucite, augite, olivine, sanidine, and nepheline. The leucite gave on analysis—

$\mathrm{SiO_2}$.	CaO.	MgO.	MnO.	$\mathrm{Al_2O_3}$.	$\mathrm{Fe_2O_3}$.	$\mathrm{K_2O}$.	$\mathrm{Na_2O}$.	Ignition.
54·54	0·99	0·25	trace	22·14	1·74	19·83	0·71	1·33

An analysis of the augite is also given. B. H. B.

Nosean-bearing Ejections from the Laacher See. By L. L. Hubbard (*Zeit. Kryst. Min.*, 17, 208; from *Tschermak's min. Mitth.*, 8, 356—399).—In the ejections found at the Laacher See, nosean is principally confined to geodes, and in its formation in a trachytic rock, sanidine has, in many cases, been produced. The latter occurs in radiated masses, and gave on analysis the following results:—

$\mathrm{SiO_2}$.	$\mathrm{Al_2O_3}$.	$\mathrm{Fe_2O_3}$.	CaO.	MgO.	$\mathrm{Na_2O}$.	$\mathrm{K_2O}$.	Total.	Sp. gr.

B. H. B.

Wiluite. By R. Prendel (*Zeit. Krys. Min.*, 17, 94—97).—The author has made an exhaustive investigation of the physical properties of the idocrase of Wilui, and proves that this so-called wiluite differs considerably from idocrase proper. B. H. B.

Two Analyses of Mica. By A. Becker (*Zeit. Kryst. Min.*, 17, 128—132).—The author has analysed (1) biotite and (2) muscovite of remarkable purity, carefully isolated from the gneiss, 338 metres below the surface, at a mine at Halsbrücke, near Freiberg, in Saxony. The analytical results were as follow :—

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	MgO.	K_2O.
1....	34·70	4·58	17·17	2·11	19·05	0·50	9·52	8·91
2....	46·74	1·52	32·56	1·55	0·92	—	1·18	10·37

	Na_2O.	H_2O.	F.	Total.
1	1·24	3 56	0·20	101·54
2	1·02	3 55	—	99·41

The formulæ of the two minerals are—

(1) $5(KNaH)_4SiO_4 + 8(FeMnMg)_2SiO_4 + 3(Al_2Fe_2)_2(SiO_4)_3$.
(2) $2(KNaH)_2SiO_3 + (Al_2Fe_2)_2(SiO_4)_3$. B. H. B.

Chemical Composition of Vesuvian. By J. H. Vogel (*Zeit. Kryst. Min.*, 17, 215—216).—The author gives the results of analyses of nine specimens of vesuvian from different localities :—1. Cziklowa, yellowish-green crystals, sp. gr. 3·38, directly determined water 1·53 per cent.; 2. Becco della Corbassera, Ala, yellowish-green masses, sp. gr. 3·386, H_2O 1·11; 3. Canzocoli, near Predazzo, large, yellowish-brown crystals, sp. gr. 3·404, H_2O 1·57; 4. Zermatt, dark-brown crystals, sp. gr. 3·488, H_2O 1·05; 5. Egg, sp. gr. 3·406; 6. Haslau, dark-brown masses, sp. gr. 3·419; 7. Sandford, brown crystals, sp. gr. 3·419; 8. Eker, sp. gr. 3·328; 9. Arendal, large, dark-brown crystals, sp. gr. 3·38.

B. H. B.

Petrography of South-West Africa. By H. Wulf (*Zeit. Kryst. Min.*, 17, 199—200; from *Tschermak's min. Mitth.*, 8, 193—238).—The author gives analyses of scapolite from the scapolite-gneiss of the copper mine, and of Husab on the Tsoachaub, to the east of Wallfisch Bay. Analyses are also given of augite from the same rock, of wollastonite from the wollastonite-augite-gneiss of Reed, and from the wollastonite-diopside rock of the copper mine. Epidote from Diepdal gave on analysis the following results:—

B. H. B.

Meteorite from Phu-Hong. By S. Meunier (*Compt. rend.*, **109**, 875—878).—This meteorite fell on September 22nd, 1887, at Phu-Hong, in Cochin China. It has a granular and even oolitic fracture, which is of a violet-grey colour, and the polished surface gives Widmannstatt's figures. Under the microscope, it is seen to consist of a transparent matrix, with opaque ramifying filaments and irregular granules. The transparent portion consists of peridote and magnesium pyroxene; the needles are arranged in very numerous spheroidal masses or chondrites.

The sp. gr. of the meteorite at 12° is 3·601; 35·37 per cent. is magnetic; 29·62 per cent. is soluble in hydrochloric acid, and 35·12 is not attacked by the acid. The magnetic portion contains 91·22 per cent. of iron and 9·05 per cent. of nickel, with distinct traces of cobalt. The composition of the soluble and insoluble non-magnetic portions are given in the following table:—

	SiO_2.	MgO.	CaO.	Na_2O.	FeO.	Al_2O_3.	Cr_2O_3.	Mn.
Insoluble..	63·60	28·48	1·91	0·87	4·10	1·22	0·92	trace
Soluble ...	40·09	45·97	—	—	14·00	—	—	—

The meteorite belongs to the type *limerickite*, and the author discusses the claims of certain other meteorites and terrestrial rocks to be included in the same type.

C. H. B.

Analysis of Water from the Roundwood Colliery. By J. F. Cleeves and J. C. Platts (*J. Soc. Chem. Ind.*, **7**, 729).—The sample was taken at a depth of 500 yards from the surface, and at a distance of 1,800 yards from the bottom of the shaft. The temperature was 19°, and the sp. gr. 1·0622. Analysis gave the following results expressed in grams per litre:—

SiO_2.	Al_2O_3 and Fe_2O_3.	$BaCl_2$.	$MgBr_2$.	$MgCl_2$.	$CaCl_2$.	NaCl.	Totals.
0·129	0·019	0·292	0·413	5·087	22·850	67·351	96·141

Chlorine required..............	59·38
Chlorine found	59·50

The water contains a large amount of gases dissolved in it, prominent among them being marsh gas.

D. B.

Organic Chemistry.

Constitution of Petroleum. By J. A. Le Bel (*Bull. Soc. Chim.* [3], 2, 305—307).—The author considered that normal paraffins might alone be present in petroleum, the occurrence of the secondary paraffins being due to isomeric change occurring during its manipulation. He found, however, after isolation of the amylenes from natural petroleum, and subsequent treatment with concentrated hydrochloric acid in the cold, that dimethylethyl chloride boiling at 86° was obtained, which proves the occurrence of other than normal paraffins in petroleum, and according to him negatives the fermentation theory of petroleum formation, since no fermentation is known which produces both classes of compounds at a time. T. G. N.

Diallyl Tetrabromides. By G. Wagner (*Ber.*, 22, 3056—3057).—The author has previously stated that diallyl is probably a mixture of two isomerides (compare Abstr., 1889, 226), a view which, if correct, would explain the existence of the two tetrabromides, $C_6H_{10}Br_4$. Ciamician and Anderlini (this vol., p. 20), in assuming that these two bromides are geometrically isomeric, have probably overlooked the author's previous paper. F. S. K.

Action of Hydrocyanic Acid on Calomel. By Fouquet (*J. Pharm.* [5], 20, 397—400).—The statement that corrosive sublimate is produced by the action of hydrocyanic acid on calomel is incorrect. Mercury is set free with the formation of mercuric cyanide and hydrochloric acid in equivalent quantities. The reaction is almost always incomplete; but it may be started again by neutralising the free hydrochloric acid. J. T.

Ammoniomercuric Cyanides. By R. Varet (*Compt. rend.*, 109, 903—904).—Alcoholic ammonia is saturated with mercuric cyanide, a current of ammonia gas being passed through the liquid while solution is taking place. The solution is heated at 50° to 60°, again saturated with dry ammonia, and allowed to cool. After some time, it deposits transparent, prismatic needles of the compound $HgCy_2,2NH_3$, which become opaque and rapidly lose ammonia when exposed to the air. At 100°, it loses the whole of the ammonia in a few hours.

If concentrated aqueous ammonia is saturated with mercuric cyanide, mixed with more ammonia, and cooled, it yields long, white, prismatic needles of the compound $HgCy_2,2NH_3,\frac{1}{2}H_2O$; this readily loses water and ammonia on exposure to air, although it is more stable than the preceding compound. At 100°, it decomposes completely, and mercuric cyanide is left.

The compound $HgCy_2,NH_3$ is obtained in small, hard, transparent crystals by heating aqueous ammonia with a large excess of mercuric cyanide in a closed vessel at 40°. It dissolves in ammonia, alters when exposed to air, and loses all its ammonia at 100°. The action of dry ammonia on finely-powdered mercuric cyanide yields a yellowish-white product of the composition $10HgCy_2,NH_3$.

If ordinary ammonia is saturated with mercuric cyanide, mixed with one-tenth its volume of ammonia solution, and cooled to 0°, it yields small, white crystals of the compound $HgCy_2,NH_3,\frac{1}{2}H_2O$, very soluble in aqueous or alcoholic ammonia, very unstable when exposed to air. At 100°, it loses the whole of its water and ammonia.

C. H. B.

Interaction of Haloïd Salts of Mercury and Zinc. By R. Varet (*Compt. rend.*, 109, 809—812).—A concentrated solution of zinc bromide is added drop by drop to a boiling saturated solution of mercuric cyanide, with vigorous agitation. The greater part of the precipitate redissolves, but the liquid remains turbid. It is filtered and allowed to cool, when it deposits white crystals of the compound $Hg_2ZnBr_2Cy_4 + 8H_2O$, which alters little, if at all, on exposure to air, is somewhat soluble in water, and becomes anhydrous at 100° or in a vacuum. When the hydrated compound is heated, it loses water, blackens, and decomposes into mercury, cyanogen, mercuric bromide, and zinc carbonate. Nitric acid converts it into zinc nitrate, mercuric cyanide, and mercuric bromide, hydrocyanic acid being evolved. Dry ammonia expels the combined water, and forms a compound, $Hg_2ZnBr_2Cy_4 + 2NH_3$, which loses ammonia when exposed to air, and is decomposed by water.

That this compound has the constitution $ZnCy_2,HgCy_2,HgBr_2 + 8H_2O$, and is not a compound of mercuric cyanide with zinc bromide, is proved by the following facts. Potassium iodide added to the aqueous solution produces at first a precipitate of zinc cyanide, followed by a precipitate of mercuric iodide; and Berthelot has shown that potassium iodide combines with mercuric cyanide with liberation of heat, but has no action on zinc cyanide. Cupric sulphate liberates cyanogen, and produces a peach-blossom coloured precipitate of mercuric cupric bromo-cyanide.

The addition of zinc cyanide to a boiling concentrated solution of mercuric bromide yields the same compound, and it is evident that its formation limits the action between mercuric bromide and cyanide and zinc cyanide and bromide, whatever may be the arrangement of the atoms in the initial system. C. H. B.

Mannose. By E. Fischer and J. Hirschberger (*Ber.*, 22, 3218—3224).—The mannose employed in these experiments was obtained from vegetable ivory nuts by a modification of Reiss' method (Abstr., 1889, 667), instead of by the oxidation of mannitol. Comparative experiments made with mannose from the latter source showed the complete identity of the two sugars. The method of preparation was as follows: Sifted ivory-nut shavings (1 part) were digested with 6 per cent. hydrochloric acid (2 parts) on the water-bath for six hours, filtered hot, the residue pressed and again extracted with water. The brown solution, after treatment with animal charcoal, was neutralised with caustic soda solution, and an excess of phenylhydrazine acetate added. The resulting hydrazone was purified and converted into mannose by the method previously described (Abstr., 1889, 481).

Mannonic Acid.—For the preparation of this acid, a solution of mannose (1 part) in water (5 parts) is mixed with bromine (2 parts) at the ordinary temperature, frequently shaken, and allowed to remain 24 hours after the bromine has dissolved. The latter is then eliminated in the usual manner, and the resulting solution of mannonic acid converted into the *phenylhydrazide*, $C_{12}H_{18}N_2O_6$, by Fischer and Passmore's method (this vol., p. 152); this forms small, colourless, brilliant prisms which melt at 214—216° with decomposition, are soluble in hot water, but sparingly in cold water or alcohol. It may also be obtained directly from ivory nuts in the following manner: The ivory-nut shavings are heated with 6 per cent. hydrochloric acid, and the solution treated with animal charcoal as previously described. The quantity of mannose in solution is determined by precipitating a known quantity with phenylhydrazine, and for every part of sugar found, 2 parts of bromine added to the solution. The whole is frequently shaken until all the bromine has dissolved, and then allowed to remain. After evaporating off the free bromine, the solution is nearly neutralised with lead carbonate, filtered, precipitated with lead acetate solution, and again filtered. The filtrate may be then converted into the hydrazide as before. The latter, after recrystallisation, is decomposed by boiling baryta-water, the liberated phenylhydrazine extracted with ether, and the boiling liquid exactly precipitated with sulphuric acid. The filtrate, on evaporation, leaves a syrup, which solidifies to a slightly brown, crystalline mass. This is extracted twice with a little alcohol, and the residual white compound recrystallised from this solvent. The crystals obtained form stellate groups of colourless needles, and have the composition $C_6H_{10}O_6$, and are therefore the *lactone* of mannonic acid; this melts at 149—153°, is readily soluble in water, but less so in alcohol. Its aqueous solution is dextrorotatory, $[\alpha]_D = 53{\cdot}81$, and has a neutral reaction, but quickly dissolves carbonates on boiling, forming salts of mannonic acid. The *calcium* salt, $(C_6H_{11}O_7)_2Ca + 2H_2O$, forms microscopic prisms. The *strontium* salt, with 3 mols. H_2O, crystallises from alcohol in small prisms. The *barium* salt has not yet been obtained crystalline.

Mannonic acid is oxidised by nitric acid to a bibasic acid, which differs from saccharic and metasaccharic acids, and seemingly also from isosaccharic acid. This compound is undergoing further examination.

The authors have previously stated that mannose undergoes fermentation with yeast, and they have been able to confirm this by a repetition of the experiment with larger quantities. A 5 per cent. solution, when mixed with fresh yeast at the ordinary temperature, evolves carbonic anhydride in 10—15 minutes, and in 24 hours the reaction is complete. From the filtered solution, ethyl alcohol can be separated by fractional distillation, the yield seemingly being the same as that from dextrose. The liquid obtained by boiling ivory nuts with 6 per cent. hydrochloric acid also ferments after neutralisation with lime, although more slowly. As from 900—1000 tons of such shavings are obtained yearly, and these yield 33 per cent. of their weight of sugar, it would seem that a commercial process for the preparation of alcohol from this source might be successfully founded.

Mannose is acted on by acetic chloride in exactly the same manner as dextrose. The *acetochloromannose* obtained likewise forms a syrup, which is sparingly soluble in water, but is decomposed by long-continued boiling with the latter into mannose and acetic and hydrochloric acids. H. G. C.

Sugar from the Quebracho. By C. TANRET (*Compt. rend.*, **109**, 908—910).—The bark of the quebracho (*Aspidosperma quebracho*) yields a sugar, *quebrachite*, of the composition $C_7H_{14}O_6$, which crystallises from alcohol in anhydrous, rhomboidal prisms with a very sweet taste. It is very soluble in water, and somewhat soluble in boiling alcohol, but insoluble in ether. It melts at 186—187°, boils in a vacuum, and condenses in beautiful needles; rotatory power $[\alpha]_D = -80°$; sp. gr. at 0° = 1·54. Quebrachite ferments only in contact with beer-yeast, and has no action on Fehling's solution, but reduces ammoniacal silver nitrate. It is not affected by boiling dilute solutions of acids or alkalis, and gives no precipitate with basic lead acetate, but is precipitated by ammoniacal lead acetate provided the solution is not very dilute. Monohydrated sulphuric acid dissolves it readily, especially at 100°, with slight discoloration, forming *quebrachisulphuric acid*, a lævogyrate acid which yields soluble, non-crystallisable barium and calcium salts. When heated with acetic anhydride and zinc chloride, it yields a crystalline derivative which melts at 89°. With nitric and sulphuric acids, it yields an unstable nitrin, and when heated with nitric acid it gives rhodizonic acid.

When heated with hydriodic acid, quebrachite yields methyl iodide and an inosite which crystallises from alcohol in very brilliant, slender, efflorescent, prismatic needles, soluble in 2·3 parts of water at 12°, very slightly soluble in boiling alcohol, and insoluble in ether. It melts at 238°, is somewhat less volatile than quebrachite, and has a lævorotatory power of $[\alpha]_D = -55°$. With nitric acid it gives the inosite reaction. C. H. B.

Formation of Raffinose. By F. HERLES (*Chem. Centr.*, 1889, ii, 421—422; from *Böhm. Zeit. Zucker-Ind.*, **13**, 455).—The author has subjected cane-sugar to the action of calcium hydroxide at various temperatures, but without being able to detect any formation of raffinose, a result in agreement with that obtained by Cech (*Chem. Centr.*, 1889, i, 682). He draws the conclusion that the formation of raffinose takes place in the beetroot. He also confirms the correctness of Herzfeld's statement (*ibid.*, 404), that it is formed by freezing the beetroot. The author finds that the preservation of the beetroot for too long a time favours the formation of raffinose. J. W. L.

Melitriose and Melibiose. By C. SCHEIBLER and H. MITTELMEIER (*Ber.*, **22**, 3118—3124; compare Abstr., 1889, 953).—Melitose, prepared from cotton-seed meal exactly as described by Berthelot

(*Compt. rend.*, **103**, 533), is not changed by boiling baryta-water, does not reduce Fehling's solution, and crystallises unchanged from alcohol. Berthelot's statement (*loc. cit.*) that melitose is decomposed by alcohol into raffinose and eucalyn is, therefore, incorrect, and melitose is identical with raffinose.

When melitriose is treated with a dilute solution of invertin at the ordinary temperature for two hours, it is decomposed into melibiose and levulose; but when it is kept for 36 hours at 40° with a concentrated solution of invertin, it is decomposed into dextrose, galactose, and levulose; Berthelot's eucalyn is, therefore, identical with melibiose.

When melibiose is reduced with sodium-amalgam at the ordinary temperature, the solution being kept as neutral as possible, it is converted into a substance (*melibiotite*) which does not reduce Fehling's solution, but if a little of the solution is boiled for a short time with a few drops of sulphuric acid, it acquires powerful reducing properties, galactose being one of the decomposition-products of melibiotite. F. S. K.

Molecular Weights of Maltose and of several Inulin-like Substances. By Å. G. EKSTRAND and R. MAUZELIUS (*Chem. Centr.*, 1889, ii, 444; from *Vetensk. Akad. Forhandl.* 1889, 157).—The molecular formulæ given below were determined by Raoult's method:—Anhydrous maltose, $C_{12}H_{22}O_{11}$. Triticin, $C_{36}H_{60}O_{30}$, from the root of *Dracæna rubra*, melts at 140°, and has the specific rotation $[\alpha]_D = -36{\cdot}61$. Triticin, from *Triticum repens*, melts at 160°, and has the specific rotation $[\alpha]_D = -41{\cdot}07$. Graminin, $C_{48}H_{80}O_{10}$, from *Trisetum alpestre*, melts at 220°, and has the specific rotation $[\alpha]_D = -44{\cdot}47$. Irisin, $C_{96}H_{160}O_{80}$, from *Iris pseudo-acorus*, melts at 160°, and has the specific rotation $[\alpha]_D = -51{\cdot}20$. Phleïn, from *Phleum pratense*, melts at 215°, and has the specific rotation $[\alpha]_D = -47{\cdot}94$; the molecular weight could not be determined. J. W. L.

Animal Cellulose. By R. SCHÜTZE (*Chem. Centr.*, 1889, ii, 588; from *Mitt. pharm. Inst. Erlangen*, 2 *Heft*, 280—281).—The author has examined the mantle of *Phallusia mammillaris*, it being purified by boiling first with water, then repeatedly with 20 per cent. potassium hydroxide solution and 10 per cent. hydrochloric acid, and finally by digestion with hydrofluoric acid and hydrochloric acid.

The white cellulose substance contained 43·47 per cent. of carbon and 6·25 per cent. of hydrogen.

Solution of cupric oxide in ammonia dissolves the substance, and solution of iodine in zinc chloride or sulphuric acid stains it variously from red to violet. Nitric and sulphuric acids form an explosive nitrate with it, which is somewhat soluble in ether.

When heated with 10 per cent. sulphuric acid in a closed flask at 100°, a substance is formed which reduces Fehling's solution, and which ferments with yeast, with formation of carbonic anhydride.

The ether extract of the mantle contained small quantities of cholesterin, fat and free fatty acids, oleïc, valeric, and probably also palmitic and stearic acids.

The mineral matter included in the cuticle freed from fat consisted of: Silica 2·76, alumina 9·52, ferric oxide 15·81, phosphoric acid (combined with iron and aluminium) 12·72, calcium phosphate 3·91, calcium carbonate 49·22, and magnesium carbonate 6·03 per cent.

J. W. L.

Lignin. By G. LANGE (*Zeit. physiol. Chem.*, **14**, 217—226).—The investigation of the lignin of beech and ash wood previously recorded (Abstr., 1889, 1235) has in the present research been extended to that of pine wood (*Pinus abies*, L.). The lignin was prepared from this by the same methods as those previously employed; it was found to consist of 52 to 55 per cent. of cellulose, two brown substances called lignic acid; and as a result of fusing with alkali, formic, acetic, and traces of higher fatty acids, oxalic acid, catechol, protocatechuic acid, ammonia, and traces of higher bases were obtained. No succinic acid was obtained, as Erdmann stated (*Annalen*, **138**, 1). The percentage compositions of the lignic acids obtained from the three varieties of wood were as follows:—

	Lignic acid soluble in alcohol.		Insoluble in alcohol.	
Beech	C, 61·475;	H, 5·48	C, 59·04;	H, 5·37
Ash	,, 61·61	,, 5·47	,, 58·83	,, 5·15
Pine	,, 61·28	,, 4·95	,, 60·51	,, 5·22

Experiments designed to ascertain the constitution of these substances were unsuccessful.

W. D. H.

Gum Tragacanth. By J. OGLE (*Pharm. J. Trans.* [3], **20**, 3).—A sample of Syrian tragacanth yielded moisture 18·92, soluble gum 35·94, ash 2·75, and insoluble gum 42·39 per cent. The precipitate produced in the aqueous solution by the addition of alcohol was found not to be identical with arabin, and no evidence of the presence of starch could be obtained.

R. R.

Absence of Rotatory Power in Amine Salts. By J. A. LE BEL (*Bull. Soc. Chim.* [3], **2**, 305).—The order in which the substitution of radicles is effected in the NH_3 molecule does not influence the nature of the resulting amine, from which it follows that either the molecule alters its configuration according to the substitution, or that intramolecular migration of the substituted radicles occurs; if then in the former case the radicles are definitely located a compound of the formula $Cl{\cdot}NHR^1R^2R^3$ should exhibit rotatory power, since R^1, R^2, and R^3 cannot be in the same plane. With a view to determine this experimentally, the author prepared methylethylpropylamine hydrochloride, which he found to be devoid of rotatory power, and consequently the first hypothesis is untenable.

T. G. N.

Propargylamine and Derivatives of Allylamine. By C. PAAL and C. HERMANN (*Ber.*, **22**, 3076—3085).—*Dibromopropylamine hydrobromide*, $C_3H_5Br_2{\cdot}NH_2,HBr$, is obtained when an ice-cold, aqueous solution of allylamine is slightly acidified with concentrated hydrobromic acid, and then treated with bromine (1 mol.); the yield is quantitative. It separates from hot water in well-defined, transparent crystals, melts at 164°, and is only sparingly soluble in hot alcohol and cold water, but readily in hot water; it is not decomposed by moderately concentrated sulphuric acid, even when boiled therewith for half an hour. The *salt* $(C_3H_5Br_2\cdot NH_2)_2,2HBr,PtCl_4$ crystallises in orange-red plates and decomposes at 200°, but without melting. The *salt* $C_3H_5Br_2\cdot NH_2,HBr,AuCl_3$ crystallises in dark-red needles, melts at 124°, and is moderately easily soluble in water.

Bromallylamine hydrobromide melts at 175° and not at 223—224°, as previously stated (compare Paal, Abstr., 1889, 117).

In preparing bromallylamine salts by the method previously described, it is better to neutralise the aqueous distillate containing the base with a dilute mineral acid, instead of collecting the distillate in excess of acid; in this way the formation of additive-compounds is avoided.

Tribromopropylamine hydrobromide, $C_3H_4Br_3\cdot NH_2,HBr$, prepared by treating bromallylamine hydrobromide with bromine in well-cooled, aqueous solution, crystallises from water in large, colourless plates containing water of crystallisation; the crystals effloresce on exposure to the air, and melt at 210° with partial decomposition. It crystallises from alcoholic ether in slender needles, and is moderately easily soluble in hot alcohol.

A *base*, $C_3H_5Br_2N$ or $(C_3H_5Br_2N)_2$, is formed when tribromopropylamine hydrobromide is treated with alcoholic potash; on distilling with steam, neutralising the distillate with hydrobromic acid, and concentrating the solution, the *hydrobromide*, $C_3H_5Br_2N,HBr$, is obtained in colourless crystals. This salt melts at 214°, does not combine with bromine, and is readily soluble in water, but only sparingly in alcohol. The *salt* $(C_3H_5Br_2N)_2,2HBr,PtCl_4$ crystallises in golden scales, and decomposes at 230°, but without melting. The salt $C_3H_5Br_2N,HBr,AuCl_3$ forms small, yellow, well-defined crystals. The free *base* is a yellowish, unstable oil; it does not give the carbylamine reaction, and it yields an oily nitrosamine which is insoluble in water and dilute mineral acids.

Propargylamine, $C_3H_3\cdot NH_2$, is formed when a dibromopropylamine salt is heated for 1¼ hours at 100° in a sealed tube with an alcoholic solution of sodium ethoxide (4 mols.). The contents of the tube are transferred to a flask and heated on the water-bath until most of the alcohol has distilled, the distillate being collected in an alcoholic solution of oxalic acid. The acid *oxalate*, $C_3H_3\cdot NH_2,C_2H_2O_4$, separates during the process in slender, colourless needles, which are perfectly pure if the above conditions are observed. It is only very sparingly soluble in boiling alcohol, but readily in water, from which it separates in large plates melting at 143°; its dilute aqueous solution gives a purple-red coloration with auric chloride. The yield of the oxalate is about 50 per cent. of the theoretical; the residue in the flask contains not inconsiderable quantities of a non-volatile base. All attempts to isolate propargylamine were unsuccessful; it seems to be much more readily soluble in water and concentrated alkalis than ammonia or methylamine. *Propargylamine silver* is precipitated when a solution of silver nitrate in excess of ammonia is added to an ammoniacal solution of the oxalate; it is a colourless compound, darkens gradually on exposure to the air, and explodes when heated. The *picrate*, $C_3H_3\cdot NH_2,C_6H_3N_3O_7$, prepared by precipitating an alcoholic solution of the base with picric acid, crystallises in large, reddish plates, melts at 189°, and is insoluble in ether. The *hydrochloride*, $C_3H_3\cdot NH_2,HCl$, prepared by passing hydrogen chloride into an alcoholic solution of the base, crystallises in colourless plates, is readily soluble in water and alcohol, and decomposes on exposure to light. The *hydrobromide*, $C_3H_3\cdot NH_2,HBr$, crystallises in thin, colourless plates, begins to soften at 130°, melts at 171°, and decomposes on exposure to light.

Methylpropargylamine hydriodide, $C_3H_3\cdot NHMe,HI$, is obtained when an alcoholic solution of propargylamine is treated with methyl iodide; it crystallises in long, colourless, very hygroscopic needles, melts at 83°, and decomposes on exposure to light. The free *base* is a yellowish, volatile oil, of ammoniacal odour. The *oxalate*, $C_4H_7N,C_2H_2O_4$, crystallises from dilute alcohol in colourless needles melting at 141°.

Ethylpropargylamine hydriodide crystallises in long needles; *propylpropargylamine hydrobromide* crystallises in plates melting at 180°.

Isoamylpropargylamine is formed when isoamyldibromopropylamine hydrobromide is treated with sodium ethoxide, as described above; the contents of the tube are treated with a little water to dissolve the sodium bromide, the solution saturated with potassium carbonate, the supernatant alcohol separated, dried over potash and distilled, the distillate being collected in an alcoholic solution of oxalic acid. The *oxalate*, $C_3H_3\cdot NH\cdot C_5H_{11},C_2H_2O_4$, is thus obtained in small, colourless needles melting at 204°; it crystallises from water with 1 mol. H_2O. The free *base* is liquid. The *hydrobromide*, $C_8H_{15}N,HBr$, crystallises in nacreous plates melting at 186°. F. S. K.

Action of Heat on Chloral-ammonia. By A. BÉHAL and CHOAY (*Compt. rend.*, **109**, 817—820).—Personne showed that when chloral-ammonia is heated at 100° it yields chloroform and formamide, but the decomposition is not complete. If chloral-ammonia is heated in a retort at 100° until chloroform ceases to distil over, a black viscous mass with a slightly alliaceous odour is left; this contains ammonium chloride, formamide, and some other compounds.

If this residue is boiled with strong alcohol, the latter on cooling deposits crystals of the chloralimide described by Pinner and Fuchs, the yield being about 5 per cent. of the original chloral-ammonia. Chloralimide forms long, colourless, tasteless needles slightly soluble in water, more soluble in alcohol, very soluble in ether. It is decomposed by a cold aqueous solution of platinic chloride with formation of chloral and ammonium platinochloride. It is not affected by water in sealed tubes at 150°, but at 170° decomposes completely into chloroform and formamide, which undergo partial decomposition and yield some ammonium chloride, carbonic anhydride, and hydrochloric and formic acids. Chloralimide in doses of 0·25 to 0·50 gram has remarkable antipyretic and analgesic properties.

If the residue in the retort, either before or after extraction with alcohol, is boiled with a large quantity of water, the liquid deposits crystals on cooling, and if these are purified by treatment with animal charcoal and recrystallisation from alcohol, the compound $C_4Cl_3H_5N_2O_2$ is obtained in long, colourless, tasteless, inodorous prisms, very slightly soluble even in boiling water, more soluble in alcohol, especially if heated, and very soluble in ether. It melts at 216—217°, and almost immediately decomposes with evolution of gas. It is partially decomposed by platinic chloride, and when heated with excess of acetic anhydride it yields an acetyl-derivative of the composition $C_4Cl_3H_4AcN_2O_2$, which crystallises in long needles very soluble in acetic acid, almost insoluble in water, and only slightly soluble in alcohol or benzene. This derivative is not affected by a neutral or acid alcoholic solution of platinic chloride; it is stable even at a high temperature, but does not melt without decomposing.

The first compound, $C_4Cl_3H_5N_2O_2$, is probably didehydrotrichlorodihydroxypiperazine, formed by the condensation of 2 mols. of chloral-ammonia with elimination of 3 mols. of hydrogen chloride, but this view requires further investigation. C. H. B.

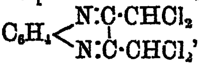
The Indian Grass Oils. By F. D. Dodge (*Amer. Chem. J.*, **11**, 456—469).—These are at least five in number, namely, oils of citronella, lemon-grass, Indian or Turkish geranium, ginger-grass, and vetivert or cus-cus. They are derived from various tropical grasses of the genus *Andropogon*, but there is some confusion as to the particular species from which the individual oils are obtained.

Citronella Oil. The commercial varieties are often adulterated with kerosene; the pure oil is a clear, greenish-yellow liquid with a sharp burning taste and a strong aromatic odour. Its sp. gr. at 16° is 0·8770, at 26·5° 0·8750. It distils between 200° and 240°, leaving 10 per cent. of a thick oily residue, having a pungent odour. It gives most of the reactions of aldehydes, combining with hydrogen sulphites and with phenylhydrazine, although not with ammonia; it also reacts with acetic and benzoic chlorides, and gives a mirror with an ammoniacal silver solution. Two litres of the oil were distilled in a current of steam, and collected in fractions of 1100 c.c. and 400 c.c., the residue of 500 c.c. not being readily volatile. The first fraction (1100 c.c.) was treated with a solution of sodium hydrogen sulphite, the mixture being kept cool with ice and water. The liquid solidified to a white magma, and the sodium hydrogen sulphite compound was then pressed between flannel and washed with ether; the filtrate yielded 350 c.c. of residual oil. The sodium hydrogen sulphite compound was mixed with dry sodium carbonate and distilled in a current of steam; about 700 c.c. of aldehyde was thus obtained. This was shown by analyses, and a vapour-density determination, to have the formula $C_{10}H_{18}O$, and is thus isomeric with borneol and geraniol. The author names it *citronellic aldehyde*, and considers it to be β-methyl-δ-isobutylallylacetaldehyde, $CH_3Pr^{\beta}\cdot CH\colon CHMe\cdot CH_2\cdot CHO$, since this formula is most in accordance with its reactions. It unites with 2 atoms of bromine, and when reduced with sodium amalgam and acetic acid it yields *citronellyl alcohol*, $C_{10}H_{20}O$, boiling at 225—230°; this decolorises bromine solution, and has a pleasant odour of roses. It forms compounds with phenylhydrazine, with aniline and paratoluidine, and with acetic acid, but these products have not yet been isolated. It is dextrorotatory, and when oxidised, appears to yield fatty acids; with potassium permanganate, it yields a mixture of acids smelling strongly of ordinary valeric acid. When treated with phosphoric anhydride, some large, colourless plates (melting at 140°) were deposited, and two oils formed, one boiling at 175°, which was shown by analysis to be an impure terpene, and one boiling above 300°, which had a pleasant odour resembling the high-boiling fractions of citronella oil.

The 350 c.c. filtered from the sodium hydrogen sulphite compounds yielded (1.) 75 c.c of a light oil, boiling at 177°, and having a pleasant, citrene-like odour; this was analysed, and its vapour-density determined, the results indicating that it was an impure terpene; (2.) 120 c.c. of a thicker oil, of rose-like odour, boiling at 222—224°, and of sp. gr. = 0·8741 at 26·5°, which appeared to be citronellyl alcohol; (3.) 100 c.c. boiling above 240°, dark brown, viscid, and having a peculiar odour.

The residual 500 c.c. of the original oil not readily volatile in steam was treated with sodium hydrogen sulphite, and yielded about 10 c.c. of citronellic aldehyde, and a residual 475 c.c., which when distilled behaved like the residue from the other sulphite precipitate, but yields a much larger amount of high-boiling products, which oxidise readily, and are difficult to treat. Citronella oil therefore contains citronellic aldehyde and alcohol, together with a terpene and oils boiling above 240°. The study of these oils is to be continued. C. F. B.

Derivatives of Tetrachlorodiacetyl and of Tetrachloracetone. By S. Levy, F. C. Witte and A. Curchod (*Annalen*, **254**, 83—114; compare Abstr., 1889, 1160 and 1136).—The compound, $C_{16}H_{14}Cl_2N_4O$, prepared by boiling tetrachlorodiacetyl (Abstr., 1889, 390) with excess of phenylhydrazine in alcoholic solution, combines with phenylhydrazine when warmed therewith, with evolution of ammonia; it is decomposed by alcoholic potash with liberation of aniline, and when treated with fuming nitric acid in sulphuric acid solution, it is converted into a yellow compound, which is precipitated on adding water.



Tetrachlorodimethylquinoxaline, $C_6H_4<\begin{matrix}N:C\cdot CHCl_2\\ \quad | \\ N:C\cdot CHCl_2\end{matrix}$, separates in crystals when tetrachlorodiacetyl (1 mol.) is treated with orthophenylenediamine (1 mol.) in hot aqueous solution. It crystallises from alcohol in small, colourless, nacreous plates, and from benzene in large, well-defined, triclinic plates, $a : b : c = 0·8198 : 1 : 0·9698$; $\alpha = 92° 4'$, $\beta = 121° 56'$, $\gamma = 85° 22'$; it melts at 177°, and distils at a high temperature with partial decomposition. It is readily soluble in hot chloroform, alcohol, and benzene, but only sparingly in the cold solvents and in ether, and is insoluble in water; it dissolves in concentrated sulphuric acid with a yellow coloration

The compound $C_2H_4(NH\cdot CHCl\cdot CO\cdot CO\cdot CHCl_2)_2$ can be obtained by gradually adding an aqueous solution of tetrachlorodiacetyl to an ice-cold aqueous solution of ethylenediamine, but it is best prepared by dissolving the two substances in 95 per cent. alcohol.

and warming until the colour of the solution changes to red. It crystallises from dilute alcohol in colourless, slender needles, melts at 222—223° with decomposition, and is readily soluble in alcohol, ether, chloroform, and benzene, but only sparingly in light petroleum, and almost insoluble in water.

Trichloramidodiacetyl, $CHCl_2\cdot CO\cdot CO\cdot CHCl\cdot NH_2$, prepared by gradually adding ammonia (3—4 c.c.) to a dilute alcoholic solution of tetrachlorodiacetyl (2 grams) and heating the mixture to boiling, crystallises from benzene in colourless needles, melts at 127°, and is readily soluble in alcohol and ether, but only moderately in water or benzene and very sparingly in light petroleum. It has feeble basic properties, and is decomposed by soda with evolution of ammonia. When treated with hydrochloric acid, it is converted into two substances, one of which crystallises in large prisms melting at 157°, the other in small, colourless needles of lower melting point.

Tetrachlorodiacetyldicyanhydrin,

$$CHCl_2\cdot C(OH)(CN)\cdot C(OH)(CN)\cdot CHCl_2,$$

is formed when tetrachlorodiacetyl is heated with excess of concentrated hydrocyanic acid at 30—40° for 4 to 5 hours. The product is extracted with ether, and repeatedly treated with light petroleum to free it from the monocyanhydrin. It separates from a mixture of ether and light petroleum in spherical aggregates, sinters together at about 110°, and melts at about 135—137° with decomposition. It is readily soluble in water, ether, and alcohol, but only sparingly in carbon bisulphide, chloroform, and benzene, and insoluble in light petroleum. It is decomposed when warmed with water at a temperature below 100°. The *diacetyl*-derivative, $C_{10}H_8Cl_4N_2O_4$, prepared by heating the cyanhydrin with acetic chloride, crystallises from dilute alcohol in colourless needles, melts at 163°, decomposes at a higher temperature, and is readily soluble in ether, alcohol, and chloroform, but only sparingly in benzene and boiling water, and insoluble in light petroleum.

The *monocyanhydrin*, $CHCl_2\cdot C(OH)(CN)\cdot CO\cdot CHCl_2$ (see above), crystallises from benzene, in which it is readily soluble, in colourless plates, melts at 110—111°, and decomposes at about 155°.

Tetrachlorodimethyltartarimide, 
$$NH{<}\begin{matrix}CO\cdot C(OH)\cdot CHCl_2\\ |\\ CO\cdot C(OH)\cdot CHCl_2\end{matrix},$$

is obtained, together with a small quantity of a yellowish acid, when the dicyanhydrin (2 grams) is heated at 110° for two hours with 35 per cent. hydrochloric acid (15 c.c.). It separates from a mixture of benzene and ether in dendritic crusts, melts at 239—240°, and is readily soluble in alcohol, ether, and hot water, but almost insoluble in chloroform, benzene, and light petroleum. The *triacetyl*-derivative, $C_{12}H_{11}Cl_4NO_7$, crystallises from dilute alcohol in small, colourless prisms or needles, melts at 176—177° with decomposition, and is readily soluble in alcohol and ether, but only sparingly in hot, and insoluble in cold water.

Tetrachlorodimethyltartaramide,

$$CHCl_2\cdot C(OH)(CONH_2)\cdot C(OH)(CONH_2)\cdot CHCl_2,$$

is formed when concentrated sulphuric acid is gradually added to a concentrated glacial acetic acid solution of the dicyanhydrin, and the mixture warmed gently until the crystals which separate from the solution have redissolved. It crystallises from boiling chloroform in slender, colourless needles, melts at 183°, and is readily soluble in water, alcohol, and ether, but only very sparingly in boiling chloroform, and insoluble in light petroleum. It is converted into the imide by 35 per cent. hydrochloric acid at 110°, or when warmed with sulphuric acid in glacial acetic acid solution.

Tetrachlorhydroxyisobutyramide (m. p. 156°) is best prepared from tetrachloracetonecyanhydrin (Abstr., 1889, 1136), by dissolving the latter in glacial acetic acid, adding concentrated sulphuric acid, and heating to boiling for a few minutes. It crystallises from ether in four-sided pyramids, is readily soluble in alcohol and moderately easily in benzene, but only sparingly in chloroform and insoluble in light petroleum.

The compound $C_4H_4Cl_3NO_2$, probably the amide of trichloropropyleneoxidecarboxylic acid, is obtained when the preceding compound is treated with sodium carbonate in the cold. It crystallises in needles, melts at 127°, and is readily soluble in ether, alcohol, chloroform, and benzene, moderately easily in carbon bisulphide, and sparingly in light petroleum.

Tetrachlorhydroxyisobutyric acid, $OH\cdot C(CHCl_2)_2\cdot COOH$, prepared by heating the amide at 110—120° with hydrochloric acid of sp. gr. 1·16, crystallises from light petroleum in needles, melts at 69—71°, and is readily soluble in water, ether, alcohol, chloroform, and benzene, but only sparingly in carbon bisulphide and light petroleum. The *potassium* salt, $C_4H_3Cl_4O_3K$, crystallises from water in transparent prisms, and is very readily soluble in water, but only sparingly in alcohol; it is decomposed by hot water. F. S. K.

Preparation of Acetic Chloride and Chloracetic Acid. By V. AUGER and A. BÉHAL (*Bull. Soc. Chim.* [3], 2, 144—145).—To prepare acetic chloride, sulphur (1 mol.) or sulphur dichloride (1 mol.) is placed in a flask with glacial acetic acid (2 mols.), and chlorine is passed into the mixture cooled by ice and salt, until no further absorption occurs; after distillation of the resulting product at 60°, and agitation of the distillate with mercury or powdered copper to remove a sulphur compound, subsequent fractionation yields a pure product; 600 grams of acetic acid gave 500 grams of acetic chloride.

Chloracetic acid is obtained under conditions similar to those above, except that the mixture of sulphur and acetic acid is to be boiled; chloracetic acid is obtained in a very pure condition, only traces of acetic chloride and of acetic anhydride being produced; 800 grams of acetic acid yielded, after 12 hours' chlorination, 1000 grams of the monochlorinated derivative. T. G. N.

Action of Triethylamine on Ethyl α-Bromobutyrate, and Ethyl α-Bromopropionate. By M. E. DUVILLIER (*Bull. Soc. Chim.* [3], 2, 139—142; compare Abstr., 1888, 249).—The action of triethylamine (3 mols.) on ethyl α-bromobutyrate (1 mol.) at 100° yielded a considerable amount of α-hydroxybutyric acid, and this was accompanied by a small quantity of butyric and crotonic acids, whilst traces of tetrethylammonium hydroxide were produced.

The substitution of ethyl α-bromopropionate for ethyl α-bromobutyrate determines the production of much lactic acid and of small quantities of tetrethylammonium hydroxide, and of betaïne (1 per cent.), in which latter respect the bromo-derivative differs from the corresponding chloro-compound, from which, under similar conditions, Brühl could not obtain betaine (this Journal, 1876, i, 699).

T. G. N.

Preparation of Alkyl Salts of β-Ketonic Acids. By J. Hamonet (*Bull. Soc. Chim.* [3], 2, 334—337; compare Abstr., 1888, 235).—The product of the action on a normal acid chloride (1 mol.) of sublimed ferric chloride (2 mols.) is poured into cold absolute alcohol, and when the reaction is completed the upper layer of liquid, which contains the salt of the β-ketonic acid, is dried and fractionated.

Propionic chloride yields by this process ethyl α-propiopropionate, a colourless liquid of sp. gr. 0·9987 at 0°, boiling at 196—197°.

Butyric chloride and heptoic chloride, when similarly treated, yield respectively *ethyl α-butyrobutyrate*, boiling at 217—219°, and *ethyl α-heptoheptoate*, boiling at 290—292°.

As ethyl α-butyrobutyrate, when treated by Ceresole's method, yields butyrobutyric acid, whose barium salt decomposes on warming into a carbonate and butyrone, it is to be regarded as a β-ketonate.

Isobutyric acid yielded, by the author's method, valerone and *ethyl valerovalerate*, boiling at 232—234°, and of sp. gr. 0·9492 at 0°.

From a mixture of propionic and butyric chlorides the author obtained, by this method, ethyl propyl ketone, boiling at 122°, and *ethyl α-propiobutyrate*, boiling at 207—209°, and of sp. gr. 0·9884 at 0°.

The theory of the reactions is discussed. T. G. N.

Ethylenelactic Acid from Flesh Extract. By E. Klimenko (*Ber.*, 22, 3182—3183).—The author corrects the statement of Siegfried (*Ber.*, 22, 2711) that he (Klimenko) was unable to isolate an amorphous zinc salt from lactic acid obtained from flesh extract.

F. S. K.

Alkyl Hydrogen Oxalates, Dichloroglycollates, and Chloroxalates: Tetralkyl Oxalates. By R. Anschütz (*Annalen*, 254, 1—42; compare Abstr., 1886, 785 and 1011).—The alkyl hydrogen oxalates gradually undergo spontaneous decomposition into the neutral salt and oxalic acid; they decompose potassium acetate in alcoholic solution, forming alkyl potassium oxalates.

Methyl phenyloxamate, NHPh·CO·COOMe, prepared by heating methyl oxalate with aniline, crystallises from alcohol, in which it is readily soluble, in large, yellowish plates, and from light petroleum in small, colourless needles, melting at 114°. The corresponding *propyl* salt, NHPh·CO·COOPr, crystallises from alcohol in colourless needles, melts at 92°, and is readily soluble in alcohol, but only sparingly in light petroleum. The *isopropyl* salt crystallises from light petroleum in long, white, silky needles and melts at 52°. The *isobutyl* salt forms small, colourless plates, melts at 85°, and is readily soluble in alcohol. The *amyl* salt crystallises from light petroleum in needles, and melts at 50°.

Dimethyl dichloroglycollate, $OMe\cdot CCl_2\cdot COOMe$, prepared by heating methyl oxalate with phosphoric chloride for 12 to 18 hours at 130—135°, and fractionating the crude product under reduced pressure, is a colourless liquid boiling at 179—181° (at 72°, about 12 mm.).

Diisobutyl dichloroglycollate, $C_4H_7\cdot O\cdot CCl_2\cdot COOC_4H_7$, is a colourless liquid boiling at 128° (about 14 mm.).

The alkyl chloroxalates can be obtained by distilling the dialkyl dichloroglycollates under the ordinary pressure.

Methyl chloroxalate, $COCl\cdot COMe$, is best prepared by heating dimethyl dichloroglycollate at 200—215° for 40 hours; it is a colourless liquid boiling at 118—120°.

The corresponding *ethyl* salt, $COCl\cdot COEt$, boils at 135—136° (at 30°, about 10 mm.), the normal *propyl* salt at 153—154° (at 50°, about 12 mm.), the *isobutyl* salt at 163—165° (at 52°, about 10 mm.), and the *amyl* salt at 183—185° (at 68°, about 10 mm.).

Tetralkyl-derivatives of oxalic acid can be obtained by treating the dialkyl dichloroglycollates with sodium compounds of alcohols in alcoholic ethereal solution.

Tetramethyl oxalate, $C(OMe)_3\cdot COOMe$, is a colourless liquid boiling at 75—76° (about 12 mm.). The corresponding *ethyl* salt, $C(OEt)_3\cdot COOEt$, boils at 98° (about 12 mm.), the normal *propyl* salt at 256—257° (at 129—130°, about 12 mm.), the *isobutyl* salt at 146° (about 10 mm.), and the *amyl* salt at 190° (about 10 mm.).

Dimethyl diethyl oxalate, $OMe\cdot C(OEt)_2\cdot COOMe$, is formed when dimethyl dichloroglycollate is treated with sodium ethoxide in ethereal solution; it boils at 90—92° (about 13 mm.). If the reaction is carried out in alcoholic ethereal solution, a liquid boiling at 94·5—96·5° (about 12 mm.), probably methyl triethyl oxalate, is obtained.

When dimethyl dichloroglycollate is heated with oxalic acid at about 50°, carbonic oxide, carbonic anhydride, and hydrogen chloride are evolved, and the residue consists of methyl oxalate; other dialkyl dichloroglycollates could probably be converted into the corresponding alkyl oxalate in like manner.

When tetramethyl oxalate is treated with phosphoric chloride, it is converted into methyl oxalate with evolution of methyl chloride; tetrethyl oxalate yields ethyl oxalate under the same conditions.

F. S. K.

Constitution of Succinic Chloride. By W. O. EMERY (*Ber.*, 22, 3184—3186).—Methyl succinate, prepared by treating succinic chloride with sodium methoxide in ethereal solution, is identical with the compound obtained by heating silver succinate with methyl iodide at 100°; it melts at 19° and boils at 80° (10—11 mm.).

F. S. K.

Substituted Succinic Acids. By C. A. Bischoff (*Ber*., 22. 3179—3180).—The author has hydrolysed a number of ethereal salts of alkyl- and benzyl-isobutenyltricarboxylic acids; two isomeric acids were obtained in every case. A large number of ethereal salts of other unsaturated tricarboxylic acids will be examined in this direction. F. S. K.

Synthesis of Aconitic Acid from Acetylenedicarboxylic Acid. By J. M. Lovén (*Ber*., 22, 3053—3056).—When dibromosuccinic acid is boiled for a long time with a slight excess of alcoholic potash, it is converted into oxalic and aconitic acids.

Acetylenedicarboxylic acid, under the same conditions, gives the same products, so that the bromosuccinic acid is first converted into acetylenedicarboxylic acid; the yield of aconitic acid is 30 per cent. or more of the acetylenedicarboxylic acid employed. F. S. K.

Oxidation of Ketones by Potassium Permanganate in Alkaline Solution. By G. Glücksmann (*Monatsh*., 10, 770—782).—Potassium permanganate has no action on pinacoline in cold or warm neutral solution; but when the ketone (20 parts), suspended in water, is gradually treated with a mixture of potassium permanganate (63 parts) and sodium hydroxide (20 parts), dissolved in water (2 litres), oxidation takes place, the products being the until now unknown *trimethylpyruvic acid*, $C_6H_{10}O_3$, and a little trimethylacetic acid. The new acid crystallises in colourless, irregular-pointed prisms, having a peculiar acid odour, is sparingly soluble in cold, but readily soluble in hot water and in ether, is fairly soluble in benzene, carbon bisulphide, chloroform, and carbon tetrachloride, is volatile in a current of steam, melts at 90—91°, and has the constitution $CMe_3{\cdot}CO{\cdot}COOH$.

With phenylhydrazine, trimethylpyruvic acid forms a compound $C_{12}H_{16}N_2O_2$, which crystallises from dilute alcohol in long, pale-yellow needles, and melts at 157—158° with evolution of carbonic anhydride and formation of aniline. On heating with a 20 per cent. solution of hydrochloric acid, trimethylpyruvic acid is not regenerated, but an aldehyde, probably that of trimethylacetic acid, is the product. The calcium salt of trimethylpyruvic acid, $(C_6H_9O_3)_2Ca + 3H_2O$, is very soluble in water; the sodium salt is anhydrous, and crystallises in long, colourless, rhombic plates; the silver salt, which is also anhydrous, in gleaming scales.

Trimethylpyruvic acid is converted into trimethylacetic acid when oxidised with silver oxide or with potassium dichromate and sulphuric acid. On reduction with eight times its weight of 4 per cent. sodium amalgam it is converted into *trimethylethylidenelactic acid*, $CMe_3{\cdot}CH(OH){\cdot}COOH$, in nearly theoretical quantity. This acid forms colourless, probably monosymmetric crystals ($a : b : c =$ 1·45 : 1 : 1·10, approx.), melts at 87—88°, is readily soluble in water and in ether, and gives copper, silver, and zinc salts, which are not very characteristic.

The oxidation of pinacoline to trimethylpyruvic acid is not in accordance with Popow's rule for the oxidation of ketones, and the author, to explain the reaction, supposes that in the operation an intermediate condensation-product, $CMe_3{\cdot}CO{\cdot}CH{:}CMe{\cdot}CMe_3$, is formed with elimination of 1 mol. of water, and that this condensation-product, on oxidation with 3 atoms of oxygen, is converted into trimethylpyruvic acid and pinacoline, the latter again undergoing the condensation and oxidation processes. The author has also succeeded in obtaining pyruvic acid by the oxidation of acetone with permanganate in alkaline solution, and suggests that the formation of trimethylpyruvic acid from pinacoline may perhaps be a typical reaction. G. T. M.

Isomeride of Tricarballylic Acid. By E. GUINOCHET (*Compt. rend.*, **109**, 906—908).—The action of sodium amalgam on the tribromotricarballylic acid formed by the action of bromine on aconitic acid yields an isomeride of tricarballylic acid. It crystallises in confused, almost opaque, macled prisms, and melts at 181°; carballylic acid melts at 158°, and crystallises in large, perfectly transparent prisms. It is only slightly soluble in water, whilst carballylic acid is very soluble. Its barium salt is crystallisable, anhydrous, and somewhat soluble in water; the calcium salt crystallises, with 12 mols. H_2O, in long, hard, transparent, efflorescent prisms. C. H. B.

Fucusol. By K. BIELER and B TOLLENS (*Ber*, **22**, 3062—3063). —A claim for priority. (Compare Maquenne, this vol., p. 33.)

Constitution of the Aromatic Nucleus. By S. A. SWORN (*Phil. Mag.* [5], **28**, 402—415, and 443—451).—Arguments are brought forward in favour of Thomsen's octahedral formula for benzene (Abstr., 1887, 362), these being chiefly based on the evidence of direct linkage between symmetrically disposed carbon-atoms (para-linkage). In some cases arguments derived from the study of pyridine-derivatives are applied by analogy to the derivatives of benzene, the author considering that this is justified by the result of recent researches. It is first shown that the central nucleus of anthracene is truly aromatic, and that in this nucleus the carbon-atoms are directly linked to one another. The abnormally low molecular volume and absorption of ultra-violet rays by anthracene, the oxidation of anthracene to a substance of the quinone type, and the oxidation of acridine to a quinoline-derivative, are all advanced in favour of the above views. The diketonic nature of quinone and its behaviour on reduction are best explained on the assumption of a para-linkage, the author being of opinion that when a para-linkage is broken the nucleus opens out into a hexagonal ring, and the remaining para-linkages are severed with the formation of olefinic bonds, this view being supported by Baeyer's work on the additive compounds of terephthalic acid. The formulæ of Meyer and Ladenburg represent benzene as containing para-linkages, but the optically active conine would have no asymmetric carbon-atom in the symbol derived from these formulæ, a requirement which is, however, satisfied by that of Thomsen. In the same way, symbols for naphthalene and fluorene cannot be satisfactorily derived from the formulæ of Meyer and Ladenburg, but can be readily deduced from the Thomsen formula.

An objection to the Thomsen formula, which the author himself raises, is that were the configuration of the benzene-molecule as a whole octahedral, we should expect the crystals of benzene to belong to the regular system, whereas they are rhombic. It is considered, therefore, that the above formula requires still further development before it can be brought into accordance with all the facts.

H. C.

Paracyanobenzyl Chloride and its Derivatives. By W. MELLINGHOFF (*Ber.*, **22**, 3207—3217).—*Paracyanobenzyl chloride*, $CN{\cdot}C_6H_4{\cdot}CH_2Cl$, is obtained in a similar manner to orthocyanobenzyl chloride (Gabriel and Otto, Abstr., 1887, 1035), by passing chlorine into paracyanotoluene nearly at its boiling point, until the weight has increased 30 per cent., allowing to cool, and recrystallising the solid portion from alcohol. It forms colourless, well-developed, rhombic prisms, $a : b : c = 0{\cdot}7495 : 1 : 0{\cdot}4314$, melts at 79·5°, boils at 263° (uncorr.), and is sparingly soluble in hot water, more easily in alcohol, ether, chloroform, and benzene.

Paracyanobenzyl cyanide, $CN{\cdot}C_6H_4{\cdot}CH_2{\cdot}CN$, is formed when the above compound is treated with potassium cyanide. It crystallises from alcohol in needles, melts at 100°, boils above 360°, and is slightly soluble in hot water, more readily in alcohol, ether, and chloroform. It is the dinitrile of homoterephthalic acid, into which it may be converted in the manner shown below. There are seven possible intermediate products, all of which have been prepared.

Paracyanophenylacetamide, $CN{\cdot}C_6H_4{\cdot}CH_2{\cdot}CONH_2$, is prepared by warming the dry powdered dinitrile with 38 per cent. hydrochloric acid (15 parts) until effervescence commences. It separates from dilute alcohol in crystals which melt at 196·5 (uncorr.), and is soluble in hot water and alcohol. In addition to this compound, paracyanophenylacetic acid and a substance of unknown constitution, $C_{17}H_{11}N_3$, are also formed.

ω-Chloroparatoluamide, $CONH_2{\cdot}C_6H_4{\cdot}CH_2Cl$, is obtained by allowing paracyanobenzyl chloride to remain with concentrated sulphuric acid in the cold for 12 hours. It is a white, crystalline precipitate, melts at 173° (uncorr.), and is soluble in the common solvents.

ω-Cyanoparatoluamide, $CONH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CN$, is formed by heating the foregoing compound with potassium cyanide. It crystallises from alcohol in small, colourless plates, melts at 182° (uncorr.), and is readily distinguished from the isomeric paracyanophenylacetamide by its appearance.

Paracyanophenylacetic acid, $CN{\cdot}C_6H_4{\cdot}CH_2{\cdot}COOH$, is prepared by heating paracyanobenzyl cyanide with fuming hydrochloric acid until the temperature has reached 105°, and then almost neutralising with ammonia. It forms prismatic crystals melting at 152° (uncorr.), and forms an emerald-green copper salt.

ω-Chloroparatoluic acid, $COOH{\cdot}C_6H_4{\cdot}CH_2Cl$, is formed when ω-chloroparatoluamide is heated with 25 times its weight of officinal hydrochloric acid for 1¼ hours. It crystallises from alcohol in microscopic needles, melts at 199° (uncorr.), and yields a light-brown precipitate with solutions of copper salts.

ω-Cyanoparatoluic acid, $COOH·C_6H_4·CH_2·CN$, is formed from the compound just described by acting on its potassium salt with potassium cyanide. It melts at 201° (uncorr.), and is readily soluble in hot water, alcohol, and ether, less so in cold water.

Homoterephthalamide, $CONH_2·C_6H_4·CH_2·CONH_2$.—To prepare this substance, paracyanobenzyl cyanide is dissolved in 8 parts of cold concentrated sulphuric acid, and allowed to remain for 12 hours; water is then added, and the acid neutralised with ammonia. The amide forms a white precipitate or nodules of crystals, and melts at 235° (uncorr.). It is very sparingly soluble in indifferent solvents, but dissolves readily in concentrated hydrochloric acid.

Homoterephthalamic acid, $COOH·C_6H_4·CH_2·CONH_2$, is obtained from ω-cyanoparatoluic acid by the action of cold concentrated sulphuric acid, and may be purified by crystallisation from alcohol, in which it is sparingly soluble. It melts at 261° (uncorr.), and forms a light-blue copper salt.

Homoterephthalisoamic acid, $CONH_2·C_6H_4CH_2·COOH$, is formed in like manner to the foregoing from paracyanophenylacetic acid. It melts at 229° (uncorr.), and is distinguished from its isomeride by greater solubility in alcohol, and by forming a malachite-green copper salt.

Homoterephthalic acid, $COOH·C_6H_4·CH_2·COOH$, is best obtained from the diamide by heating it for 3—4 hours with 20 parts of 25 per cent. hydrochloric acid, and crystallising the product from dilute alcohol. It dissolves in 7 parts of alcohol at 30°, and in 100 parts of water at 50°, but is almost insoluble in ether and benzene. It melts at 285—288° (uncorr.), and gives with copper salts a verdigris-like precipitate.

The compounds described as homoterephthalic acid by Paternò (*Gazzetta*, **7**, 361), and as insolinic acid by Hofmann (*Annalen*, **97**, 177), probably consist of impure terephthalic acid. H. G. C.

Chloranisoïls. By L. Hugounenq (*Bull. Soc. Chim.* [3], **2**, 273—280).—Chlorine is passed into cold anisoil (432 grams), in the dark, until the weight increases to 680 grams; after washing and subsequent steam distillation, the portion which fractionates at 230—237·5° is retained. This liquid resisted crystallisation, and not until it had been exposed to the cold of a winter's night were acicular crystals obtained, which, after removal of the trichlorinated derivative by pressure, were recrystallised from alcohol. As thus obtained, dichloranisoil melts at 27—28°, but the presence of traces of trichloranisoil reduces the melting point to 16°. From the alcoholic mother liquor, large, orthorhombic prisms of *dichloranisoïl* separate, having the axial ratios $a : b : c = 0·6556 : 1 : 0·5231$. The substance boils at 232—233° under a pressure of 743·45 mm. (corr.); it is soluble in alcohol, ether, benzene, and chloroform, but is insoluble in water. When heated at 145° in sealed tubes with hydriodic acid (sp. gr. 1·7), methyl iodide and dichlorophenol (1 : 2 : 4) were obtained.

Dichloronitroanisoïl is obtained by the action of fuming nitric acid on dichloranisoïl; it crystallises from alcohol in pale, yellowish-green needles, melting at 43·5°.

Trichloranisoïl is formed by passing chlorine into cold anisoïl until the hydrogen chloride evolved and absorbed by cold water equals the weight of anisoïl employed; the product is washed, dissolved in boiling alcohol, and recrystallised, when needles are obtained which melt at 60·5°, are soluble in benzene, chloroform, and carbon bisulphide, and distil at 240° under a pressure of 738·2 mm. (corr.). When heated at 180° in sealed tubes with concentrated hydrochloric acid, or at 140—150° with hydriodic acid, trichlorophenol [1 : 2 : 4 : 6] is produced.

Trichloronitroanisoïl [$OMe : Cl_3 : NO_2 = 1 : 2 : 4 : 6 : 3$], forming long, nacreous needles melting at 48—50°, results from the action of a mixture of sulphuric and fuming nitric acids on the preceding derivative. A *trichlorodinitroanisoïl* [1 : 2 : 4 : 6 : 3 : 5], crystallising in prisms which melt at 90—91°, is formed by the action of nitric and sulphuric acids on trichloroanisoïl at 70—75°.

Tetrachloranisoïl results from the action of chlorine at 70° on anisoïl containing 5 to 6 per cent. of iodine; some pentachloranisoïl is also produced, and may be separated by recrystallisation from hot alcohol. Tetrachloranisoïl crystallises in slender needles, which are soluble in alcohol, ether, chloroform, benzene, and carbon bisulphide; it is sublimable, and boils with partial decomposition at 278° under a pressure of 745·85 mm. (corr.). When hydrolysed by hydrochloric acid at 175°, or by hydriodic acid at 150°, orthotetrachlorophenol, hitherto undescribed, is produced; this substance the author is studying.

Pentachloranisoïl crystallises in long, hard crystals, melts at 107—108°, and is slightly soluble in cold alcohol, easily in benzene, carbon bisulphide, chloroform, and boiling alcohol. Under a pressure of 745·45 mm., it boils at 289° with partial decomposition. When heated with hydriodic acid at 180°, it yields pentachlorophenol.

T. G. N.

Derivatives of Symmetrical Dinitroresorcinol. By F. KEHRMANN (*J. pr. Chem.* [2], **40**, 494—497).—*Chlorodinitroresorcinol* [$(OH)_2 : Cl : (NO_2)_2 = 1 : 3 : 2 : 4 : 6$] is obtained by suspending finely powdered dinitroresorcinol in ether, and passing chlorine, diluted with carbonic anhydride, through the liquid. It forms long, yellow, vitreous prisms melting at 181—182°, and soluble in most solvents. The *neutral potassium salt* was obtained.

The *chlorodiamidoresorcinol stannochloride* is obtained by reducing the nitro-compound with excess of stannous chloride, but attempts to isolate the hydrochloride or base result in the formation of *chloramidohydroxyquinoneimide* [$O : Cl : OH : NH : NH_2 = 1 : 2 : 3 : 4 : 6$], which is best obtained by treating the stannochloride with ferric chloride in aqueous solution; it crystallises in violet needles, and is converted into chlorodihydroxyquinone (next abstract) by dilute potash solution.

A. G. B.

Derivatives of Metadichloroquinone. By F. KEHRMANN and W. TIESLER (*J. pr. Chem.* [2], **40**, 480—494).—Metadichloroquinone is best prepared as follows :—Commercial trichlorophenol (200 grams) is dissolved in sufficient glacial acetic acid at 40—50°, and is mixed with a solution of chromic anhydride (120 grams) in sufficient water to dissolve it and twice that volume of glacial acetic acid. After the mixture has remained at 30—40° for a quarter of an hour, much water is added; this precipitates the metadichloroquinone in yellow needles; it melts at 121°. *Metadichloroquinol*, $C_6H_2Cl_2(OH)_2$, crystallises in flat, long leaflets melting at 164°. The *diacetyl-derivative* forms slender needles melting at 98°, and soluble in the usual solvents.

When alcoholic potash (10 per cent.) is dropped into an alcoholic solution of metadichloroquinone, the liquid becomes first green, and then brownish-red, but as soon as the potash is in excess, the colour begins to fade; red crystals of a potassium salt are then deposited, the yield being 5—6 per cent. of the quinone.

Chlorodiimidoquinol $[(NH)_2 : (OH)_2 : Cl = 1 : 4 : 2 : 5 : 6]$ is prepared by dropping strong ammonia into a saturated (at 50—60°) solution of metadichloroquinone, not more ammonia than one quarter of the volume of the quinone solution being added in all. After half an hour, crystals separate, which are washed with alcohol, and purified by crystallisation from glacial acetic acid; they amount to 20—25 per cent. of the quinone. Chlorodiimidoquinol forms lustrous bronze-coloured, thin, leafy crystals, which sublime without melting, but with partial carbonisation, at 258—260°; it is insoluble in cold water and alcohol, but dissolves partially in hot alcohol with a violet colour; it dissolves in strong hydrochloric and sulphuric acid with a blue colour, and is precipitated on dilution. When heated with dilute acids, it loses nitrogen as ammonia, and is converted into a chlorodihydroxyquinone (see below). When heated with potash solution, it is converted into the red *potassium salt* obtained above; when this is dissolved in water and a slight excess of strong hydrochloric acid added, large, yellow-red, leafy crystals of *chloroparadihydroxyquinone*, $C_6HClO_2(OH)_2$, gradually separate; this quinone melts at 240°. The *ammonium salt* forms an insoluble, brownish-red, crystalline precipitate when ammonium chloride is added to the solution of the potassium salt; the salts of most heavy metals give insoluble brown precipitates under the same circumstances; the *strontium* and *silver* salts are described.

When chlorine, diluted with carbonic anhydride, is passed through a dilute acid solution of chloroparadihydroxyquinone. chloranilic acid is obtained; if bromine be used, bromochloranilic acid is formed.

Iodochlorodihydroxyquinone $[O_2 : (OH)_2 : I : Cl = 1 : 4 : 2 : 5 : 3 : 6]$ is obtained, as a red, crystalline powder, when a strongly acid solution of the chlorodihydroxyquinone is dropped into the calculated mixture of potassium iodide and iodate; it is insoluble in cold water, and is decomposed by hot water; it decomposes at 275°; hot dilute hydrochloric acid converts it into chloranilic acid with separation of iodine.

Nitroso- and nitro-chloranilic acids are obtained respectively when chloroparadihydroxyquinone is treated with nitrous and nitric acids respectively. These acids are still under investigation.

Chloroparadiamidoquinol hydrochloride, obtained by digesting chlorodiimidoquinol with stannous chloride and hydrochloric acid, crystallises in large, colourless, rhombic octahedra or prisms very soluble in water. The free base has not been obtained.

Tetracetylparadiamidochloroquinol, [$(OAc)_2$: $(NHAc)_2$: Cl = 1 : 4 : 2 : 5 : 6], is obtained by heating the above hydrochloride with acetic anhydride and sodium acetate for half an hour and adding water; it crystallises from hot glacial acetic acid in lustrous, white, four-sided tables, melting at 255°, and sparingly soluble.

Chloroparadiacetamidoquinone [O_2 : $(NHAc)_2$: Cl = 1 : 4 : 2 : 5 : 6] is formed when the above tetracetyl-compound is dissolved in dilute alkali, acidified, and ferric chloride added in slight excess. It crystallises in brilliant, golden needles, melts at 225—226°, and is soluble in hot alcohol and glacial acetic acid. When suspended in ether and treated with hydrochloric acid and stannous chloride, *chloroparadiacetamidoquinol* is formed; this crystallises in colourless prisms melting at about 300°, and soluble in hot water, alcohol, and ether.

A discussion of the constitution of some of the foregoing compounds concludes the paper. A. G. B.

Desmotropy in Phenols. By J. Herzig and S. Zeisel (*Monatsh.*, 10, 735—769; compare Abstr., 1888, 822; and 1889, 247 and 966).—On adding bromine to tetrethylphloroglucinol in molecular proportion, half the halogen is converted into hydrogen bromide, and a mixture of two isomeric bromotetrethylphloroglucinols is formed. In this operation it is necessary to brominate a solution in absolute alcohol, the presence of water in the alcohol leading to the formation of dibromotetrethylphloroglucinol. The two isomeric monobromotetrethylphloroglucinols are best separated by fractional crystallisation from petroleum (b. p. 60—90°), in which the α-compound is least soluble, and from which it crystallises in thick quadratic plates $a : b : c = 1{\cdot}0029 : 1 : 1{\cdot}3749$) melting at 85—88°. The β-compound is more soluble, and crystallises in needles melting at 115—118°. If the α-compound is dissolved in cold potash, soda, or ammonia, and, after remaining some time, precipitated with hydrochloric acid, it is converted into the β-compound; the pure β-compound is, however, not always the most stable form, for when a solution in acetic acid is precipitated with water, a mixture of the α- and β-compounds is obtained. If the acetic acid solution is boiled, the conversion of the β- into the α-compound takes place completely, and the same result is produced on boiling a solution of the β-compound in benzene or some other solvent without chemical action on it. Sodium β-bromotetrethylphloroglucinol, $C_{14}H_{20}BrO_3Na$, is obtained in long, colourless crystals, readily soluble in water, on dissolving the β-compound in a small excess of pure caustic soda; the potassium salt much resembles it; the silver salt is crystalline and soluble in water and in alcohol. The α-compound furnishes the same salts.

On heating with acetic anhydride, both α- and β-bromotetrethylphloroglucinol gave the same monacetate, $C_{14}H_{20}BrO_3Ac$, which crystallises in monoclinic prisms ($a : b : c = 1{\cdot}7 : 1 : x$) and melts at

66—68°. When β-potassium bromotetrethylphloroglucinol is heated with an excess of ethyl iodide for three hours, ethyliodotetrethylphloroglucinol, crystallising from petroleum in asymmetric plates ($a:b:c = 1:1{\cdot}0941:0{\cdot}8947$) and melting at 51—53°, is formed. Both α- and β-bromotetrethylphloroglucinol give the same tetrethylphloroglucinol (m. p. 210—212°) on reduction with zinc, and the same dibromide on bromination in dilute alcoholic solution. The dibromide melts at 80—82°, crystallises from dilute alcohol in flat needles of considerable length, contains no hydroxyl-group, and gives, on reduction with zinc and acetic acid, tetrethylphloroglucinol (m. p. 209—211°), and on heating with acetic anhydride, the above described monacetate.

The general behaviour of the isomeric bromotetrethylphloroglucinols leads the authors to attribute the constitution

$$[O : Et_2 : O : Et_2 : O : H,Br = 1 : 2 : 3 : 4 : 5 : 6],$$

to the α-compound, and $[OH : Et_2 : O : Et_2 : O : Br = 1 : 2 : 3 : 4 : 5 : 6]$ to the β-compound; the dibromide produced from both being formed by isomeric change, and represented by the constitution

$$[O : Et_2 : O : Br_2 : O : Et_2 = 1 : 2 : 3 : 4 : 5 : 6].$$

G. T. M.

Constitution of Asarone. By J. F. Eykman (*Ber.*, **22**, 3172—3176).—The vapour-density of asarone, the crystalline constituent of asarum oil, determined under reduced pressure, was found to be 102·9; an optical examination of a mixture of asarone and safrole showed that asarone contains a propenyl- and not an allyl-group. The constitution of asarone is therefore $[(OMe)_3 : C_3H_5 = 1 : 2 : 5 : 4]$, where $C_3H_5 = CH{:}CHMe$.

The liquid constituent of asarum oil is probably a methyl ether of isoeugenol. F. S. K.

New Sugar with an Aromatic Nucleus. By Maquenne (*Compt. rend.*, **109**, 812—814).—A commercial sugar, *pinite*, derived from the resin of the *Pinus lambertiana* of Nebraska, resembles the pinite described by Berthelot which was derived from the same source, but differs from it in melting point and rotatory power. Both are very soluble in water, slightly soluble in alcohol, crystallise in nodules, and have a high rotatory power. Berthelot's pinite has a rotatory power of $[\alpha]_j = +58\ 6$; the new sugar, which the author distinguishes as β-pinite, has a rotatory power $[\alpha]_D = 65°{\cdot}51$ and melts at 186—187° (corr.). It has the same melting point and rotatory power as sennite, and probably is identical with it.

β-Pinite has a composition intermediate between $C_7H_{14}O_6$ and $C_6H_{16}O_7$. When boiled for a short time with fuming hydriodic acid, it yields methyl iodide and a sugar, $C_6H_{12}O_6$, which crystallises in small tetrahedra, melts at 245° (corr.), dissolves very readily in water, and is almost insoluble in alcohol and quite insoluble in ether. Cryometric estimation of its molecular weight gave the numbers 176—178, so that it is isomeric with glucose. When heated with nitric acid, it yields rhodizonic acid, which can be converted into tetrahydroxyquinone by the action of hydrochloric acid. It follows from these results that β-pinite is the methyl salt of the sugar $C_6H_{12}O_6$, and the latter is a benzene-derivative isomeric with inosite; it may be distinguished as β-inosite.

Berthelot's pinite also yields methyl iodide and β-inosite when treated with hydriodic acid. C. H. B.

Lactones derived from Glycines. By P. W. ABENIUS (*J. pr. Chem.* [2], **40**, 498—504: compare Abstr., 1888, 825).—*Glycolylphenylglycine*, $OH·CH_2·CO·NPh·CH_2·COOH$, is prepared by heating chloracetophenylglycocine with aqueous soda for half an hour, adding excess of hydrochloric acid, and extracting with ether; by distilling the ether and crystallising the residue from a mixture of benzene and alcohol, the new glycine is obtained in large, transparent, rhombic tables melting at 127—128°, soluble in water and alcohol, and sparingly in ether and benzene. The *calcium salt* (with 6 mols. H_2O) and the *barium salt* (with 7 mols. H_2O), are described.

Anhydroglycolylphenylglycine,  $NPh<\begin{matrix}CO·CH_2\\CH_2·CO\end{matrix}>O$ (compare Knorr's phenylmorpholine, Abstr., 1889, 1219), is obtained by heating glycolylphenylglycine at 160°; it crystallises from hot alcohol in silky needles which melt at 169° and dissolve with difficulty.

Glycolylphenylglycinamide, $OH·CH_2·CO·NPh·CH_2·CONH_2$, obtained by passing dry ammonia through an alcoholic solution of the last-mentioned compound, crystallises in lustrous leaflets, melts at 128—129° and dissolves easily in water and alcohol, but only sparingly in benzene.

Glycolylorthotolylglycine and anhydroglycolylorthotolylglycine have been described before (Abstr., 1888, 825); the *potassium salt* (with 1 mol. H_2O), the *silver salt*, and the *barium salt* (with 7 mols. H_2O) of the former are here described.

Glycolylorthotolylglycinamide, $OH·CH_2·CO·N(C_6H_4Me)·CH_2·CONH_2$, obtained from the latter in like manner to glycolylphenylglycinamide, crystallises in rhombic tables and melts at 152°. A. G. B.

Metaphenylenediamine from Resorcinol. By A. SEYEWITZ (*Compt. rend.*, **109**, 814—817).—Resorcinol is heated in sealed tubes at 280—300° for three hours with four times its weight of anhydrous (but not fused) calcium chloride, previously saturated with dry ammonia. The product is agitated with twenty times its weight of cold water for ten minutes, filtered, the amine extracted with ether after addition of a slight excess of potassium hydroxide, and the ethereal solution saturated with dry hydrogen chloride, which precipitates crystals of metaphenylenediamine hydrochloride in quantity amounting to about 60 per cent. of the resorcinol taken. No unaltered resorcinol is left in the tube. The amine is not formed below 200°, and even at 250° some resorcinol remains unaltered. Direct experiments show that the maximum yield is obtained by heating for three hours at 300°; longer heating reduces the quantity of diamine obtained. C. H. B.

Condensation-products of Carbodiimides and Orthodiamines. By I. Moore (*Ber.*, 22, 3186—3201; compare Abstr., 1889, 983).—*Dimethyldiphenyldiamidomethyleneorthophenylenediamine*, $C_{19}H_{16}N_4Me_2$, prepared by boiling the phenylene-base with methyl iodide and potash in alcoholic solution, crystallises from alcohol in colourless needles or prisms and decomposes at about 200°, but without melting; it is readily soluble in hot benzene and hot alcohol, but only sparingly in boiling water, and almost insoluble in ether. The *tetranitroso-compound*, $C_{19}H_{12}N_4(NO)_4$, separates in slender needles when the base is treated with sodium nitrite in well-cooled glacial acetic acid solution; it gradually decomposes at about 110°, melts at about 137—138°, and is readily soluble in ether, glacial acetic acid, hot benzene, and alcohol, but insoluble in water. It dissolves freely in warm dilute hydrochloric acid and dilute sulphuric acid, and it gives Liebermann's nitroso-reaction.

Diacetylditolyldiamidomethyleneorthophenylenediamine,

$$C_{21}H_{20}N_4Ac_2,$$

prepared by warming the paratolyl-base (*loc. cit.*) with acetic anhydride, crystallises from warm dilute alcohol in colourless needles, melts at 142—143°, and is readily soluble in alcohol, benzene and ether, but almost insoluble in light petroleum. The *dibenzoyl-derivative*, $C_{21}H_{20}N_4Bz_2$, is obtained when the base is heated with benzoic anhydride at 130—140° for an hour; it crystallises from boiling alcohol in colourless needles or slender prisms, melts at 184—185°, and is readily soluble in hot alcohol and hot benzene, but only sparingly in ether and almost insoluble in light petroleum. The *tetrabenzoyl*-derivative, $C_{21}H_{18}N_4Bz_4$, prepared by heating the base with benzoic anhydride at 240—250° for 2½ hours, crystallises from boiling alcohol in colourless, slender needles, melts at 273—274°, and is readily soluble in boiling cumene, moderately easily in hot alcohol and benzene, and almost insoluble in light petroleum. The *tetranitroso*-derivative, $C_{21}H_{18}N_4(NO)_4$, crystallises in slender, yellow needles, gradually decomposes at about 120° and melts at about 130°; it is readily soluble in alcohol, ether, and warm benzene, but almost insoluble in light petroleum. It gives Liebermann's nitroso-reaction.

Tetraphenyldiamidodimethyleneorthophenylenediamine, $C_{32}H_{26}N_6$, is obtained when diphenyldiamidomethyleneorthophenylenediamine is heated at 200° with carbodiphenylimide. It crystallises in colourless, well-defined rhombic prisms, $a : b : c = 0·6633 : 1 : 0·5685$, melts at 138—139°, and is readily soluble in alcohol, ether, and benzene, but almost insoluble in light petroleum. When distilled, it is decomposed into aniline and diphenyldiamidomethyleneorthophenylenediamine; it is also decomposed by 20 per cent. hydrochloric acid at 150°, yielding diphenylcarbamide and phenylenediamine. The *hydrochloride*, $(C_{32}H_{26}N_6)_2,3HCl$, crystallises in thin, colourless plates and is readily soluble in alcohol and hot water. The *platinochloride* $(C_{32}H_{26}N_6)_4,3H_2PtCl_6$, which crystallises in orange-red plates, is only sparingly soluble in hot alcohol and insoluble in water and ether. The *sulphate*, $C_{32}H_{26}N_6,2H_2SO_4$, crystallises from alcohol in colourless, prismatic needles and is readily soluble in hot alcohol and hot water, but insoluble in ether. The *tetramethyl*-derivative, $C_{32}H_{24}N_6Me_4$, crystallises from warm benzene in colourless, prismatic needles, melts at 181—182°, and is readily soluble in warm alcohol, ether, and benzene, and in mineral acids. The *tetracetyl*-derivative, $C_{32}H_{24}N_6Ac_4$, crystallises from a mixture of benzene and light petroleum in colourless, well-defined prisms, melts at 125—126°, and is readily soluble in alcohol, ether, and benzene, but only sparingly in light petroleum. The *tetrabenzoyl*-derivative, $C_{32}H_{24}N_6Bz_4$, crystallises from hot alcohol in small, colourless needles or prisms, melts at 181—182°, and is readily soluble in hot alcohol and benzene, but only sparingly in ether, and almost insoluble in light petroleum.

Tetraparatolylamidodimethyleneorthophenylenediamine, $C_{36}H_{36}N_6$, can be prepared by heating orthophenylenediamine (1 mol.) with carbodiparatolylimide (1 mol.) at 130—140°, and then adding a further quantity (1 mol.) of the imide and heating again for 3—4 hours at 200°. It crystallises from hot alcohol in colourless needles, melts at 115—116°, and is readily soluble in hot alcohol and benzene, but only very sparingly in ether and light petroleum. It dissolves in concentrated sulphuric acid, yielding a colourless solution, and it is decomposed by 30 per cent. hydrochloric acid at 150°, yielding orthophenylenediamine and diparatolylcarbamide. The *hydrochloride*, $(C_{36}H_{36}N_6)_2,3HCl$, crystallises from dilute hydrochloric acid in colourless, prismatic needles and is readily soluble in alcohol and hot water, but only very sparingly in ether, and insoluble in benzene. The *platinochloride* $(C_{36}H_{36}N_6)_4,3H_2PtCl_6+15H_2O$ separates in orange-red plates when platinic chloride is added to a dilute hydrochloric acid solution of the base; it loses its water at 100° and is insoluble in water, ether, and benzene, but readily soluble in warm alcohol. The *sulphate*, $C_{36}H_{36}N_6,2H_2SO_4$, crystallises in colourless needles and is readily soluble in hot alcohol and hot water, but almost insoluble in benzene and ether. The *tetracetyl*-derivative, $C_{36}H_{32}N_6Ac_4$, separates from benzene in small, granular crystals, melts at 114—115°, and is readily soluble in alcohol, hot benzene, and hot light petroleum, but very sparingly in cold ether. The *tetrabenzoyl*-derivative, $C_{36}H_{32}N_6Bz_4$, crystallises from alcohol in colourless needles, melts at 145—146°, and is readily soluble in hot alcohol, ether, and benzene, but almost insoluble in light petroleum.

F. S. K.

Pentamidobenzene. By A. W. PALMER and C. L. JACKSON (*Amer. Chem. J.*, 11, 448—456; compare Abstr., 1888, 825, and A. Barr, *ibid.*, 822).—*Triamidodinitrobenzene*, $C_6H(NH_2)_3(NO_2)_2$, was prepared by heating tribromodinitrobenzene, melting at 192°, with alcoholic ammonia at 100° under pressure. It was obtained in two forms—in reddish-yellow needles and in black, amorphous masses; it does not melt even above 300°, but is decomposed if heated more intensely, and is insoluble in most ordinary solvents, but dissolves slightly in alcohol and in chloroform, from which solutions it crystallises in small, yellow plates. When reduced with tin and hydrochloric acid, it yields a *trihydrochloride of pentamidobenzene*, $C_6H(NH_2)_2(NH_3Cl)_3$; this crystallises in small, colourless, rhombic plates, turning brown after a time, and forming a tarry substance when heated with hot water or oxidising agents. This substance is sparingly soluble in alcohol, and dissolves easily in water, from which it is precipitated by passing in hydrogen chloride; it is insoluble in ether, benzene, and chloroform. The free base cannot easily be prepared from it. Evidence was also obtained of the formation of a pentahydrochloride of this base. *Trianilidodinitrobenzene*, $C_6H(NHPh)_3(NO_2)_2$, was also prepared by heating aniline with tribromodinitrobenzene; it melts at 179° and crystallises from alcohol in orange-red needles, from ether in groups of short prisms; from solution in benzene or chloroform it is deposited in an amorphous form. It dissolves readily in benzene, chloroform, and hot alcohol, moderately in ether, carbon bisulphide, acetic acid, and acetone. It is not acted on by hydrochloric acid, but dissolves in nitric and sulphuric acids, forming yellow solutions. This research has been discontinued owing to the publication of a paper by Barr on the same subject. C. F. B.

Action of Carbon Bisulphide on certain Azo-compounds and Hydrazones. By P. JACOBSON and V. SCHENCKE (*Ber.*, 22, 3232—3245).—It has previously been shown by Jacobson (Abstr., 1888, 487) that by the action of carbon bisulphide on benzeneazo-β-naphthol, two anhydro-compounds of α-amido-β-naphthol are formed, namely, *thiocarbamidonaphthol*, $C_{10}H_6<\substack{O\\N}>C\cdot SH$, and *carbanilamidonaphthol*, $C_{10}H_6<\substack{O\\N}>C\cdot NHPh$. The authors have examined the action of carbon bisulphide on benzeneazoparacresol, benzeneazopseudocumenol, and benzenedisazoresorcinol, and find that in all these cases the reaction proceeds in a manner exactly analogous to that described above. They have also extended their experiments to the hydrazones of β-naphthaquinone and phenanthraquinone, and show that the same reaction takes place in these cases also. The results obtained form, therefore, a further confirmation of the supposition that the atoms in the characteristic groups of these azo-compounds and orthoquinonehydrazones are combined together in the same manner; whereas, from their modes of formation, it would be expected that the groups would be represented by the formulæ  $\begin{array}{l}\cdot C\cdot OH\\ \;\|\\ \cdot C\cdot N{=}N\cdot Ph\end{array}$ and  $\begin{array}{l}\cdot C{=}O\\ \;|\\ \cdot C{=}N{-}NHPh\end{array}$ respectively. Between the various constitutional formulæ which have been proposed, this reaction, which occurs at a high temperature, cannot of course decide.

In carrying out the reaction, 1 part of the azo-compound or hydrazone is heated with 2—3 parts of carbon bisulphide in a sealed tube for eight hours. The temperature necessary is 190—210°, except in the case of benzenedisazoresorcinol, when the reaction takes place at 150—155°, but proceeds less smoothly than with the other compounds.

The products of the reaction of benzeneazoparacresol and carbon bisulphide are *thiocarbamidocresol*, $C_6H_3Me<\substack{O\\N}>C\cdot SH$, and *carbanil-*

amidocresol, $C_6H_3Me\genfrac{<}{>}{0pt}{}{O}{N}C\cdot NHPh$. The former crystallises from dilute alcohol in colourless, stellar aggregates of needles, melting at 216—217°. The second compound crystallises from the same solvent in long, colourless needles which melt at 205—206°. Its *picrate* melts at 216—217°, and its *acetyl*-compound at 86—87°.

The first product of the reaction of benzeneazopseudocumenol and carbon bisulphide, *thiocarbamidocumenol*, $C_6HMe_3\genfrac{<}{>}{0pt}{}{O}{N}C\cdot SH$, crystallises in colourless needles melting at 252—253°. By the action of iodine on its sodium salt, it is converted into the *bisulphide*, $S_2[C\genfrac{<}{>}{0pt}{}{O}{N}C_6HMe_3]_2$, which separates from chloroform solution in colourless, prismatic crystals melting at 150—151°. The second compound formed, *carbanilamidocumenol*, $C_6HMe_3\genfrac{<}{>}{0pt}{}{O}{N}C\cdot NHPh$, crystallises in broad, colourless needles melting at 145°. Its *picrate* melts at 197—198°.

The products of the reaction of benzenedisazoresorcinol and carbon bisulphide are more difficult to purify than those previously mentioned. The first, *thiocarbodiamidoresorcinol*, $C_6H_2[\genfrac{<}{>}{0pt}{}{O}{N}C\cdot SH]_2$, forms an amorphous, yellowish-white powder, which commences to blacken at 250°, and melts with decomposition at 270°. *Carbanildiamidoresorcinol*, $C_6H_2[\genfrac{<}{>}{0pt}{}{O}{N}C\cdot NHPh]_2$, is likewise an amorphous powder, which blackens at 240°, and melts with complete decomposition at 270°. It unites with 2 mols. of picric acid forming a picrate which melts above 240°.

The two compounds obtained by the reaction of naphthaquinonehydrazone and carbon bisulphide are isomeric with those obtained from benzeneazo-β-naphthol, in which the nitrogen and oxygen atoms are in the α- and β-positions respectively. In the compounds to be described these positions are reversed. *Thiocarbamido-α-naphthol*, $C_{10}H_6\genfrac{<}{>}{0pt}{}{N}{O}C\cdot SH$, crystallises in long, colourless needles, which melt with decomposition at 259—260°, and are readily soluble in warm alcohol, acetic acid, and benzene. It is converted by potassium ferricyanide into the *bisulphide*. The second compound, *carbanilamido-α-naphthol*, $C_{10}H_6\genfrac{<}{>}{0pt}{}{N}{O}C\cdot NH\cdot Ph$, crystallises from chloroform in colourless needles melting at 232—233°, and is easily soluble in benzene, alcohol, and acetic acid. Its *picrate* forms microscopic prisms and melts at 213—214°.

Phenanthraquinonehydrazone and carbon bisulphide.—*Thiocarbamidophenanthrol*, $C_{14}H_8\genfrac{<}{>}{0pt}{}{O}{N}C\cdot SH$, is formed in very small quantity, and is an amorphous, colourless powder. *Carbanilamidophenanthrol*, $C_{14}H_8\genfrac{<}{>}{0pt}{}{O}{N}C\cdot NHPh$, crystallises from glacial acetic acid in pale-yellow needles, united to stellate aggregates, which melt at

192—193°. It is readily soluble in alcohol and benzene, less so in acetic acid, and is resolved by alcoholic potash into aniline, ammonia, carbonic anhydride, and hydrophenanthraquinone. Its *picrate* forms microscopic prisms melting at 235—236°, and its *acetyl*-derivative crystallises in small, colourless plates, and melts at 163—164°.

The hydrazones of orthodiketones (formerly regarded as mixed azo-compounds) do not act in this manner with carbon bisulphide. Parahydroxyazo-compounds are attacked, but resinous products are formed. Azobenzene, on the other hand, is converted at 280—300° into the compound

$C_6H_4<\overset{N}{\underset{S}{}}>C{\cdot}SH$, described by Hofmann (Abstr., 1887, 823).

H. G. C.

Ethylenephenylhydrazine. By O. BURCHARD (*Annalen*, **254**, 115—128; compare Abstr., 1889, 138).—*a*-Ethylenephenylhydrazine (m. p. 90·5°) dissolves in concentrated sulphuric acid, and on adding a trace of nitric acid an intense purple-red coloration is produced. When it is treated with sodium nitrite in dilute hydrochloric acid solution, nitrosoethylenediphenyldiamine (m. p. 160°) is precipitated. The *sulphate*, $C_2H_4(NPh{\cdot}NH_2)_2,H_2SO_4$, crystallises from dilute alcohol in colourless needles, and is only sparingly soluble in alcohol. The *nitrate*, $C_2H_4(NPh{\cdot}NH_2)_2,2HNO_3$, crystallises from alcohol in colourless needles or plates, is readily soluble in water, and melts at 172—173° with decomposition. The *oxalate*, $C_2H_4(NPh{\cdot}NH_2)_2,C_2H_2O_4$, crystallises in needles melting at 183° with decomposition. The *diacetyl*-derivative, $C_2H_4(NPh{\cdot}NHAc)_2$, crystallises from alcohol in slender, colourless needles, melts at 222°, and is readily soluble in glacial acetic acid, but only sparingly in cold alcohol, and insoluble in ether.

Ethylenephenylhydrazinedisuccinic acid,

$$C_2H_4(NPh{\cdot}CO{\cdot}C_2H_4{\cdot}COOH)_2,$$

prepared by heating the hydrazine (1 mol.) with succinic anhydride (2 mols.) in alcoholic solution, separates from dilute alcohol in colourless crystals, melts at 203°, and is almost insoluble in alcohol, but readily soluble in water. The *sodium* salt is crystalline; the *lead* salt separates from hot water, in which it is only very sparingly soluble, in the form of a crystalline powder.

Succinylethylenephenylhydrazine,

$C_2H_4<\begin{matrix}NPh{\cdot}NH{\cdot}CO\\NPh{\cdot}NH{\cdot}CO\end{matrix}>C_2H_4$, is obtained when the hydrazine is heated at about 180° with succinic anhydride. It is a colourless powder, readily soluble in alcohol and chloroform, but insoluble in ether; it has no well-defined melting point, as it begins to sinter together at 100—110°, and only becomes completely liquid at about 126°. When boiled with alcoholic potash, it is converted into a compound, probably ethylenephenylhydrazinesuccinic acid, which has acid properties; this substance is a colourless powder, melts at 137—140° with previous softening, and is readily soluble in alcohol, but only very sparingly in ether and chloroform.

Oxalylethylenephenylhydrazine,

$C_2H_4<\begin{matrix}NPh{\cdot}NH{\cdot}CO\\NPh{\cdot}NH{\cdot}CO\end{matrix}$, prepared by heating the oxalate at about 183°, is a colourless, amorphous powder soluble in alcohol.

Ethylenetriphenylthiosemicarbazide,

$$NHPh\cdot CS\cdot NH\cdot NPh\cdot C_2H_4\cdot NPh\cdot NH_2,$$

separates as an oil when an alcoholic solution of the hydrazine is warmed with phenylthiocarbimide; it crystallises from alcohol in slender needles, melts at 164·5°, and is moderately easily soluble in alcohol.

Ethylenetetraphenyldithiosemicarbazide, $C_2H_4(NPh\cdot NH\cdot CS\cdot NHPh)_2$, is a crystalline powder, melts at 194·5°, and is sparingly soluble in alcohol.

Acetonethylenephenylhydrazine, $CMe_2:N\cdot NPh\cdot C_2H_4\cdot NPh\cdot NH_2$, prepared by boiling the hydrazine with acetone in alcoholic solution, crystallises from alcohol in colourless plates, melts at 71—72°, and has basic properties. The *acetophenone* condensation-product, $C_2H_4(NPh\cdot N:CMePh)_2$, crystallises from alcohol in golden needles, melts at 117—118°, and is only sparingly soluble in alcohol.

Attempts to prepare condensation-products with dialdehydes and diketones were unsuccessful. F. S. K.

Oximes. By H. Goldschmidt (*Ber.*, **22**, 3101—3114).—*Carbanilidobenzaldoxime*, $CHPh:N\cdot O\cdot CO\cdot NHPh$, is obtained when benzaldoxime (1 mol.) is warmed with phenylcarbimide (1 mol.) in benzene solution. It crystallises from benzene, alcohol, and ether in colourless needles, melts at 135—136°, and is decomposed when heated above its melting point, yielding diphenylcarbamide, benzonitrile, water and carbonic anhydride; other carbanilidoximes give analogous decomposition-products under the same conditions. When warmed with alcoholic potash, it is decomposed into benzaldoxime and ethyl phenylcarbamate, and when boiled with alkalis, it yields benzaldoxime and aniline.

Carbanilidoanisaldoxime, $OMe\cdot C_6H_4\cdot CH:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in long needles melting at 82°.

Dicarbanilidosalicylaldoxime,

$$NHPh\cdot CO\cdot ON:CH\cdot C_6H_4\cdot O\cdot CO\cdot NHPh,$$

crystallises from benzene in small scales melting at 115°.

Carbanilidofurfuraldoxime, $C_4H_3O\cdot CH:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in needles melting at 138°.

Carbanilidoacetoxime, $CMe_2:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in needles and melts at 108°.

Carbanilidoacetophenoneoxime, $CMePh:N\cdot O\cdot CO\cdot NHPh$, crystallises in small, colourless needles, and melts at 126°.

Carbanilidobenzophenoneoxime, $CPh_2:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in colourless, microscopic needles melting at 176°.

Carbanilidocarvoxime, $C_{10}H_{14}:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in prisms and melts at 130°. The corresponding derivative of isocarvoxime crystallises from benzene in needles melting at 150°.

Carbanilidocamphoroxime, $C_{10}H_{16}:N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in needles and melts at 94°; it is decomposed when heated at 120—130°, yielding diphenylcarbamide, campholenenitrile, carbonic anhydride, and water.

Propionaldoxime and valeraldoxime combine with phenylcarbimide with development of heat, yielding oily compounds; mesityloneoxime also gives an oily product.

Carbanilidoquinoneoxime, $C_6H_4O{:}N\cdot O\cdot CO\cdot NHPh$, crystallises in short, yellow prisms, begins to decompose at about 110°, and decomposes completely at 160°, but without melting. It is decomposed by boiling alcohol, yielding quinoneoxime, and when treated with alkalis it is decomposed into quinoneoxime, aniline, and carbonic anhydride; other carbanilidoximes of this class show a similar behaviour with alkalis.

Carbanilidothymoquinoneoxime, $C_{10}H_{12}O{:}N\cdot O\cdot CO\cdot NHPh$, crystallises in long, yellow needles melting at 131—132°.

Carbanilido-α-naphthaquinoneoxime, $C_{10}H_6O{:}N\cdot O\cdot CO\cdot NHPh$, crystallises in yellow prisms, begins to decompose at about 160°, and melts at 170°.

Carbanilido-β-naphthaquinone-β-oxime, prepared from β-nitroso-α-naphthol, crystallises from benzene (with benzene) in greenish-yellow, microscopic prisms, and decomposes at 119—120°.

Carbanilido-β-naphthaquinone-α-oxime, prepared from α-nitroso-β-naphthol, crystallises in small, yellow needles and melts at 126—128°.

When β-naphthaquinonedioxime (1 mol.) is warmed with phenylcarbimide (2 mols.) in benzene solution, diphenylcarbamide is precipitated and the solution contains β-naphthaquinonedioxime anhydride (m. p. 78°). Toludiquinoyltetroxime is also converted into the anhydride under the same conditions, the phenylcarbimide being converted into diphenylcarbamide.

Carbanilidoisonitrosobutyl methyl ketone, $COMe\cdot CPr{:}N\cdot O\cdot CO\cdot NHPh$, crystallises from benzene in colourless plates and melts at 92—93°.

Carbanilidomethylpropylglyoxime, $NOH{:}CMe\cdot CPr{:}N\cdot O\cdot CO\cdot NHPh$, is obtained when the preceding compound is treated with hydroxylamine hydrochloride in alcoholic solution; it crystallises from benzene in colourless plates melting at 129—131°.

Dicarbanilidomethylpropylglyoxime,

$$NHPh\cdot CO\cdot O\cdot N{:}CMe\cdot CPr{:}N\cdot O\cdot CO\cdot NHPh,$$

prepared by treating methylpropylglyoxime with phenylcarbimide in benzene solution, crystallises in nacreous plates, melts at 164—170° with decomposition, and is only sparingly soluble in warm benzene.

Carbanilido-α-benzilmonoxime, $COPh\cdot CPh{:}N\cdot O\cdot CO\cdot NHPh$, prepared from α-benzilmonoxime, crystallises from benzene in small prisms, melts at 144°, and is decomposed when warmed with alkalis, yielding aniline and α-benziloxime; it turns yellow on exposure to light.

Carbanilido-γ-benzilmonoxime, prepared from γ-benzilmonoxime, crystallises from benzene, with ½ mol. of benzene, in colourless needles, loses its benzene at 100°, and melts at 143°; it turns yellow on exposure to light, and is decomposed by alkalis, yielding aniline and the γ-oxime.

Dicarbanilido-α-benzildioxime,

$$NHPh\cdot CO\cdot O\cdot N{:}CPh\cdot CPh{:}N\cdot O\cdot CO\cdot NHPh,$$

crystallises in colourless, microscopic plates, melts at 180°, and is only sparingly soluble in the ordinary solvents; it is decomposed by alkalis.

Dicarbanilido-β-benzildioxime crystallises from benzene in small prisms, melts at 187°, and is decomposed by alkalis.

Dicarbanilido-γ-benzildioxime crystallises from benzene in colourless needles containing benzene, and melts at about 175°; when warmed with alkalis, it is decomposed into aniline and benzildioxime anhydride (m. p. 94°).

The fact that all the benziloximes react with phenylcarbimide with equal readiness, yielding compounds of equal stability, is evidence in favour of Auwers' and Meyer's views, namely, that the benziloximes are stereochemically isomeric.

Carbanilidoisobenzaldoxime, $C_{14}H_{12}N_2O_2$, is obtained when isobenzaldoxime (1 mol.) is treated with phenylcarbimide (1 mol.) in ethereal solution, the precipitate quickly separated by filtration, and recrystallised from cold ether. It separates from benzene in colourless needles, and from ether in quadratic plates melting at 94° with decomposition. It is much more readily decomposed by alkalis than its isomeride (see above), yielding diphenylcarbamide, aniline, and isobenzaldoxime; this behaviour is not in accordance with Beckmann's formula for isobenzaldoxime, neither is the fact that carbanilidoisobenzaldoxime readily undergoes intra-molecular change. When a few bubbles of hydrogen chloride are passed into a cold, saturated benzene solution of carbanilidoisobenzaldoxime it is wholly converted into the isomeride (m. p. 135—136°), some of which separates from the solution in crystals; the same change is brought about, but more slowly, by a trace of phenylcarbimide. F. S. K.

Amidoximes and Azoximes. By F. TIEMANN (*Ber.*, 22, 3124—3130).—General remarks on the papers of Wurm (this vol., p. 258), Zimmer (next abstract), Stieglitz (next page), and Koch (this vol., p. 260).

Action of Aldehydes on Benzenylamidoxime. By H. ZIMMER (*Ber.*, 22, 3140—3147).—Tiemann has shown (this vol., p. 44) that acetaldehyde forms a condensation-product with benzenylamidoxime. The author has extended this reaction to other aldehydes.

Benzenylhydrazoximephenylethylidene,  $CPh{<}{\substack{N\cdot O\\ NH}}{>}CH\cdot CH_2Ph$, is formed when phenylacetaldehyde acts on benzenylamidoxime. It forms small, white needles sparingly soluble in boiling water, easily so in ether, chloroform, and benzene, and melts at 136°. Aqueous hydrochloric acid resolves the compound into its components, but dry hydrogen chloride forms with it a crystalline *hydrochloride*. When oxidised with the calculated quantity of potassium permanganate, the hydrazoxime yields *benzenylazoximephenylethenyl*,

$$CPh{<}{\substack{N\cdot O\\ N}}{>}C\cdot CH_2Ph.$$

This is crystalline, insoluble in water, soluble in alcohol and chloroform, sparingly so in ether, and melts at 118°. Neither acids nor alkalis have any action on it.

Benzenylhydrazoximepropylidene, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{NH}>CHEt$, obtained by the action of propaldehyde on benzenylamidoxime, forms colourless crystals sparingly soluble in water, easily so in organic solvents, and melts at 64°. When heated with alkalis or acids, it is resolved into its components. The *hydrochloride* is crystalline. *Benzenylazoximepropenyl*, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{\text{—}N}>CEt$, is a colourless oil boiling at 230—235°. It is soluble in alcohol, insoluble in water. Acids and alkalis are without action on it.

Benzenylhydrazoximeisobutylidene, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{NH}>CH\cdot CHMe_2$, forms silky needles soluble in boiling water, in organic solvents, and in cold concentrated hydrochloric acid. When heated with acids or alkalis, it is resolved into its components. The *hydrochloride* is crystalline. *Benzenylazoximeisobutenyl* is an oil soluble in alcohol, ether, and chloroform, boils at 253—255°, and is indifferent towards acids and alkalis.

Benzenylhydrazoximeisoamylidene, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{NH}>CH\cdot CH_2\cdot CHMe_2$, is sparingly soluble in boiling water, easily so in organic solvents, crystallises in colourless needles, and melts at 83°. It is decomposed by hot acids or alkalis, and forms a crystalline *hydrochloride*. *Benzenylazoximeisoamenyl* is an almost colourless oil of slightly aromatic odour, and is soluble in organic solvents. It boils at 257°, and is indifferent to acids and alkalis.

No analogous hydrazo-compound could be obtained from benzaldehyde, dibenzenylazoxime melting at 107° being at once formed.

Benzenylhydrazoximesalicidene, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{NH}>CH\cdot C_6H_4\cdot OH$, crystallises in colourless needles, and melts at 155°. It is sparingly soluble in water, easily so in organic solvents and in cold alkalis.

Benzenylazoximesalicenyl, $CPh<\genfrac{}{}{0pt}{}{N\cdot O}{\text{—}N}>C\cdot C_6H_4\cdot OH$, is isomeric with Spilker's salicenylazoximebenzenyl, $OH\cdot C_6H_4\cdot C<\genfrac{}{}{0pt}{}{N\cdot O}{\text{—}N}>CPh$ (this vol., p. 143), and resembles it in all its properties. It is, therefore, probable that these two compounds are identical, a molecular rearrangement taking place during one or other mode of formation.

The hydrochlorides of all these hydrazoximes are decomposed by water, and are only formed by the action of dry hydrogen chloride.

L. T. T.

Behaviour of Amidoximes towards Diazobenzene-derivatives. By J. STIEGLITZ (*Ber.*, 22, 3148—3160).—When benzenylamidoxime acts on diazobenzene chloride or sodium diazobenzenesulphonate, diazoamidobenzene and a compound $C_{14}H_{13}N_3O$ are formed. The latter compound seems to be formed from 2 mols. of the amidoxime, the diazo-compound playing the part of determining agent only, probably acting, as it sometimes does, as a mixture of aniline and nitrous acid. The author has obtained the same compound $C_{14}H_{13}N_3O$ by the action of nitrous acid, and of some mild oxidising agents, though the yields were small. This compound *benzenylhydrazoximeamidobenzylidene*, $\mathrm{CPh}<^{\mathrm{N\cdot O}}_{\mathrm{NH}}>\mathrm{CPh\cdot NH_2}$, crystallises in rhombic plates, and melts at 124—125°, being resolved into benzonitrile and benzenylamidoxime. It is insoluble in water, sparingly soluble in ether, moderately so in alcohol, benzene, and chloroform. It has no acid properties, and is only very slightly basic, its unstable *hydrochloride* only being formed when dry hydrogen chloride is passed into a chloroform solution of the base. This salt is soluble in water, but after a time the aqueous solution gradually deposits the free base. It crystallises in colourless, microscopic needles, which melt at 144—145°, and at a few degrees higher temperature decompose into ammonium chloride, dibenzenylazoxime, and small quantities of benzonitrile. The same decomposition takes place very rapidly when the alcoholic solution is boiled. The *platinochloride* forms a pale-yellow precipitate melting at 125·5°, and charring at 130—140°. The *picrate* forms a golden-yellow precipitate, melts at 148—149°, and explodes at a few degrees higher. The free base is not attacked by cold dilute acids or alkalis, but when boiled with alkali is at once resolved into benzonitrile and benzenylamidoxime. When heated with strong aqueous hydrochloric acid at 100°, benzenylamidoxime, benzoic acid, dibenzenylazoxime, and ammonia are formed. Boiling glacial acetic acid, or alcoholic solution of hydrogen chloride, yields dibenzenylamidoxime. The absence of a free oximido-group is shown by ferric chloride giving no coloration. This base is stable towards nitrous acid. Heated with carbon bisulphide at 100°, it yields the compound $C_8H_6N_2S_2$ (Schubart, this vol., p. 49), probably after previous partial decomposition into benzenylamidoxime and benzonitrile. Taking all these facts into consideration, the author considers the above to be its most probable formula.

Orthohomobenzenylhydrazoximeamido-orthohomobenzylidene,

$$\mathrm{C_6H_4Me\cdot C}<^{\mathrm{N\cdot O}}_{\mathrm{NH}}>\mathrm{C(NH_2)\cdot C_6H_4Me},$$

was obtained by the action of sodium diazobenzenesulphonate on orthohomobenzenylamidoxime. It forms colourless, microscopic crystals easily soluble in chloroform, alcohol, and benzene, less so in ether, and insoluble in water and aqueous acids and alkalis. It melts at 109—110°, and although stable at ordinary temperatures, gradually decomposes in hot summer weather into orthotolunitrile and orthohomobenzenylamidoxime. The same decomposition is readily effected by hydrochloric acid at 100°. The author had not enough of this hydrazoxime to prepare *orthohomobenzoyl-orthohomobenzenylamidoxime*, $\mathrm{C_6H_4Me\cdot C(NH_2)\!:\!N\cdot O\cdot CO\cdot C_6H_4Me}$, directly from it, but obtained the latter compound by the action of orthotoluic chloride on orthohomobenzenylamidoxime. It crystallises in long, silky needles resembling asbestos, is easily soluble in alcohol, chloroform, ether, and benzene, and in acids, is almost insoluble in water and alkalis, and melts at

117—118°. At 180° water is given off, and *di-orthohomobenzenylazoxime*,  $C_6H_4Me\cdot C\genfrac{<}{>}{0pt}{}{N\cdot O}{N}C\cdot C_6H_4Me$, is formed. This forms very thin, silky needles exceedingly soluble in alcohol, ether, benzene, and chloroform, and melts at 58—59°. It sublimes unchanged, and volatilises in steam or alcohol vapour.

Metanitrobenzenylhydrazoximeamido-metanitrobenzylidene,

$$NO_2\cdot C_6H_4\cdot C\genfrac{<}{>}{0pt}{}{N\cdot O}{NH}C(NH_2)\cdot C_6H_4\cdot NO_2,$$

was obtained by the action of sodium diazobenzenesulphonate on metanitrobenzenylamidoxime; it is a pale-yellow substance almost insoluble in the usual solvents. It is most soluble (1 : 2000) in alcohol. It melts at 150—151°. When boiled with alkalis, it is decomposed into the nitrile and amidoxime, but a trace of *metanitrobenzenylazoximemetanitrobenzenyl*,  $NO_2\cdot C_6H_4\cdot C\genfrac{<}{>}{0pt}{}{N\cdot O}{N}C\cdot C_6H_4\cdot NO_2$, is also formed. The latter is, however, best obtained by the action of strong cold sulphuric acid on the hydrazoxime. A mixture of metanitrobenzenylamidoxime and metanitrobenzonitrile gave no trace of the azoxime with sulphuric acid. The azoxime may also be obtained from the hydrazoxime by boiling the latter with glacial acetic acid. It forms microscopic, micaceous needles sparingly soluble in cold organic solvents, melts at 168°, and sublimes unchanged. The author obtained the same compound by acting on metanitrobenzenylamidoxime with metanitrobenzoic chloride.

Attempts to get analogous compounds by the action of diazobenzene chloride on compounds of the general formula $NHR\cdot CPh{:}N\cdot OH$ have as yet proved fruitless.

In the course of his work, the author finds that in the action of hydroxylamine on thiamides and thianilides the presence of excess of alkali is an advantage.

Thiobenzorthotoluide, $CSPh\cdot NH\cdot C_6H_4Me$, is formed by fusing benzorthotoluide with phosphoric pentasulphide. It crystallises from benzene in pale-yellow prisms, and melts at 85—86°. When heated with an alcoholic solution of hydroxylamine hydrochloride, it yields *benzenylorthotoluidoxime*, $NOH{:}CPh\cdot NH\cdot C_6H_4Me$. When excess of alkali is present, the reaction is very much accelerated. This compound crystallises in hexagonal prisms, is easily soluble in acids, alkalis, and organic solvents, and melts at 147°. L. T. T.

Constitution of Benzhydroxamic Acid. By G. MINUNNI (*Ber.*, 22, 3070—3071).—The compound $N_2HPh{:}CPh\cdot OH$ is formed when benzhydroxamic acid is heated at 130—140° with phenylhydrazine; it crystallises from dilute alcohol in colourless needles, and melts at 165—166°. The formation of this compound shows that benzhydroxamic acid has the constitution $OH\cdot CPh{:}NOH$. F. S. K.

Oils of Wintergreen and Birch. By H. TRIMBLE and H. J. M. SCHROETER (*Pharm. J. Trans.*; 20, 166—168).—The authors find that the oils of wintergreen and birch are physically and chemically identical, each consisting of methyl salicylate and small quantities of benzoic acid and ethyl alcohol, together with from 0·3 to 0·447 per cent. of a hydrocarbon of the formula $C_{15}H_{24}$. A sample of artificial oil of wintergreen had the physical, but not the chemical properties of these oils, and was not pure methyl salicylate. R. R.

Methysticin. By C. POMERANZ (*Monatsh.*, 10, 783—793; compare Abstr., 1888, 1207, and 1889, 278).—This compound exists in the root of *Macropiper methysticum*, from which it may be best prepared by exhaustion with boiling 80 per cent. alcohol; the solution is concentrated and allowed to remain in a cool place for some days, when a crystalline deposit separates, and this on recrystallisation from boiling alcohol furnishes pure methysticin in the form of inodorous, tasteless, prismatic needles melting at 137°. It has the formula $C_{15}H_{14}O_5$, is insoluble in cold water, only slightly soluble in hot water, light petroleum, and ether, but is readily dissolved by boiling alcohol, and cannot be distilled unchanged. On treatment with potash or soda, the compound is dissolved with formation of the potassium or sodium salt respectively of an acid which the author has named *methysticinic acid.* The free acid, $C_{14}H_{12}O_5$, crystallises in yellow, prismatic needles resembling piperic acid, is sparingly soluble in ordinary solvents, dissolves readily in solutions of the alkalis, melts at 180° with evolution of carbonic anhydride, and is coloured red by a solution of ferric chloride. On oxidation with a solution of potassium permanganate, it is converted into a compound identical with Fittig and Remsen's piperonylic acid, $CH_2{:}O_2{:}C_6H_3{\cdot}COOH$ $[O_2 : COOH = 1 : 2 : 4]$, which melts at 227°, and gives a characteristic calcium salt.

Methysticol is obtained on boiling methysticinic acid with alkalis or dilute acids. It melts at 94°, is insoluble in alkalis, but is readily dissolved by alcohol or ether, crystallises in flat prisms, forms a compound with phenylhydrazine which melts at 143°, and has the formula $C_{11}H_{12}O_3$.

In consideration of its behaviour with potash, methysticin must be regarded as the methyl salt of methysticinic acid, $CH_2{:}O_2{:}C_6H_3{\cdot}C_7H_7O_3$ $[O_2 : C_7H_7O_3 = 1 : 2 : 4]$, the group $C_7H_7O_3$, if methysticinic acid is regarded as a β-ketonic acid, being represented by the chain $—CH{:}CH{\cdot}CH{:}CH{\cdot}CO{\cdot}CH_2{\cdot}COOH$. The author has not succeeded in detecting the least trace of benzoic acid in the oxidation-product of methysticin (compare Nölting and Kopp, *Mon. Sci.*, 1874, 921).

G. T. M.

Tannins. By C. ETTI (*Monatsh.*, 10, 805—806; compare this vol., p. 164).—Since the tannin $C_{16}H_{14}O_9$, obtained from the aqueous extract of the wood of the Slavonian oak, is a dimethoxy-derivative of a ketonic acid formed by the condensation of 2 mols. of gallic acid, each of which has two hydroxyl-groups placed symmetrically to the carboxyl-group; and since the formation of the ketonic acid must be accompanied by the spliting off of a molecule of water from one of the carboxyl-groups, the ketonic acid must have the constitutional formula

$$C_6H_2(\overset{3,\,4,\,5}{OH})_3{\cdot}\overset{1}{C}O{\cdot}C_6H(\overset{2,\,3,\,4}{OH})_3{\cdot}\overset{6}{C}OOH.$$

It has yet to be determined which of the hydroxyl-groups represent the two methoxyl-groups in the tannin. G. T. M.

Ethyl Diphenacylacetoacetate. By C. PAAL and A. HOERMANN (*Ber.*, **22**, 3225—3232).—Paal has previously shown (Abstr., 1884, 598) that ethyl phenacylacetoacetate (ethyl acetophenoneacetoacetate) is converted by dilute aqueous potash into phenacylacetone. In this reaction, a small quantity of a semi-solid insoluble substance is always obtained, consisting of a crystalline mass, saturated with oil. The latter may be removed by extraction with cold alcohol, and the residue recrystallised from the hot liquid. Two kinds of crystals are thus obtained and can be separated mechanically. The compound present in smaller quantity, $C_{16}H_{13}BrO$, does not combine with phenylhydrazine or hydroxylamine, and is very stable towards reducing agents, but the amount obtained was too small for further examination.

The second compound may be obtained pure by recrystallisation from alcohol, and forms large, transparent monosymmetric tables which have the composition $C_{22}H_{22}O_5$, and consist of *ethyl diphenacylacetoacetate*, $CAc(CH_2{\cdot}COPh)_2{\cdot}COOEt$, the ethyl salt of a triketonic acid. It forms large, monosymmetric crystals, $a : b : c = 1{\cdot}6766 : 1 : 1{\cdot}1152$; $\beta = 86° 18'$. It melts at 82—83°, is insoluble in water, sparingly soluble in alcohol, but readily in chloroform, acetic acid, and benzene. With phenylhydrazine, it yields a *dihydrazone*, $C_{34}H_{34}N_4O_3$, which forms yellow, crystalline flocks melting at 88—92°, and readily undergoing decomposition. With hydroxylamine it forms, according to the conditions of the experiment, a *mono-*, *di-*, or *trioxime*; all three are amorphous, soluble in alkalis and most organic solvents, but insoluble in water. The mono- and di-oxime melt at 61—63°, and the trioxime at 66—68°.

The ethyl salt is very stable towards aqueous potash, but is readily converted by alcoholic potash into the potassium salt of diphenacylacetic acid, which is identical with the acid previously obtained by Paal and Kues (Abstr., 1887, 261), and yields, with phenylhydrazine, the same derivative, 1-3-diphenyl-5-phenacyl-6-pyridazonephenylhydrazone,

$N{<}^{NPh{\cdot}CO}_{CPh{\cdot}CH_2}{>}CH{\cdot}CH_2{\cdot}CPh{:}N_2HPh$.

When heated with alcoholic ammonia, diphenylacetic acid is converted into 2 : 6-diphenylpyridine-4-carboxylic acid.

By the action of alcoholic ammonia on ethyl diphenacylacetoacetate, two compounds, melting at 192° and 136° respectively, are obtained, both of which yield one and the same acid on hydrolysis, and appear to be the *amide* and *ethereal salt* of this acid.

H. G. C.

Benzenylazoximemethenylcarboxylic Acid and some of its Derivatives. By A. WURM (*Ber.*, **22**, 3130—3139).—*Ethyl benzenylamidoximeoxalate*, $NH_2{\cdot}CPh{:}N{\cdot}O{\cdot}CO{\cdot}CO{\cdot}OEt$, is obtained as a precipitate or oil when a well-cooled chloroform solution of benzenylamidoxime (2 mols.) is added to a similar solution of ethyl chloroxalate (1 mol.). When this substance is separated from the benzenylamidoxime hydrochloride, simultaneously formed, by boiling with water, and subsequently precipitated from alcoholic solution, it forms small, glistening, white needles which decompose suddenly at 118°. It is insoluble in water, chloroform, and benzene, sparingly soluble in ether, and very soluble in alcohol. When digested for some days with water at 100° or saponified with weak alkali, it yields *benzenylamidoximeoxalic acid*, $NH_2\cdot CPh\colon N\cdot O\cdot CO\cdot COOH$, which crystallises in scales soluble in boiling water, and melts at 159°. When the chloroform filtrate from the oxalate is allowed to evaporate spontaneously, *ethyl benzenylazoximemethenylcarboxylate*,

$CPh\langle{}^{N\cdot O}_{\;N}\rangle C\cdot COOEt$, is obtained. It may also be prepared by heating together benzenylamidoxime and ethyl chloroxalate, and is the substance formed by the sudden decomposition already mentioned of the oximeoxalate; finally it may be prepared by heating the silver salt with ethyl iodide. It crystallises in needles or plates, is moderately soluble in ether and alcohol, readily in chloroform, and very sparingly in cold water. It melts at 51° and distils unchanged at 260°. When hydrolysed, it yields the *free acid*, which crystallises in needles, is soluble in ether and alcohol, sparingly so in cold water, and melts at 98°. It is very slightly volatile in steam, and chars when heated above its melting point. The *potassium* and *calcium salts* are white and crystalline, the *silver* and *lead salts* white powders, the *copper salt* a green powder, and the *methyl salt* (obtained by heating methyl iodide and the silver salt together at 100°) forms pale, silky-white needles which are insoluble in water, but easily soluble in the usual organic solvents; it melts at 38°, and boils at 216°. The *benzyl salt*, obtained by digesting the silver salt with benzyl chloride at 200°, forms long needles soluble in alcohol and ether, insoluble in water; it melts at 105°, turns brown at 210°, and distils with considerable decomposition at 300°. The *amide*, $C_9H_5N_2O_2\cdot NH_2$, is formed when the ethyl salt is digested at 100° with a saturated alcoholic solution of ammonia, or by the action of ammonium carbonate on the chloride. It crystallises in needles insoluble in water and alkali, soluble in organic solvents, and melts at 173°. The *chloride* is prepared by acting on the dry, pure acid with excess of phosphoric oxychloride. It is a clear, limpid liquid with an intensely irritating odour, and boils at 153—155°. It is miscible with chloroform and benzene, is moderately soluble in ether and alcohol, and is heavier than water, in contact with which the chloride is gradually decomposed.

Dibenzenyldiazoximeoxalene,

$CPh\langle{}^{N\cdot O}_{\;N}\rangle C—C\langle{}^{O\cdot N}_{N}\rangle CPh$, is obtained by the action at 40° of the above chloride on the sodium salt of benzenylamidoxime suspended in chloroform. It crystallises in very pale, glistening scales which are soluble in alcohol and ether, sparingly so in chloroform, insoluble in ether, and melt at 142°. It dissolves in boiling water without change, and is tolerably stable towards acids and alkalis. This substance is isomeric with Zinkeisen's oxalenediazoximedibenzenyl (this vol., p. 123), and analogous to the succinic derivative obtained by Schulz (Abstr., 1885, 1219). It is probable that during its formation a transitory, intermediate product,  $\mathrm{CPh}<{}^{\mathrm{N\cdot O}}_{\mathrm{N}}>\mathrm{C\cdot CO\cdot O\cdot NMe\cdot CPh}$, is formed.

L. T. T.

Action of Ethyl Chloracetate on Benzenylamidoxime. By H. Koch (*Ber.*, **22**, 3161—3163).—When ethyl chloracetate (1 mol.) is gradually added to an alcoholic mixture of benzenylamidoxime (1 mol.) and sodium ethoxide (2 mols.), and the whole boiled for three hours, *sodium benzenylamidoximeglycollate* is obtained. This forms white crystals very soluble in water, moderately so in alcohol. Acids liberate from this salt *benzenylamidoximeglycollic acid*,

$$NH_2\cdot CPh\colon N\cdot O\cdot CH_2\cdot COOH.$$

It crystallises in white needles, melts at 123—124°, and is easily soluble in alcohol and ether, sparingly in water. It has both acid and basic properties, dissolving readily in acids and in bases, but its aqueous solution has a strongly acid reaction. When a solution of the acid in hydrochloric acid is boiled for some time the, *anhydride*,  $\mathrm{CPh}<\begin{matrix}\mathrm{N\cdot O\cdot CH_2}\\ \mathrm{NH\cdot CO}\end{matrix}$, is formed. This internal anhydride is, however, best obtained by heating the acid for some hours at 130—140°. It is easily soluble in alcohol, ether, glacial acetic acid, and boiling water; crystallises in colourless needles, and melts at 148°. It has no longer basic properties, but is still a strong acid, and yields well-developed salts. It is very stable, not being affected by bromine-water or sodium nitrite. Permanganates and analogous oxidising agents readily attack it, benzonitrile being formed. It appears to be analogous in composition and character to benzenylimidoximecarbonyl, $\mathrm{CPh}<{}^{\mathrm{N\cdot O}}_{\mathrm{NH}}>\mathrm{CO}$.

L. T. T.

Oxidation of Paratolyl Benzyl Ketone. By E. Bucher (*Chem. Centr.*, 1889, ii, 445; from *Arch. sci. phys. nat. Genève*, **22**, 75—76).—The usual oxidising agents split up the paratolyl benzyl ketone molecule; if, however, certain of its bromine-derivatives are heated with water at 180°, better results are obtained. By treating the ketone with bromine in carbon bisulphide, the author has obtained the five bromine substitution-derivatives: *paratolyl bromobenzyl ketone*, $CHPhBr\cdot CO\cdot C_6H_4Me$, melting at 79°; *paratolyl dibromobenzyl ketone*, $CPhBr_2\cdot CO\cdot C_6H_4Me$, melting at 128·5°; *bromoparatolyl dibromobenzyl ketone*, $CPhBr_2\cdot CO\cdot C_6H_4\cdot CH_2Br$, melting at 127°; *dibromoparatolyl dibromobenzyl ketone*, $CPhBr_2\cdot CO\cdot C_6H_4\cdot CHBr_2$, melting at 120°; and *tribromoparatolyl dibromobenzyl ketone*, $CPhBr_2\cdot CO\cdot C_6H_4\cdot CBr_3$, melting at 124°. By heating the dibromo-derivative with water in a sealed tube, the diketone, $COPh\cdot CO\cdot C_6H_4Me$, is obtained, and from the pentabromo-derivative the *diketonic acid*, $COPh\cdot CO\cdot C_6H_4\cdot COOH$, may be prepared by the same treatment.

J. W. L.

Azo-colours from Naphtharesorcinol. By S. v. Kostanecki (*Ber.*, **22**, 3163—3168).—Believing that Zincke and Thelen's hydroxynaphthaquinonehydrazine (Abstr., 1884, 1359) was really a naphtharesorcinol-derivative, analogous to the nitroso-derivatives lately described by himself, the author has re-examined it. He finds that when heated with acetic anhydride and dry sodium acetate for a few minutes, or even if digested with excess of acetic anhydride for some hours, a *diacetyl-derivative*, $N_2Ph{\cdot}C_{10}H_5(OAc)_2$, is formed. This crystallises from alcohol in needles melting at 122—123°. The formation of only a monacetyl-derivative was one of the chief reasons for Zincke and Thelen's formula, and taking this and its general behaviour into consideration, the author believes this compound to be really phenylazonaphtharesorcinol, $C_{10}H_5(OH)_2{\cdot}N_2Ph$.

When this compound is dissolved in a little alkali, the requisite quantity of sodium nitrite added, and the mixture poured into dilute hydrochloric acid, *nitrosophenylazonaphtharesorcinol*,

$$N_2Ph{\cdot}C_{10}H_4(ON{\cdot}OH){\cdot}OH,$$

is formed. This crystallises in glistening, brownish-red scales, easily soluble in glacial acetic acid, but very sparingly in alcohol and boiling water and alkalis. It dissolves in concentrated sulphuric acid to a dark-green solution; it decomposes at 175°. It dyes mordanted stuffs, but much less intensely than nitrosophenylazoresorcinol. When reduced with tin and hydrochloric acid, it yields amidonaphthalic acid and aniline. This proves that the isonitroso-group has taken the remaining β-position in the nucleus.

When phenylazonaphtharesorcinol is dissolved in excess of alkali, and diazobenzene chloride added, *diphenyldisazonaphtharesorcinol*, $C_{10}H_4(N_2Ph)_2(OH)_2$, is formed. This crystallises in long, red needles, and is insoluble in alkalis, but soluble in chloroform and alcohol; it melts with decomposition at 225°. When reduced with tin and hydrochloric acid, it yields amidonaphthalic acid and aniline, like the above nitroso-compound, and has thus the composition

$$[(N_2Ph)_2 : (OH)_2 = 1 : 3 : 2 : 4].$$

It is very similar in appearance and character to the analogous resorcinol-derivative. L. T. T.

Oil of Camphor. By J. TRIMBLE and H. J. M. SCHROETER (*Pharm. J. Trans.*, **20**, 145—148).—A sample of the crude oil of camphor, as obtained from Japan, was found to have a reddish-brown colour, sp. gr. 0·9632 at 16°; it boiled at 180°. The odour resembled that of camphor and sassafras. By fractional distillation, &c., the following definite constituents were isolated from the sample:—

Formula.	Boiling point.	Per cent.
$C_{10}H_{16}$	150°	0·40
$C_{10}H_{16}$	159	12·00
$C_{10}H_{16}$	168	13·00
$C_{10}H_{16}$	171	5·00
$C_{10}H_{18}O$	176	15·00
$C_{10}H_{16}$	180	4·00
$C_{10}H_{18}O$	204	10·00
$C_{10}H_{18}O_2$	213	30·00
$C_{10}H_{10}O_2$	232	7·00
$C_{10}H_{12}O_2$	247	2·00

The highest-boiling fraction (250—280°; 1·60 per cent.) was a bluish-green oil; the quantity was insufficient to ascertain if it was a definite substance.

These compounds were fragrant oils, usually colourless, and having high dextro-rotatory powers. The authors also experimented on seven other samples of oil of camphor, which differed considerably from the former in physical properties, and also in the proportionate amounts of the several fractions, some of these being indeed entirely wanting in certain samples (compare Yoshida, Trans., 1885, 779).

R. R.

Strophanthus Hispidus. By T. R. FRASER (*Pharm. J. Trans.* [3], **20**, 328—335).—This paper is a very detailed account of pharmacological processes and of the reactions of the various extracts obtained from seeds and other parts of Strophanthus. The main results of the author's investigations have already appeared (Abstr., 1888, 606).

Strophanthin melts at 172·5°, dissolves in 55 parts of absolute alcohol, 300 parts of acetone, and 1000 parts of amyl alcohol, and is only very slightly hydrolysed by ptyalin. Strophanthidin is physiologically extremely active. R. R.

Sénégin, from Polygala senega, L. By A. FUNARO (*J. Pharm.* [5], **20**, 450—453; from *Gazzetta*, **19**, 21).—Sénégin, extracted by Gelhen in 1804, was found by Quevenne to yield a white powder, which he named *polygalic acid*. Bolley, in 1855, concluded that these two substances were identical, and also the same as *saponin*, obtained by Bussy from the root of Saponaria. The author finds five samples of sénégin to give a mean of C = 54·13; H = 7·45; but these amounts differ notably from Bolley and Quevenne's figures, and also from the results published by Rochleder and by Christophson for saponin. On boiling sénégin with dilute acids, glucose is formed, and a gelatinous substance separates, containing C = 62·26, H = 8·21. These figures are very wide of those obtained for sapogénin, prepared in a crystalline form by Rochleder. The formation of *sénégénin*, $C_{40}H_{32}O_{14}$, and glucose from sénégin is represented as follows: $C_{64}H_{104}O_{34} + 4H_2O = C_{40}H_{64}O_{14} + 4C_6H_{12}O_6$.

The author evidently considers that saponin and sénégin are different compounds, although closely related. J. T.

Pyrroline derivatives. By C. PAAL and N. P. BRAIKOFF (*Ber*, 22, 3086—3096).—*Ethyl orthotolyldiphenylpyrrolinecarboxylate*,

$$[C_6H_4Me : COOEt : Ph_2 = 1 : 3 : 2 : 5],$$

prepared by boiling ethyl phenacylbenzoylacetate with orthotoluidine in glacial acetic acid solution, crystallises from alcohol in long, colourless needles, melts at 134—135°, and is readily soluble in alcohol, ether, glacial acetic acid, and benzene. The corresponding *acid*, $C_{24}H_{19}NO_2$, obtained by hydrolysing the ethyl salt with alcoholic potash, crystallises from hot alcohol in colourless scales, melts at 226—227°, sublimes undecomposed, and is only moderately easily soluble in ether, alcohol, and benzene.

Orthotolyldiphenylpyrroline, $C_{23}H_{19}N$, is obtained by distilling the acid over lime; it crystallises from alcohol in flat, colourless needles, melts at 114—115°, boils above 300° without decomposition, and is readily soluble in most organic solvents.

Ethyl paratolyldiphenylpyrrolinecarboxylate crystallises from glacial acetic acid in slender, colourless needles, melts at 145°, and is readily soluble in hot alcohol, benzene, and ether, but only sparingly in light petroleum. The *acid* crystallises from hot glacial acetic acid in small, colourless plates, melts at 205—206°, sublimes without decomposition, and is readily soluble in boiling nitrobenzene, but only sparingly in ether, alcohol, and benzene, and insoluble in light petroleum.

Paratolyldiphenylpyrroline can be prepared, as described in the case of the corresponding ortho-compound; it crystallises from glacial acetic acid in colourless needles, boils without decomposition, and is identical with the substance obtained by Baumann (Abstr, 1887, 736), by distilling paratolylpyrrolinedibenzoic acid over baryta.

Ethyl metaxylyldiphenylpyrrolinecarboxylate $[C_6H_3Me_2 : COOEt : Ph_2 = 1 : 3 : 2 : 5]$, prepared by boiling ethyl phenacylbenzoylacetate with metaxylidine in glacial acetic acid solution, is a thick oily compound. The *acid*, $C_{25}H_{21}NO_2$, crystallises from glacial acetic acid in colourless needles, melts at 253—254°, sublimes undecomposed, and is moderately easily soluble in hot alcohol and benzene.

Metaxylyldiphenylpyrroline, $C_{24}H_{21}N$, crystallises in short, colourless needles, melts at 147—149°, distils without decomposition, and is soluble in most organic solvents.

Ethyl α-naphthyldiphenylpyrrolinecarboxylate, $C_{29}H_{23}NO_2$, crystallises in colourless needles or plates, melts at 181—182°, and is readily soluble in hot alcohol and glacial acetic acid, but only moderately easily in benzene. The *acid*, $C_{27}H_{19}NO_2$, crystallises from glacial acetic acid in colourless plates, melts at 271·5—272°, sublimes undecomposed, and is sparingly soluble in boiling alcohol and benzene, and insoluble in light petroleum. The *potassium* salt is sparingly soluble in boiling water and insoluble in concentrated potash.

α-Naphthyldiphenylpyrroline, $C_{26}H_{19}N$, crystallises from hot alcohol in small, yellowish needles, melts at 148—149°, distils without decomposition, and dissolves freely in most organic solvents when warmed therewith.

Ethyl β-naphthyldiphenylpyrrolinecarboxylate, crystallises from hot alcohol and glacial acetic acid in small, colourless needles melting at

181—182°. The *acid* is obtained by boiling the ethereal salt for a long time with a large excess of alcoholic potash; it crystallises from hot glacial acetic acid in colourless plates, melts above 350°, sublimes undecomposed, and is only sparingly soluble in all ordinary solvents.

β-Naphthyldiphenylpyrroline forms flat, colourless needles or long plates, melts at 207—208°, and is soluble in hot alcohol, glacial acetic acid, and benzene.

Ethyl orthohydroxyphenyldiphenylpyrrolinecarboxylate,

$$OH{\cdot}C_6H_4{\cdot}C_4NHPh_2{\cdot}COOEt,$$

prepared by boiling ethyl phenacylbenzoylacetate with orthamidophenol in alcoholic solution, separates from alcohol or acetic acid in colourless, indented crystals, melts at 158—159°, and is soluble in alkalis and all organic solvents. The *acid*, $C_{23}H_{17}NO_3$, crystallises from glacial acetic acid in colourless, ill-defined needles, melts at 244—245°, sublimes without decomposition, and is readily soluble in ether, alcohol, and glacial acetic acid, but only sparingly in benzene, chloroform, and light petroleum.

Orthohydroxyphenyldiphenylpyrroline, $C_{22}H_{17}NO$, crystallises from glacial acetic acid in yellowish needles, melts at 175—176°, and is readily soluble in ether, alcohol, benzene, and alkalis.

Ethyl paraphenylenedi-diphenylpyrrolinecarboxylate,

$$C_6H_4(C_4NHPh_2{\cdot}COOEt)_2,$$

crystallises from alcohol in yellowish scales, melts at 249—250°, and is soluble in glacial acetic acid and benzene. The *acid*, $C_{40}H_{28}N_2O_4$, separates from hot alcohol in small crystals, melts above 300°, sublimes undecomposed, and is moderately easily soluble in alcohol and glacial acetic acid, but only sparingly in benzene and light petroleum.

F. S. K.

Action of Hydroxylamine on Pyrrolines. By G. CIAMICIAN and C. U. ZANETTI (*Ber.*, **22**, 3176—3179; compare Abstr., 1889, 1208).—Acetonylacetoxime, $NOH{:}CMe{\cdot}CH_2{\cdot}CH_2{\cdot}CMe{:}NOH$ (m. p., 136·5°, corr.), identical with the compound prepared by Pual (Abstr., 1885, 505), is formed when 2 : 5-dimethylpyrroline is boiled for about six hours with hydroxylamine hydrochloride and sodium carbonate in alcoholic solution. This reaction tends to prove that the compound (m. p., 173°) obtained by treating pyrroline with hydroxylamine (*loc. cit.*) is, in reality, the oxime of succinaldehyde.

When acetonylacetoxime is reduced with sodium and alcohol, it is converted into a *base*, the hydrochloride of which is a colourless, crystalline compound, and has the composition $C_6H_{16}N_2,2HCl$. This base has the same composition as the diamidohexane obtained by Tafel (Abstr., 1889, 976) by reducing the dihydrazone of acetonylacetone.

With hydroxylamine metadimethylpyrroline yields a compound which is soluble in water, and has powerful reducing properties; this new substance is converted into a base $C_6H_{16}N_2$ when it is reduced with sodium and alcohol.

F. S. K.

Derivatives of 1-Hydroxyquinoline. By E. LIPPMANN and F. FLEISSNER (*Monatsh.*, **10**, 794—797).—Amidohydroxyquinoline has been isolated by Fischer and Renouf (Abstr., 1884, 1370), but may be more conveniently prepared from the corresponding nitroso-compound, which is obtained as hydrochloride by adding sodium nitrite (25 grams) to hydroxyquinoline (50 grams) in an aqueous solution containing hydrochloric acid (100 grams). The hydrochloride of the nitroso-compound forms an orange-coloured, crystalline mass, which is only slightly soluble in water, but more soluble in dilute hydrochloric acid; it is decomposed on boiling its aqueous solution, but may be obtained in yellow- or brownish-coloured scales or needles by very careful recrystallisation. With sodium acetate, it gives a gelatinous precipitate which becomes crystalline on standing. Nitrosohydroxyquinoline, $NO\cdot C_9NH_5\cdot OH$ [= 4 : 1], crystallises from alcohol in pale-yellow or greenish needles, only slightly soluble in benzene, ether, and chloroform, and decomposes on heating to 230°. The *platinochloride*, $(C_9H_6N_2O_2)_2,H_2PtCl_6$, crystallises in brown, glistening scales, and is decomposed on boiling with water. In order to determine the relation of the nitroso-group to the hydroxyl-group, the authors converted it by means of nascent hydrogen into amidohydroxyquinoline, which, on oxidation with potassium dichromate and sulphuric acid, and reduction with sulphurous anhydride, furnished quinol. If the reduction is brought about by means of tin, added a little at a time to a solution of the nitroso-compound in hydrochloric acid, a violent reaction ensues, and a crystalline double salt is obtained. On freeing this from tin by hydrogen sulphide, and adding to the solution sodium acetate, a *dichloramidohydroxyquinoline*, $C_9NH_3Cl_2(NH_2)\cdot OH$, separates out as a white, crystalline mass, whilst amidohydroxyquinoline remains in solution. The dichloro-derivative crystallises from alcohol, benzene, or chloroform in slender, white, silky needles, which decompose at 160°, and furnishes a hydrochloride crystallising from dilute hydrochloric acid in yellow needles, and readily decomposed by boiling water. If stannous chloride is substituted for the metal, amidohydroxyquinoline is the sole reduction-product, and from this a dihydroxyquinoline sulphate decomposing at 220°, and identical with the compound described by Fisher and Renouf (*loc. cit.*), may be obtained. It must, therefore, be concluded that the nitroso-compound contains the nitroso-group in the para-position relatively to the hydroxyl-group. G. T. M.

Bromoquinolinesulphonic Acids. By A. CLAUS (*J. pr. Chem.* [2], **40**, 444—447).—Bromoquinolinesulphonic acids may be obtained: (1) By synthesis from bromamidobenzenesulphonic acid; (2) by brominating quinolinesulphonic acids; (3) by sulphonating bromoquinolines; (4) by substituting bromine for a hydroxyl-, amido-, &c., group in a hydroxy-, amido-, &c., quinolinesulphonic acid. Of these four possible methods, the third gives the best results. The orientation of the acid is settled by treatment with tin and hydrochloric acid (Lellmann, Abstr., 1888, 296), which produces a hydroquinolinesulphonic acid. The hydroquinolinesulphonic acids are being investigated in the author's laboratory.

Hydroquinoline-4-sulphonic acid crystallises in large, rhombic tables, or monoclinic leaflets, which begin to melt at 318° (uncorr.) with decomposition.

Hydroquinoline-1-sulphonic acid crystallises in pointed needles, and decomposes at 243° (uncorr.).

Hydroquinoline-3-sulphonic acid forms characteristic, glassy, short, monoclinic prisms, the measurements of which are given. It decomposes at 277° (uncorr.).
A. G. B.

Sulphonic Acids of 4′-Bromoquinoline. By A. CLAUS and W. SCHMEISSER (*J. pr. Chem.* [2], **40**, 447—454).—4′ : *4-Bromoquinolinesulphonic acid* is obtained by heating 4′-bromoquinoline with sulphuric acid for some time at 250°—300°; it crystallises from alcohol in beautiful, silky needles, and from water both in long, slender needles (with $1\frac{1}{2}$ mols. H_2O), and in large, anhydrous prisms which become needles when recrystallised from hot water. It is insoluble in ether, decomposes above 300° without melting, and is stable in alkaline solutions. When treated with tin and hydrochloric acid, it is converted into hydroquinoline-4-sulphonic acid. The *potassium salt* (with 1 mol. H_2O), the *sodium salt*, the *calcium salt* (with 7 mols. H_2O), the *barium salt* (with 3 mols. H_2O), the *copper salt* (with 7 mols. H_2O), and the *silver salt* are described. The *ethyl salt* forms transparent needles melting at 125° (uncorr.). The *chloride*, $C_9NH_5Br{\cdot}SO_2Cl$, crystallises from chloroform in needles, and from ether in thick prisms, which melt at 82° (uncorr.). The *amide* forms small, slender needles melting at 255° (uncorr.).

4′ : *2-Bromoquinolinesulphonic acid* is formed, together with the above 4-sulphonic acid, when 4′-bromoquinoline (1 part) is heated with sulphuric acid (5 parts) containing 30—40 per cent. of sulphuric anhydride for about an hour on the water-bath. If the heating is longer, or the temperature higher, the 2-sulphonic acid is converted into the 4-sulphonic acid. The two acids are separated by crystallising from water, and treating with 96 per cent. alcohol, when the 4-sulphonic acid dissolves. 4′ : 2-Bromoquinolinesulphonic acid crystallises in colourless, rhombic tables, which are sparingly soluble in cold water and insoluble in other solvents; it can be heated to 300° without melting or decomposing. It is not acted on by hot alkalis. Tin and hydrochloric acid convert it into a hydroquinolinesulphonic acid which melts at 255°, and has not yet been described; it is probably *hydroquinoline-2-sulphonic acid*. The *sodium salt*, the *potassium salt* (with 1 mol. H_2O), the *barium salt* (with 1 mol. H_2O), the *calcium salt* (with 4 mols. H_2O), the *copper salt* (with 1 mol. H_2O), and the *silver salt* are described. The *ethyl salt* forms short, needle-shaped crystals melting at 100° (uncorr.). The *chloride*, $C_9NH_5Br{\cdot}SO_2Cl$, crystallises from chloroform in colourless needles, and from alcohol in beautiful, lustrous leaflets; it melts at 130° (uncorr.). The *amide* crystallises from hot water in small, white, slender needles melting at 213° (uncorr.), and soluble in alcohol.

When these two acids are brominated, they yield different tribromoquinolines. The 2-sulphonic acid yields a tribromoquinoline

which crystallises in colourless, lustrous prisms melting at 171° (uncorr.); while the 4-sulphonic acid yields a tribromoquinoline which crystallises in slender, colourless needles melting at 300° (uncorr.).
A. G. B.

Sulphonic Acids of 4-Bromoquinoline. By A. Claus and O. Würtz (*J. pr. Chem.* [2], **40**, 454—460).—When 4-bromoquinoline (1 part) is heated in a flask with sulphuric acid containing 30 per cent. of sulphuric anhydride (5 parts) at 130—140° for 6—8 hours, the 1- and 3-sulphonic acids of 4-bromoquinoline are obtained, the former in considerable quantity, the latter in small quantity. They are separated by crystallising from water, when the 1-sulphonic acid crystallises first. At higher temperatures, disulphonic acids are produced at the same time.

4 : 1-*Bromoquinolinesulphonic acid* crystallises (with 2 mols. H_2O) in colourless, lustrous needles or prisms which dissolve in hot water, but not in cold water or in alcohol. The anhydrous acid is unchanged below 300°. When reduced by tin and hydrochloric acid, it yields hydroquinoline-1-sulphonic acid. The *sodium salt* (with 2 mols. H_2O), the *potassium salt* (with 2 mols. H_2O) the *calcium salt* (with 4 mols. H_2O), the *barium salt* (with 3 mols. H_2O), the *copper salt* (with 5 mols. H_2O), the *silver salt*, and the *lead salt* are described. The *ethyl salt* melts at 110° (uncorr.). The *chloride*, $C_9NH_5Br{\cdot}SO_2Cl$, crystallises from ether in small, colourless prisms, and from alcohol in tables; it melts at 125° (uncorr.). The *amide* forms small needles melting at 205° (uncorr.), and soluble except in water.

4 : 3-*Bromoquinolinesulphonic acid* crystallises in small, lustrous, colourless, anhydrous needles soluble in alcohol and in water. The *sodium salt* (with 1 mol. H_2O), the *calcium salt* (with 7 mols. H_2O), and the *barium salt* (with 2 mols. H_2O) are described. The *ethyl salt* melts at 130° (uncorr.); the *chloride* melts at 95° (uncorr.); the *amide* forms small, dark-yellow crystals melting at 195° (uncorr.).

When the acid is reduced with tin and hydrochloric acid, it yields hydroquinoline-3-sulphonic acid (?) melting at 171°; and when brominated, it yields a tribromoquinoline melting at 248° (uncorr.).
A. G. B.

3 : 1-Bromoquinolinesulphonic Acid and 4 : 3-Nitrobromoquinoline. By A. Claus and G. Zuschlag (*J. pr. Chem.* [2], **40**, 460—464).—La Coste (Abstr., 1883, 96) obtained several sulphonic acids by sulphonating parabromoquinoline. The authors, using fuming sulphuric acid (30 per cent. sulphuric anhydride) at 120—125°, only obtained one sulphonic acid.

3 : 1-*Bromoquinolinesulphonic acid* crystallises in beautiful, lustrous, white needles and prisms, which are anhydrous, do not melt at 350°, and are moderately soluble in hot water. The *potassium salt* (with 1 mol. H_2O) and the *silver salt* are described; the *ethyl salt* forms long, colourless, silky needles melting at 139°. When brominated, it yields a *tribromoquinoline* which crystallises in colourless needles, and melts at 185° (uncorr.). Reduction with tin and hydrochloric acid converts it into hydroquinoline-1-sulphonic acid.

La Coste's nitrobromoquinoline (Abstr., 1883, 91) is 4 : 3-*nitro-*

bromoquinoline; it melts at 130° (uncorr.), not 133°; its *hydrochloride*, *platinochloride*, and *methiodide* were obtained.

4 : 3-amidobromoquinoline (*loc. cit.*) melts at 160° (uncorr.), not 164°.

A. G. B.

Hydroxyquinolinesulphonic Acids. By E. LIPPMANN and F. FLEISSNER (*Monatsh.*, **10**, 798—804).—When 1-hydroxyquinoline (1 part) is heated with sulphuric acid (3 parts) in a sealed tube for three hours at 180°, the product is a light-brown syrup which scarcely smells of sulphurous anhydride, and contains a sulphonic acid, $OH{\cdot}C_9NH_5{\cdot}SO_3H + 1\frac{1}{2}H_2O$, which crystallises in pale-yellow needles, melts with decomposition at 275°, is only slightly soluble in alcohol, and is insoluble in ether. The aqueous solution is strongly acid, gives a green coloration with ferric chloride, and an almost insoluble, crystalline precipitate with lead acetate. The potassium salt is anhydrous, and crystallises from water in light, rose-coloured, glistening scales. Its aqueous solution gives a green, granular precipitate with a solution of cupric sulphate, and a crystalline precipitate with mercuric chloride; the silver salt is a crystalline powder; the barium salt is an almost insoluble powder.

Besides the above-described compound, *1-hydroxyquinolinedisulphonic acid*, $OH{\cdot}C_9NH_4(SO_3H)_2$, is simultaneously formed in small quantities. It may be more readily obtained by heating a mixture of hydroxyquinoline (25 grams), sulphuric acid (75 grams), and phosphoric anhydride (30 grams) at 200° for five hours. It is a very hygroscopic substance, and decomposes at 200°. The hydrogen potassium salt, is a crystalline precipitate; the basic salt, $OK{\cdot}C_9NH_4(SO_3K)_2$, a compound sparingly soluble in water; the basic copper salt, $Cu[O{\cdot}C_9NH_4(SO_3)_2Cu]_2 + 10H_2O$, a light-green powder.

G. T. M.

Paradiazine-derivatives. By P. W. ABENIUS (*J. pr. Chem.* [2], **40**, 425—444; compare Abstr., 1889, 134).

Bromacetanilide, $NHPh{\cdot}CO{\cdot}CH_2Br$, is obtained by mixing benzene solutions of aniline (2 mols.) and bromacetic bromide (1 mol.), evaporating the benzene at the ordinary temperature, and washing the residue with water, which leaves bromacetanilide undissolved. It crystallises in slender, white needles which melt at 130—131°, and are soluble in alcohol, ether, and benzene, but not in water.

Chloracetylphenylglycine, $CH_2Cl{\cdot}CO{\cdot}NPh{\cdot}CH_2{\cdot}COOH$, is formed when phenylglycine, suspended in ether, is shaken with an ethereal solution of chloracetic chloride (eq. mols.); the ether is distilled off, and the residue treated with water, when the chloracetylphenylglycine separates as an oil, which soon crystallises. It forms four-sided tables or prisms melting at 132—133°, soluble in alcohol and benzene.

Diphenyldiketodihydroparadiazine,  $NPh<\begin{matrix}CO{\cdot}CH_2\\CH_2{\cdot}CO\end{matrix}>NPh$, is identical with Meyer's phenylglycine anhydride (this Journal, 1878, 294); it may also be obtained by the action of alcoholic potash on bromacetanilide, and by heating chloracetylphenylglycine (1 mol.) with aniline (2 mols.) at 140—150°; this last reaction settles its constitution. It melts at 263°.

Phenylglycinylphenylglycine has been described before (Abstr., 1888, 854; compare Hausdörfer, Abstr., 1889, 1014); it melts at 129—130°.

Bromacetoparatoluidide, $C_6H_4Me\cdot NH\cdot CO\cdot CH_2Br$ [Me : NH = 1 : 4], obtained in the same way as bromacetanilide, crystallises from hot alcohol in long, colourless needles which melt at 164°.

Diparatolyldiketodihydroparadiazine,

$$C_6H_4Me\cdot N{<}\begin{matrix}CO\cdot CH_2\\ CH_2\cdot CO\end{matrix}{>}N\cdot C_6H_4Me\ [Me : N = 1 : 4],$$

is obtained from bromacetoparatoluidide, or from paratolylglycocine, in the same way as diphenyldiketodihydroparadiazine is obtained from the corresponding phenyl compounds. It crystallises from alcohol in beautiful, long, white needles which melt at 252—253°, and are soluble in glacial acetic acid, but only sparingly soluble in other solvents.

Ethylglycolylparatoluidide, $C_6H_4Me\cdot NH\cdot CO\cdot CH_2\cdot OEt$ [Me : NH = 1 : 4], is obtained as a bye-product in preparing the above paradiazine from bromacetoparatoluidide and alcoholic potash, and may be separated from the mother liquor of the paradiazine by ether, which dissolves it. It crystallises in beautiful, transparent prisms which melt at 32°, and are soluble except in water.

Parabromaceto-xylidide, $C_6H_3Me_2\cdot NH\cdot CO\cdot CH_2Br$ [Me_2:NH=1:4:3], prepared by mixing benzene solutions of paraxylidine (2 mols.) and bromacetic bromide (1 mol.), crystallises in slender, white needles which melt at 145°.

Diparaxylyldiketodihydroparadiazine,

$$C_6H_3Me_2\cdot N{<}\begin{matrix}CO\cdot CH_2\\ CH_2\cdot CO\end{matrix}{>}N\cdot C_6H_3Me_2\ [Me_2 : N = 1 : 4 : 2],$$

is obtained by the action of alcoholic potash on parabromaceto-xylidide; it crystallises from hot alcohol in beautiful, flat needles melting at 203°, and soluble in benzene and acetic acid, but not in water and ether.

Ethylglycolylparaxylidide, $C_6H_3Me_2\cdot NH\cdot CO\cdot CH_2\cdot OEt$ [Me_2 : NH = 1 : 4 : 2], is extracted by ether from the mother-liquor of the last-mentioned paradiazine; it crystallises in prisms melting at 50°, and soluble in the usual solvents.

Di-α-naphthyldiketodihydroparadiazine,

$$C_{10}H_7\cdot N{<}\begin{matrix}CO\cdot CH_2\\ CH_2\cdot CO\end{matrix}{>}N\cdot C_{10}H_7,$$

obtained from chloracetonaphthalide and alcoholic potash, crystallises from glacial acetic acid in flat needles melting at 274—275°, and sparingly soluble in alcohol, benzene, and ether.

Methyl metanitrocumate, $NO_2\cdot C_6H_3Pr\cdot COOMe$ [Pr : MeO : NO_2 = 4 : 1 : 3], is obtained by dissolving nitrocumic acid in methyl alcohol and saturating it with hydrogen chloride; it forms large crystals like nitre, which melt at 64°, and are soluble in most solvents.

Methyl metamidocumate is obtained by reducing the nitrocumate with tin and hydrochloric acid; it crystallises in colourless, transparent prisms or tables melting at 51—52°, and easily soluble except in light petroleum.

Methyl metachloracetamidocumate, $CH_2Cl\cdot CO\cdot NH\cdot C_6H_3Pr\cdot COOMe$ [Pr : COOMe : NH = 4 : 1 : 3], is prepared by mixing benzene solutions of the metamidocumate (2 mols.) and chloracetic chloride (1 mol.), evaporating the benzene at the ordinary temperature, and washing the residue with water, which leaves the chloraceto-derivative undissolved. It crystallises from hot dilute alcohol in long, slender, colourless needles melting at 101—102°, and easily soluble in most solvents except water and light petroleum. If bromacetic bromide be substituted for chloracetic chloride in the above prescription, *methyl metabromacetamidocumate* is obtained; it melts at 106—107°.

Dipropyldiphenyldiketodihydroparadiazinedicarboxylic acid,

$$C_4N_2H_4(C_6H_3Pr\cdot COOH)_2\ [COOH : Pr : N = 1 : 4 : 3],$$

is prepared by heating alcoholic potash (1 gram) with methyl metachloracetamidocumate (4 grams) in alcohol for half an hour, then adding another gram of potash, and heating for another half hour; the alcohol is now evaporated, the residue treated with water, and an excess of hydrochloric acid added; this throws down a resinous substance, which is washed and heated with alcohol. Part dissolves (see below), leaving the dicarboxylic acid as an insoluble powder, which decomposes before melting, and dissolves in alkalis, being reprecipitated by acids. The *ethyl* salt, obtained by the action of dry hydrogen chloride on an alcoholic solution of the acid, crystallises in flat, lustrous, oblique-ended needles melting at 192—193°, and soluble in alcohol.

Metethylglycolylamidocumic acid, $OEt\cdot CH_2\cdot CO\cdot NH\cdot C_6H_3Pr\cdot COOH$ [COOH : Pr : NH = 1 : 4 : 3], is that portion of the above-mentioned resin which dissolves in alcohol; the alcohol is evaporated, the residue dissolved in potash, reprecipitated by hydrochloric acid, and crystallised from weak alcohol. It forms four-sided tables melting at 140°, and soluble except in water and petroleum.

Phenylorthotolyldiketodihydroparadiazine,

$$NPh{<}{\begin{matrix}CO\cdot CH_2\\CH_2\cdot CO\end{matrix}}{>}N\cdot C_6H_4Me\ [Me : N = 1 : 2],$$

is obtained by heating chloracetorthotolylglycine (1 mol.) with aniline (2 mols.) in a sulphuric acid bath at 160°; the product is heated with water and hydrochloric acid, filtered, and the undissolved portion crystallised from alcohol. It forms slender, white needles melting at 165—166°, soluble in hot alcohol and benzene, but insoluble in ether. It forms no platinochloride.

Orthotolylparatolyldiketodihydroparadiazine,

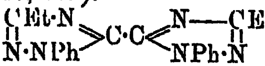
$$C_6H_4Me\cdot N{<}{\begin{matrix}CO\cdot CH_2\\CH_2\cdot CO\end{matrix}}{>}N\cdot C_6H_4Me\ [Me : N = 1 : 2 \text{ and } 1 : 4],$$

is obtained by substituting paratoluidine for aniline in the preparation of the last compound. It crystallises in long, white, felted needles melting at 179—180°, soluble in alcohol and benzene, but not in ether.

A. G. B.

Ditriazole-derivatives. By J. A. Bladin (*Ber.*, **22**, 3114—3117; compare Abstr., 1889, 138).

Di-phenylethyltriazole,



$$\begin{matrix}\mathrm{CEt{\cdot}N} \\ \| \\ \mathrm{N{\cdot}NPh}\end{matrix}\!\!>\mathrm{C{\cdot}C}<\!\!\begin{matrix}\mathrm{N{-\!-}CEt} \\ \qquad\| \\ \mathrm{NPh{\cdot}N}\end{matrix}$$

, prepared by boiling cyanophenylhydrazine with excess of propionic anhydride, crystallises from alcohol in prisms, melts at 186·5—187°, and is readily soluble in alcohol, but insoluble in water. The *hydrochloride*, $C_{20}H_{20}N_6,2HCl$, crystallises in microscopic prisms, and is decomposed by water. The *platinochloride* crystallises in orange-yellow, unstable prisms.

Di-diphenyltriazole, $C_{28}H_{20}N_6$, prepared by treating cyanophenylhydrazine with benzoic chloride, crystallises from alcohol in colourless needles, with 2 mols. H_2O, loses its water at 100°, melts at 257—258°, and is only sparingly soluble in alcohol, very sparingly in ether, and insoluble in water; it is a very feeble base.

Di-paratolylmethyltriazole, $C_{20}H_{20}N_6$, is obtained when cyanoparatolylhydrazine is boiled for a few minutes with excess of acetic anhydride. It crystallises from alcohol in long, prismatic needles, melts at 259—260° and is moderately easily soluble in alcohol, but only sparingly in benzene, and insoluble in water. The *hydrochloride* is readily soluble.

Di-paratolylethyltriazole, $C_{22}H_{24}N_6$, prepared from propionic anhydride in like manner, separates in crystals from alcohol and benzene, in which it is readily soluble, melts at 202—203°, and is insoluble in water.

Di-paratolylphenyltriazole, $C_{30}H_{24}N_6$, prepared from benzoic chloride in like manner, crystallises from alcohol in microscopic needles with 2 mols. H_2O, and from benzene in small plates with 1 mol. of benzene; it melts at about 300°, is insoluble in water, and is only a very feeble base.

F. S. K.

Bases formed by the Action of Potassium Hydroxide on the Halogen-Alkyl Salts of Papaverine. By A. Claus (*J. pr. Chem.* [2], **40**, 465-479).—In this paper the author replies to the recent criticisms of Goldschmiedt (this vol., p. 179) on the work which he (the author) and others have already published on this subject (see Abstr., 1885, 996; 1889, 414).

A. G. B.

Belladonine. By E. Dürkopf (*Ber.*, **22**, 3183-3184).—The brown syrup from which atropine has been obtained (commercially) is a mixture of belladonine, atropine, hyoscyamine, hyoscine, and their decomposition-products tropine, pseudotropine, and tropic acid. When the syrup is boiled with chloroform and ether in acid solution, the hydrocarbons, &c., are removed, and the atropine in the purified base can, by some suitable means, be converted into tropine and tropic acid; the belladonine is not changed by this treatment, but the hyoscine (18—20 per cent.) passes into solution, and can be easily isolated by means of the aurochloride. This salt, $C_{17}H_{23}NO_3,AuCl_3$, crystallises in prisms, melts at 200°, and is sparingly soluble in water.

F. S. K.

Fumarine. By R. Reichwald (*Zeit. anal. Chem.*, 28, 622—623). —Fumarine is soluble in 11·2 parts of chloroform and in 78·68 parts of benzene, but is only very sparingly soluble in water, alcohol, ether, and petroleum. When treated with Fröhde's reagent, it first turns violet, then dark-green; with vanadyl sulphate, it gives an emerald-green colour which, after some hours, becomes yellowish-green; with sulphuric acid and sugar, it gives a dirty-violet coloration; with selenosulphuric acid, a pure violet. It is not coloured by chlorine-water, but becomes violet-brown with bromine-water and sulphuric acid. A crystal of potassium nitrate thrown into its solution in sulphuric acid colours the liquid, as it dissolves, first green, then violet, and lastly yellow. Potassium dichromate added to a fumarine salt throws down fumarine chromate; on adding concentrated sulphuric acid, intense green and violet streaks are produced, passing, after a few minutes, into green. M. J. S.

Preparation and Properties of Albumin, free from Ash. By E. Harnack (*Ber.*, 22, 3046—3052; compare Abstr., 1882, 747).—Albumin, free from ash, can be obtained as follows:—The copper-compound of albumin, prepared as previously described (*loc. cit.*), is purified by dissolving it in very dilute soda, reprecipitating with acetic acid, and washing well with water, the process being repeated several times; the precipitate is then dissolved in a considerable quantity of soda, the solution kept for 24 hours, the albumin precipitated by neutralising with hydrochloric acid, washed with water, and dried at 100°.

It is thus obtained in the form of a gelatinous, transparent, brittle, yellowish-red mass which is almost free from ash, 1 gram leaving a residue of about 1 milligram on ignition. It is free from phosphorus and phosphates, and iron could not be detected. When the moist substance is treated with pure, cold water, it gradually swells up and dissolves; the solvent action being hastened considerably by boiling. The dry substance shows a like behaviour, but it dissolves much more slowly. The residue obtained on evaporating the aqueous solution to dryness seems to have the same properties as the original substance.

Albumin, free from ash, is precipitated from its aqueous solution by acids, the precipitate being insoluble in excess; also by neutral salts, for example, sodium chloride, but the precipitate dissolves again if the solution is diluted very considerably. The precipitated albumin has the same properties as the original substance, but if the precipitate is boiled with the solution, it is gradually converted into a modification insoluble in water.

Albumin, free from ash, is precipitated from its aqueous solution by salts of the heavy metals, phosphomolybdic acid, potassium ferrocyanide, &c.; but it is not precipitated by alcohol, ether, phenol, or tannic acid. F. S. K.

Heat Coagulation of certain Proteïds. By J. B. Haycraft and C. W. Duggan (*Brit. Med. J.*, 1890, i, 167—169).—It is found that there are various circumstances that affect the temperature at which any proteïd enters into the condition of a heat-coagulum. If a solution of a coagulable proteid is heated quickly, the proteid will be found to coagulate at a higher temperature than if the heat is applied more slowly. The coagulation point is considerably raised by diluting the solution, and a very dilute solution may not coagulate even on boiling. The presence of certain neutral salts lowers, of others raises the coagulation temperature. The presence of acids lowers, of alkalis raises the coagulation temperature. These facts were ascertained to be true for egg albumin, serum albumin, vitelleïn, and serum globulin.

Halliburton (*J. Physiol.*, 5) and Corin and Berard (Abstr., 1889, 1075) attempted to separate proteids by means of fractional heat coagulation. Without doubting the possibility of fractionating some proteïds, the result of the present experiments seems to cast a doubt on the method adopted, unless other differences be demonstrated to exist between the various proteïds thus separated. It is thus possible that serum albumin or egg albumin may be single proteids, and the fact that various precipitates at different temperatures are obtainable can be explained in one of two ways: either that the heat when applied for a long time (in Corin and Berard's experiments for upwards of an hour) alters the character of the proteid in solution so that its temperature of coagulation is heightened, or that the result is simply the effect of dilution; a solution of serum albumin is raised to 73°; a precipitate occurs, and is filtered off; that left in solution is now more diluted, hence its coagulation temperature is higher. W. D. H.

Precipitation of Albuminoïds from Urine. By — Boymond (*J. Pharm.* [5], **20**, 481—482).—In attempting to form a filter of talc (previously washed in hydrochloric acid and water) for the filtration of turbid urine, the whole of the globulin contained in the urine was found to be removed by the so-called neutral substance composing the filter; whether any serein (? serum-albumin) was removed has not yet been determined. Experiments were instituted with other neutral substances, and it was found that bismuth subnitrate completely removed both globulin and "serein." This research is still being prosecuted. J. T.

Hæmoglobin. By A. Jaquet (*Zeit. physiol. Chem.*, **14**, 289—296).—A sample of dog's hæmoglobin, prepared according to Zinoffsky's method (Abstr., 1886, 165), gave the following percentage composition, which may be compared with the results obtained previously with dog's hæmoglobin (Abstr., 1888, 731), and with Zinoffsky's analysis of horse's hæmoglobin, in the following table:—

	Hæmoglobin of dog.		
	Previous analysis.	Present analysis.	Of horse (Zinoffsky).
C......	53·91	54·57	51·15
H......	6·62	7·22	6·76
N......	15·98	16·38	17·94
S......	0·542	0·568	0·39
Fe	0·333	0·336	0·335
O......	22·62	20·93	23·43

The formula for dog's hæmoglobin deduced from this second analysis is $C_{758}H_{1203}N_{195}S_3FeO_{218}$.

An analysis of hen's hæmoglobin was also made; the percentage composition was C, 52·47; H, 7·19; N, 16·45; S, 0 8586; Fe, 0·3353; O, 22·5; P, 0·1973.

The relation of S : Fe = 9 : 2; the relation of Fe : P = 1 : 1. The only other preparation of birds' blood that has been analysed is that of goose's blood by Hoppe-Seyler. He also found phosphorus present (0·77 per cent.), and this has generally been regarded as due to admixture with nucleïn; the relation of phosphorus to iron in the present research seems to indicate that the phosphorus may be actually in the hæmoglobin-molecule. W. D. H.

Physiological Chemistry.

Respiration of Entozoïc Worms. By G. BUNGE (*Zeit. physiol. Chem.*, **14**, 318—324).—In an earlier communication (*ibid.*, 8, 48) it was shown that the *Ascaris mystax*, the worm that lives in the intestine of the cat, will live four or five days in media quite free from oxygen.

Renewed experiments with *Ascaris acus*, from the intestines of the pike, are confirmatory of the above; these worms live for four to six days, and exhibit movements, in media free from oxygen. In the ultimate respiratory processes of these animals there must be a formation of energetic reducing substances (nascent hydrogen and easily oxidisable organic matter) which unite with one atom of the oxygen-molecule, even to a greater extent than in animals which breathe oxygen. These animals possess no respiratory apparatus.

In order to investigate this question more fully, larger varieties of *Ascaris* were employed. The *A. megalocephala* of the horse was found unsuitable, as it only lived for two days after removal from the intestine; the *A. lumbricoides* of the pig was therefore used; this lived from five to seven days. In boiled salt solution it gave off abundance of gas, which was collected over mercury, and was completely absorbed by potash, consisting of pure carbonic anhydride, and containing no hydrogen. The quantity of gas obtained in this time was from 5 c.c. to 10 c.c. per gram of the animal's body-weight. In three experiments, a small, measured quantity of oxygen was added to this gas artificially, but there was no diminution in its volume after the admixture; thus not only hydrogen, but other reducing substances are absent also. W. D. H.

Heat developed by the Action of Oxygen on the Blood. By BERTHELOT (*Compt. rend.*, **109**, 776—781).—The experiments were made with defibrinated fresh sheep's blood which had been allowed to remain in a closed flask for 24 hours. The scarlet colour had changed to purple, the sp. gr. was 1·057 at 9°, and the specific heat 0·872. It was placed in the calorimeter, and a current of nitrogen, saturated with moisture, was passed through for some time. Dry oxygen was then passed in, and the temperature observed at frequent intervals. Before weighing the calorimetric vessel, the oxygen in the empty space was expelled by means of nitrogen.

In one experiment, 100 vols. of blood absorbed 20·2 vols. of oxygen, in another, 18·5 vols. The heat developed per 32 grams of oxygen was 14·63 Cals. in the first case and 14·91 in the second, or a mean of +14·77 Cals. The formation of silver oxide develops +14·0 Cals.; of barium peroxide, +24·2 Cals.; of lead peroxide, +24·5 Cals. per 32 grams of oxygen; and it is evident that the heat liberated by the formation of oxyhæmoglobin is of the same order of magnitude as the heat of formation of many true oxides.

The combination of carbonic oxide with hæmoglobin developed +18·0 Cals. and +19·4 Cals., or a mean of +18·7 Cals. per 28 grams, a disturbance of the same order of magnitude as the heat of formation of oxyhæmoglobin, but distinctly higher.

The heat developed by the action of oxygen on the blood is almost exactly one-seventh of the heat which would be liberated by the complete oxidation of carbon by the same quantity of oxygen, and hence it follows that of the total animal heat about one-seventh is developed in the lungs by the combination of oxygen with the blood, and the remaining six-sevenths in other parts of the body in consequence of oxidations and hydrations.

The development of heat in the lungs is almost exactly compensated by the absorption of heat due to the liberation of carbonic anhydride and water vapour, and whether the temperature of the blood in the lungs rises or falls is determined by the temperature of the inspired air, but the variation in one direction or the other is not greater than the tenth of a degree. C. H. B.

Animal Heat and the Heat of Formation and Combustion of Urea. By Berthelot and P. Petit (*Compt. rend.*, **109**, 759—764).—See this vol., p. 206.

Artificial Digestion of Proteïds. By A. Stutzer (*Landw. Versuchs. Stat.*, **36**, 321—328).—The method proposed by the author consists in treating the food first with an acid pepsin solution and then with an alkaline pancreatic liquid, and determining the nitrogen in the undissolved substance; from the relation of the indigestible to the total proteïd nitrogen, the digestibility coefficient is calculated. The method gives, according to Pfeiffer (*Journ. f. Landw.*, **34**, 444), results nearly identical with those obtained by means of direct experiments with animals.

The pepsin solution is prepared by cutting the mucous skin of a fresh pig's stomach into small pieces and keeping it for one or two days with 5 litres of water, 100 c.c. of hydrochloric acid (containing 10 grams of hydrogen chloride) and 2·5 grams of salicylic acid; it is then poured through a flannel bag and filtered, first through a coarse and then through a dense filter paper. It is best to prepare several extracts at once.

The pancreas extract is obtained by cutting up the pancreas (1000 grams) of a bullock, rubbing it up with sand, and exposing it to air for 24—36 hours. It is then treated with lime-water (300 c.c.), glycerol (sp. gr., 1·23; 1 litre), and some chloroform, kept for four to six days, filtered, heated for two hours at 37—40°, and again filtered, if necessary. Before using the extract, 250 c.c. of it is mixed with sodium carbonate solution (750 c.c. containing 5 grams of the anhydrous salt), heated at 37 to 40° for one or two hours, and filtered.

The determination of digestible substance is made as follows:—the finely powdered food (2 grams) is tied up in paper and extracted with ether from five to six hours to remove the fat. It is then treated with the pepsin solution (250 c.c.) and heated at 37 to 40° for 24 hours, 10 per cent. hydrochloric acid (2·5 c.c.) being added at intervals of about one hour until the solution contains 1 per cent. of acid. It is then filtered through asbestos. The substance, with the asbestos, is heated with the alkaline pancreas extract (100 c.c.) for six hours at 37—40°, the liquid being stirred sometimes. After this it is filtered, washed with water, dried, and the nitrogen determined in the substance.

It was found that if the substance is treated with 400 c.c. of pepsin solution containing 0·2 per cent. of hydrogen chloride, without subsequent digestion with pancreas, somewhat less nitrogen is dissolved than when the less amount of more strongly acid pepsin is employed. But if the food is afterwards digested with pancreas, the final result is the same in both cases. N. H. M.

Absorption of Sugar from the Small Intestine. By S. GINSBERG (*Pfluger's Archiv*, **44**, 306—318).—v. Mering (*Arch. Anat. physiol., physiol. Abth.*, 1877, 379) showed that the chyle from the thoracic duct of the dog contained no more sugar during the digestion of carbohydrate than at other times, but that the percentage of sugar in the portal blood was increased under these circumstances.

Heidenhain pointed out (*Pflüger's Archiv. Supp.*, 1888, 71) that this is probably due to the fact that the water and substances, like sugar, easily soluble in water are taken up by the blood-vessels as they lie immediately beneath the epithelium, and so do not reach the more centrally situated lacteals of the villi. The present research, undertaken under Heidenhain's superintendence, was directed to ascertaining, whether by greatly increasing the amount of sugar and water in the food, some might not be found even in the chyle.

The first experiments were performed on rabbits, with results given in the following table (p. 277).

These show that during a normal diet the amount of sugar in both blood and chyle is very constant. The seemingly higher percentage in the latter is due to the fact that the percentage is taken for the total blood, including corpuscles. In round numbers 100 parts of blood contain 60 volumes of plasma; hence, the percentage in the plasma would average 0·28, which is higher than that in the chyle. The rise of the percentage during sugar feeding, both in blood and chyle, is very marked.

	Percentage of sugar in		Food.
	Blood.	Chyle.	
1...............	—	0·25	Normal diet.
2...............	0·18	0·23	„
3...............	0·18	0·25	„
4...............	0·18	0·23	„
Mean............	0·18	0·24	„
5...............	0·22	0·36	5 grams sugar in 50 c.c. water.
6...............	0·39	0·76	15 „ 100 „
7...............	0·33	0·39	15 „ 100 „
8...............	0·31	0·46	25 „ 150 „
Mean............	0·31	0·49	

The second series of experiments, made on dogs with a fistula of the thoracic duct, show the same result, and are still more satisfactory, as the same animal could be used in the two experiments.

The following table contains the results of a few of the experiments performed. The sugar solution was injected into the intestine.

	Percentage of sugar in				Amount injected.
	Blood.		Chyle.		
	Before injection.	After injection.	Before injection.	After injection.	
1...	0·14	0·14	0·24	0·27	30 grams in 600 c.c. of water.
2...	0·07	0·27	0·25	0·52	10 „ 400 „
3...	0·09	0·18	0·22	0·35	20 „ 100 „
4...	0·08	0·28	0·16	0·42	30 „ 400 „

W. D. H.

Osmosis with Living and Dead Membranes. By E. W. Reid (*Brit. Med. J.*, 1890, i, 165—167).—The process of diffusion of fluids through animal membranes is well known to be influenced by the vital condition of such membranes. (Cl. Bernard, Matteucci and Cima, &c.). In the present research the skin of the frog was chiefly employed; the liquids used were those which do not markedly impair the vitality of living tissues, such as physiological saline solution, or a 5 per cent. solution of glucose in this solution. The osmometer used was either the ordinary Dutrochet instrument, or an oil-discharging osmometer in which the pressure was kept constant in order to avoid error from the occurrence of filtration. For recording purposes, advantage was taken of the photographic method in order to avoid friction; the height of the column of liquid being photographed on a very slowly revolving cylinder covered with sensitive paper. The following conclusions are drawn from the experiments:—(1.) The normal direction of easier osmotic transference of fluid through the living skin of the frog is in the direction from the outer towards the inner surface. (2.) The transference of fluid through the skin in the above direction is intimately associated with the physiological condition of its tissues. Conditions or agents tending to depress vitality diminish the transfer in the normal direction, while stimulants give rise to augmentation. (3.) The cause of the easier transfer of liquid from the outer towards the inner surface is probably to be found in the existence of an absorptive force dependent on protoplasmic activity, and comparable to the secretive force of a gland cell. (4.) In consequence of the absorptive force, acting from without inwards, an alteration of the relations of the surfaces of the skin to the two liquids used in an osmosis experiment modifies the rapidity of the transfer of liquid from one to the other side of the membrane, according as the force exerted by the living tissues is with or against the osmotic stream. W. D. H.

Effect of Feeding on the Secretion of Amidic Substances. By E. Schulze (*Bied. Centr.*, **18**, 733—734; from *Pflüger's Archiv*, **25**, 401—460).—The following are the results of the author's experiments:—(1.) The nearer the feeding of persons approaches to a pure animal diet, the greater is the amount of nitrogen as urea in proportion to the total nitrogen of the urine. (2.) The relation of uric acid to the total nitrogen decreases with meat diet as opposed to feeding with mixed food. This occurs in a still greater degree with a meat diet with use of abundance of alkaline water and absence of alcohol and narcotics, although the absolute amount of uric acid increases. (3.) The same holds good with regard to the relation of uric acid to urea. (4.) It is very probable that in fever, even in absence of respiratory derangement, there is not only an absolutely larger amount of uric acid produced, but also an increased proportion of uric acid relatively to total nitrogen and to urea. (5.) The use of plenty of alkaline water and the disuse of alcohol in treatment of gout are justified by experimental evidence which cannot be denied; these factors seem to be of greater importance than the prohibition of meat.

N. H. M.

Detection of Nitrous Acid in Saliva. By L. Ilosvay de N. Ilosva (*Bull. Soc. Chim.* [3], **2**, 388—391).—The saliva is boiled with an acetic acid solution of sulphanilic acid, the clear solution is decanted, and naphthylamine is added, when a rose coloration indicates the presence of nitrous acid, which is increased after a meal; the action of tobacco smoke retards the reaction considerably.

Nitrous acid could not be detected in the water moistening a cylinder through which air had been respired; when, however, the respired air was passed through bulbs containing a 2 per cent. solution of sodium hydroxide for some time, an indication equal to that afforded by ordinary air under similar conditions was obtained, although from experiments made with the air of stables the authors conclude that respired air does contain more nitrous acid than ordinary air.

T. G. N.

Reducing Substances in Urine. By H. H. Ashdown (*Brit. Med. J.*, 1890, i, 169—172).—The most important substance that reduces an alkaline solution of copper oxide and that is apt therefore to be mistaken for sugar in urine, is glycuronic acid. It can only be identified with certainty by isolating it and examining its properties. A ready distinction, however, between sugar and this substance is that the addition of yeast to the former, even when dissolved in the urine, causes the occurrence of the alcoholic fermentation, and to the latter does not.

In man, the diagnosis of diabetes must in future be always more carefully made, as in one case, the first hitherto recorded, the reducing substance was found to be wholly glycuronic acid; the man in whom this occurred is in perfect health, and no symptoms of diabetes are present. If this state of things be shown to occur in other cases, the question becomes important in relation to life assurance.

In animals, the appearance of glycuronic acid in the urine is readily produced by the administration of certain drugs, camphor, phenol, &c.

In the present research, the following experiments were made:—The urine secreted after drugging with morphine contains, not sugar, but glycuronic acid; after the administration of chloroform, glycuronic acid, not sugar, is present. This confirms a previous investigation of Meyer. The so-called glycosuria of curare poisoning does not depend on the presence of sugar; there is no fermentation with yeast. The quantities of urine obtainable under these circumstances are, however, so small that it was not possible to separate out glycuronic acid. The administration of ether does not cause the appearance of any reducing substance in the urine. After section of the renal nerves, a paralytic secretion occurs; this contains a reducing substance, which was found to be glycuronic acid. W. D. H.

Nitrogenous Constituents of Dog's Urine. By L. Bleibtreu (*Pflüger's Archiv*, **44**, 512—535).—This investigation was carried out by the methods used by Bohland (Abstr., 1889, 536), and by Pflüger and Bleibtreu (this vol., p. 308). The results when the animal was fed on a meat diet are compared with those obtained when a mixed diet was used; they are given in the following table (p. 280); the numbers are percentages.

The urea thus increases in proportion when the diet is chiefly albuminous, and diminishes on a mixed diet. It is also seen that in filtrate II, that is, in the urine after the separation of "extractives"

		Total nitrogen (Kjeldahl).	Nitrogen in urea.	Nitrogen not in urea. Total N = 100.	Nitrogen in filtrate II after subtracting ammonia.	Nitrogen in filtrate II which is not present in the form of urea or ammonia. Total N in filtrate = 100.
Meat diet	1.	5·155	4·59	10·96	4·682	1·96
	2.	5·14	4·931	4·07	5·0636	2·6
Mixed diet	3.	—	1·0155	—	1·061	4·3
	4.	0·721	0·61638	14·5	0·6841	9·9

by means of phosphotungstic acid, there is, in addition to urea and preformed ammonia, a nitrogenous substance which contains about 2 per cent. of the total nitrogen in this filtrate when the diet is albuminous, but rises to double or quadruple the amount when the diet is a mixed one.

W. D. H.

Nitrogenous Constituents of Human Urine. By E. SCHULTZE (*Pflüger's Archiv*, **45**, 401—460).—This is a research carried out on the same lines as that in the preceding abstract. The investigation was carried out on the human subject, its object being to compare the variations in the amount of urea-nitrogen with the non-urea-nitrogen in relation to diet. The fullest details of analysis are given; the methods adopted were those of Pflüger and Bleibtreu. The conclusions arrived at are as follows:—

1. The urea-nitrogen increases in proportion to total nitrogen as the diet approaches a purely albuminous composition.
2. The uric acid increases absolutely, but diminishes relatively, both to total nitrogen and to the urea on a meat diet, especially if large quantities of alkaline water be taken and alcoholic drinks and narcotics be avoided.
3. Probably in fever the same relation of uric acid to total nitrogen and urea holds.
4. The use of abundant quantities of water and withdrawal of alcoholic beverages in cases of gout has thus a scientific basis.

W. D. H.

Action of related Chemical Compounds on Animals. By W. GIBBS and H. A. HARE (*Amer. Chem. J.*, **11**, 435—448).—This paper contains an account of the first part of a research having for its object a systematic study of the relation between the chemical constitution of compounds and their action on the animal organism. Dogs and frogs were experimented on, and a description is given of the action of the nitrophenols, the nitranilines, and the amido- and nitrobenzoic acids on these animals when administered by the stomach or hypodermically.

The nitrophenols cause death by paralysing the heart, and not by a respiratory action; the nervous system is unaffected by them, except that the vagus nerves are slightly stimulated by the ortho- and meta-compounds, but depressed by the para-compound. The lethal dose per kilo. of body weight is 0·1 gram of the ortho-, about 0·1 gram of the meta-, or 0·01 gram of the para-compound, when injected into the jugular vein. The nitranilines all act by stimulating the peripheral vagi, and so producing a very marked slowing of the pulse. In the case of the ortho-compound, the lethal dose is 0·3 gram per kilo.; methæmoglobin is produced in the blood, and the sensory side of the spinal cord is slightly affected, but this is probably caused indirectly by the changes in the blood. Given by the stomach it produces curious paroxysms of sneezing. The meta-compound has but a very feeble effect on the nerves, and this depends on the development of methæmoglobin in the blood, all the symptoms being those of aniline poisoning. The para-compound is the most poisonous, the lethal dose being 0·04 gram per kilo. of body weight when injected into the jugular vein. The amidobenzoic acids and the nitrobenzoic acids were found to be without effect on the animal organism.

C. F. B.

Is Potassium Ferrocyanide Poisonous? By P. Carles (*J. Pharm.* [5], **20**, 486—489).—The evidence here collected from various sources leads to the conclusion that this salt is not poisonous.

Chemistry of Vegetable Physiology and Agriculture.

Influence of Yeast on the Bouquet of Wines. By A. Rommier (*Bull. Soc. Chim.* [3], **2**, 297—300).—Having previously shown that cultivated yeast determined the non-development of the cells occurring naturally on the grape when the former was added to juice in which the latter existed, the author fermented the juice of an inferior grape and of hothouse grapes respectively with yeast cultures obtained from the Champagne, Côte d'Or, and Buxy districts, and found that in each case the resulting wines had the bouquet of the wines from whence the yeasts were derived. T. G. N.

Influence of Carbonic Anhydride on the Products of Fermentation. By L. Lindet (*Bull. Soc. Chim.* [3], **2**, 195).—The carbonic anhydride evolved during fermentation by means of yeast was not allowed to escape, but retained in the vessels under pressures of 20, 200, 430, and 600 mm. of mercury respectively, without affecting the amount of alcohol produced or the weight of yeast formed.

T. G. N.

Inverting Ferment. By O. Kellner, Y. Mori, and M. Nagaoka (*Zeit. physiol. Chem.*, **14**, 297 - 317).—Koji is the name of a substance used in China and Japan in the preparation of rice wine and alcohol. It consists of the mycelium and spores of a fungus. When investigated, it was found to contain a powerful inverting ferment which changes cane sugar into dextrose and levulose, maltose into dextrose, and starch into dextrin, maltose, and dextrose; it probably does not alter lactose or inulin. The invertin of yeast acts on cane sugar only, and the name suggested for the ferment of Koji is *invertase*. Its action is much hindered by the presence of common salt, but it is not wholly destroyed even by 20 per cent. of that salt. W. D. H.

Nitrification of Ammonia. By T. SCHLOESING (*Compt. rend.*, **109**, 883—887).—Under normal conditions, nitrification of ammonia takes place without any loss of free nitrogen, but when a large excess of ammonium salt is present, there is a very distinct loss of nitrogen in this manner. This loss is due to the formation of a small quantity of nitrite, owing to absence of an excess of oxygen. The nitrite interacts with the ammonium salt, with production of free nitrogen; it also retards nitrification, and is itself but slowly oxidised.

It is possible that the free nitrogen is not the result of interaction between the nitrite and the ammonium salts, but is liberated as a result of limited oxidation of the ammonia; this point, however, can only be determined by further experiment. C. H. B.

Fermentation of Manure in Absence of Oxygen. By T. SCHLOESING (*Compt. rend.*, **109**, 835—840).—When fresh manure from cows is kept at 42° to 52° in an atmosphere of carbonic anhydride, it undergoes fermentation with evolution of hydrogen, methane, and carbonic anhydride, but no free nitrogen is evolved. Hydrogen is only liberated in the early stages of the change, and disappears from the gases as fermentation progresses. The ratio of methane to carbonic anhydride approaches unity only towards the end of the process, and varies irregularly throughout the fermentation.

No nitrogen is evolved at any stage, but the quantity of ammonia present increases. The quantity of oxygen and hydrogen in the evolved gases is greater than the quantity lost by the manure, and it is evident that the water which is present plays an active part in the fermentation, the oxygen combining with carbon to form carbonic anhydride, whilst the hydrogen is converted into methane.

C. H. B.

Formation of Cane Sugar in Etiolated Plant Shoots. By E. SCHULZE (*Chem. Centr.*, 1889, ii, 694—695; from *Ber. Deut. bot. Gesell.*, **7**, 280—281).—The etiolated shoots of *Lupinus luteus* were examined, by means of the method described by the author (compare Abstr., 1888, 624), for cane sugar, of which 30 grams (crystallised) was obtained from 800 grams of air-dry shoots, besides a considerable amount which must have been lost in the separation and purification. Before germination, not the least trace of sugar was detectable in the lupins. As is already known, starch is also formed during the process of germination of this seed in the absence of light, the other nitrogen-free substance which is present in the seeds as reserve material disappearing as the formation of sugar and starch proceeds. J. W. L.

Living Vegetable Protoplasm. By T. Bokorny (*Pflüger's Archiv*, **45**, 199—219).—The difficulty of applying chemical reagents to living structures in many cases consists in the fact that the reagent destroys the life of the material under investigation. Weak solutions of alkalis have not, however, this objection; they produce changes in the cells, but these are considered to be vital changes, that is, evidence of the living activity, and not of the death of the protoplasm.

These changes may be grouped together under the general term "aggregation." This term was first used by Darwin to express the change that occurs in the tentacles of *Drosera* on the application of weak solutions of ammonium carbonate; this consists in the collection of the protoplasm into separate particles. The term has since been extended to somewhat similar phenomena in other plants; De Vries (*Botan. Zeit.*, 1886, 1), however, limits it to the contraction of the vacuole wall, and does not speak of the formation of proteïd granules in the vacuole contents as aggregation. Pfeffer distinguishes between an outer and inner cell-membrane, the former lining the cell wall proper, the latter surrounding the vacuole fluid, and between the two is what he terms granule-plasm (Körner-plasma), but which does not necessarily always contain granules.

In the present research, a large number of careful microscopic observations are recorded. The plants, the cells of which were examined were *Spirogyra*, *Drosera*, *Tulipa*, *Crocus*, *Cotyledon coccinea*, &c. The weak alkalis chiefly used were ammonia (1 : 5000) and caffeïne (1 : 1000). Weak potassium hydroxide, various amines, tetrethylammonium hydroxide, toluylenediamine, quinine, atropine, &c., were also used in some experiments.

The following cases of aggregation could be distinguished:—(1.) The whole protoplasm contracts equally; this is somewhat different from, but very similar to plasmolysis; it is seen in crocus papillæ. (2.) The vacuole wall (inner cell-membrane of Pfeffer) contracts alone, or to a much greater extent than the rest of the cytoplasm; this is well seen in the red epidermal cells of the petals of tulips and primulas. (3.) The "granule-plasm" collects into granules or discs; these are exceedingly minute from the action of ammonia on *Spirogyra* cells, but much larger from the action of solution of caffeïne on sections of the leaves of *Cotyledon coccinea* and *Echeveria gebbiflora*. (4.) The vacuole-fluid, that is, the cell-sap with active albumin either in solution or in a greatly swollen condition, becomes pervaded with larger or smaller granules; this is seen in *Drosera*, *Spirogyra*, and several other plants. W. D. H.

Vegetable Cell-membranes. By E. Schulze, E. Steiger, and W. Maxwell (*Zeit. physiol. Chem.*, **14**, 227—273; compare Abstr., 1889, 916).—This investigation shows that the membrane of vegetable cells contains in addition to cellulose several other carbohydrates which differ from it widely in their properties. They are all insoluble in cuprammonium hydroxide, but differ in certain other reactions; by hydrolysis, however, they all yield pentaglucoses (arabinose, xylose, &c.); by warming with phloroglucinol and hydrochloric acid give a cherry-red colour; and by treatment with very dilute mineral acids differ from cellulose in being quickly converted into sugar; the varieties of sugar formed being galactose, mannose (seminose), and pentaglucoses. The term cellulose as used by Reiss (Abstr., 1889, 687) evidently includes these carbohydrates; it is, however, advisable to restrict the word cellulose to those constituents of the cell-wall which are but little affected by strongly diluted mineral acids, which are soluble in cuprammonium hydroxide, which further are coloured blue by chloride of zinc and iodine, or iodine and sulphuric acid, and which lastly are converted by strong sulphuric acid into dextrose. The term proposed for these other carbohydrates is that of "paragalactan-like substances." It appears doubtful as to whether cellulose is a single substance, but this was not specially investigated.

The paragalactan-like constituents of the cell-wall appear to be of some physiological importance; they seem to be more soluble than cellulose, and enter into solution during germination, functioning as a reserve material before that process commences. It is very doubtful if true cellulose acts in this way.

The nutritive value of these substances in the animal economy appears, like that of cellulose, to be small, as they are not digestible by the various digestive juices. On oxidation with nitric acid, they yield mucic acid. From the point of view of analyses of starch in vegetable substances, these paragalactan-like materials are of some importance, as they, like starch, pass into solution on treatment with dilute mineral acids. W. D. H.

Non-Nitrogenous Reserve Substance of the Seeds of Lupinus luteus. By E. SCHULZE and E. STEIGER (*Landw. Versuchs.-Stat.*, 36, 391—478).—The ethereal extract of the seeds of *Lupinus luteus* contained:—Glycerides, fatty acids, and wax 5·99, cholesterin 0·15, and lecithin 0·17 per cent. in the dry matter of the seed (freed from the shells). A further amount of lecithin can be extracted from the seed by alcohol, making a total of 2·10 per cent. (in dry seed). After being allowed to germinate for 14 days, 78·7 parts of dry matter remained and yielded an ethereal extract containing:—Glycerides, &c., 1·50 part, cholesterin 0·25 part, and only a trace of lecithin. The amount of lecithin extracted by alcohol was 0·44 part.

β-Galactan (Steiger, Abstr., 1886, 608) is a white, amorphous powder, consisting of microscopic globules. The aqueous solution is not coloured by iodine, and only reduces Fehling's solution when it has been heated with an acid. New determinations of rotatory power gave the mean:—$[\alpha]_D = +148·6°$. When β-galactan (100 parts) is heated with nitric acid, mucic acid (41·16 parts) is formed. The acetyl-derivative is a white powder melting at 101—102°. The amount of β-galactan contained in the dry seeds (without shells) was determined indirectly (1) as glucose, (2) as mucic acid. The first method gave in different samples:—(*a*) 10·20, (*b*) 10·02, (*c*) 9·48, and (*d*) 6·36 per cent.; the second method gave in sample (*a*) 8·5 and in (*e*) 7·65 per cent. With regard to the first method, it is shown that the seeds contain no cane-sugar which would affect the results.

Paragalactan (paragalactin, Abstract, 1887, 460), $C_6H_{10}O_5$ (?), could not be obtained free from cellulose. It dissolves partly in water when heated under a pressure of 1½ or 2 atmospheres; the filtered solution, when heated with hydrochloric acid, reduces Fehling's solution, and the residue obtained by evaporating the solution yields mucic acid when oxidised by nitric acid. It is not soluble in diastase solution. When heated with phloroglucinol and hydrochloric acid, a cherry colour is produced. 5 per cent. aqueous potash dissolves it partly; a salt seems to be formed.

Paragalactan is contained not only in the cotyledons, but also in the seed-shell. A carbohydrate probably identical with paragalactan was found in the seeds of *Soja hispida, Pisum sativum*, and *Faba vulgaris*.

When lupin seeds are allowed to germinate in the dark for six days, all the β-galactan is used up, whilst a great part of the paragalactan dissolves; glucose (not galactose), cane-sugar, and cellulose are formed. N. H. M.

Carrotene in Leaves. By ARNAUD (*Compt. rend.*, **109**, 911—914).—The proportion of carrotene in leaves varies with the species of the plant, but oscillates between 0·1 and 0·2 per cent. of the dried leaf. It varies with the age of the plant, is at a maximum during inflorescence, and then gradually diminishes, but never entirely disappears. Its quantity is affected by light, and, like chlorophyll, it tends to disappear in the dark.

Carrotene can absorb 24 per cent. of its weight of oxygen, but remains unaltered in the living leaf, and very probably undergoes alternate oxidation and reduction in such a manner that its quantity remains almost constant for short intervals of time. It is highly probable that carrotene is of very great physiological importance.

C. H. B.

Mussœnda Coffee. By W. R. DUNSTAN (*Pharm. J. Trans.* [3], **20**, 381).—It has been asserted by Lapeyrère, that the seeds of a plant which he considers to be a new species of *Mussænda*, and calls *Mussænda borbonica*, may be employed as a substitute for coffee. The plant grows in the island of Réunion, and its seeds are said to contain 0·3—0·5 per cent. of caffeïne. An examination of the plant at Kew showed that it is not a *Mussænda*, but *Gærtnera vaginata*, which belongs to the natural order *Loganiaceæ*. The author found that the seeds contained neither caffeïne nor theobromine; strychnine and brucine were also absent, and the only alkaloid that could be detected was a trace of choline. W. R. D.

Wine Statistics of Germany. (*Zeit. anal. Chem.*, **28**, 525—580).—The analyses of wines and musts here given, in continuation of those published in *Zeit. anal. Chem.*, **27**, 729, *et seq.*, include numerous brands from the wine districts of Rhein-Hesse, Rheingau, Rhine Palatinate, Baden, Würtemberg, Lower Franconia, Alsace, and Lorraine, and of vintages from 1884 to 1888. M. J. S.

Experiments on Ensilage conducted at Crawley Mill Farm, Woburn, 1884-87. By J. A. Voelcker (*Journ. Roy. Agr. Soc.* [2], 22, 483—513, and 23, 403—417).—The object of the experiments was to determine the relative feeding values of silage as compared with roots and hay-chaff. The method employed was to feed four bullocks with weighed amounts of hay-chaff and swedes, and four more with an amount of silage containing the same quantities of dry matter, woody-fibre, and nitrogen as the hay-chaff and swedes contained; all the animals had, besides, weighed amounts of decorticated cotton-cake and maize-meal. In the first year's experiments, grass silage of inferior quality and clover silage which was of thoroughly good quality were employed. In both cases a much greater increase was obtained with roots and hay-chaff than with silage.

In the second year the following series of experiments were made:—(1) sour silage against roots and hay-chaff; (2) sweet silage against roots and hay-chaff; (3) oat silage against roots and straw-chaff; (4) oat silage against hay. This time the grass employed was of very fair quality. The bullocks fattened well on both sour and sweet grass silage of good quality, but still not so well as with roots and hay-chaff; whilst oat silage proved, in this instance, to be superior to either straw-chaff with roots or to hay. It was found that the oat silage when well made keeps perfectly for at least two years. The following table shows the percentage of nitrogen, albuminoïd nitrogen, and non-albuminoïd nitrogen in the silage:—

	In fresh.			In dry.		
	Albuminoid nitrogen.	Non-albuminoid nitrogen.	Total nitrogen.	Albuminoid nitrogen.	Non-albuminoid nitrogen.	Total nitrogen.
Sweet silage (grass)..	0·45	0·22	0·67	1·27	0·62	1·89
Sour silage (grass ...	0·28	0·23	0·51	1·03	0·85	1·88
Oat silage	0·15	0·15	0·30	0·64	0·61	1·28
Hay...................	1·37	0·37	1·74	1·58	0·43	2·01

The object of the third year's experiments was to determine the value of grass made into hay as against that of the same grass converted into silage. The grass employed was of very fair quality, and the silage was extremely good and well made.

The percentage of nitrogen, albuminoïd nitrogen, and non-albuminoïd nitrogen in the grass, and in the hay and silage prepared from it, was as follows:—

	In fresh.			In dry.		
	Albuminoid nitrogen.	Non-albuminoid nitrogen.	Total nitrogen.	Albuminoid nitrogen.	Non-albuminoid nitrogen.	Total nitrogen.
Grass	0·34	0·08	0·42	1·20	0·30	1·50
Hay....	1·16	0·19	1·35	1·41	0·23	1·64
Silage (sour).........	0·24	0·27	0·51	0·87	0·98	1·85

100 parts of grass gave:—Good silage 87·15 parts, inferior and mouldy silage 4·56 parts, loss by fermentation, &c., 7·29 parts. The produce in hay was:—good hay 29·77 parts, inferior hay 2·61 parts, water and loss 67·62 parts.

The experiments show that the silage from 28,995 lbs. of grass (the produce of 2·4 acres) and the hay from 34,142 lbs. of grass (the produce of 2·8 acres) gave equal feeding results.

The results of similar experiments made at Wilmington, near Shrewsbury, showed a slightly larger gain with silage than with hay prepared from the same grass. N. H. M.

Ammonia and the Nutrition of Plants. By A. Müntz (*J. Pharm.* [5], **20**, 489—492).—Experiments were made to ascertain whether salts of ammonia could be utilised by the roots of plants without first being converted into nitrate. Seeds of bean, horse-bean, maize, barley, and hemp were freed from nitrification germs, and sown in soil freed from nitrates and germs, and placed in glazed boxes supplied with sterilised air. Ammonia in the form of sulphate was supplied. A similar set of pots was prepared containing germs of the nitric ferment. The sterilised soil contained no nitrates either at the beginning or end of the experiment; the non-sterilised soil contained no nitrates at beginning, but yielded 91·2 and 420·0 milligrams per kilo. at the end of the trial. In the sterilised pots, the plants grew well, and assimilated all the nitrogen required from the ammonium salt, showing that nitrification is not essential.

J. T.

Effect of Manuring with Ammonium Sulphate and with Sodium Nitrate. By M. Maercker (*Bied. Centr.*, **18**, 724—729).—In order to determine the effect of calcium carbonate on the manurial action of ammonium sulphate, six plots of land, supplied with phosphoric acid, or kainite, received the following:—(*a*) Nothing; (*c*) ammonium sulphate (87 to 130 lbs. per acre); (*e*) twice the amount of ammonium sulphate supplied to *c*. *b*, *d*, and *f* were treated in the same way as *a*, *c*, and *e* respectively, except that calcium carbonate (15·6 cwt. per acre) was added. The crops grown were: oats, barley, winter wheat, beetroot, mangel-wurzel, and potatoes. The plots with the larger amounts of nitrogen gave much more produce than the others, and the addition of calcium carbonate was beneficial in every case, with the exception of the beetroot, which had no ammonia.

Experiments were also made on the comparative manurial values of ammonium sulphate and sodium nitrate on barley, oats, potatoes, and beetroot. When smaller amounts of the two manures were used, the same increase of crop was obtained in all cases. The same holds good for corn crops when greater amounts of the manures were applied; whilst in the case of the root crops, a heavy manuring with sodium nitrate was found to be superior to an equal amount of nitrogen in the form of ammonia. N. H. M.

Amount of Mineral Matter and the Manurial Value of the Cupules of the Beech from Different Soils. By R. Hornberger

(*Landw. Versuchs-Stat.*, **36**, 329—335).—The beech cupules which were examined were from trees grown on two different soils, the Buntsandstein and the Muschelkalk. The cupules from the Muschelkalk are generally the larger and stronger, 1000 containing 614·4 grams of dry substance, whilst 1000 cupules from the Buntsandstein yield only 500·5 grams of dry matter. The following are the analytical results:—

	Pure ash p. c. in dry.	Nitrogen p. c. in dry.
I. Cupules from Buntsandstein....	2·582	0·330
II. „ „ Muschelkalk	1·825	0·379

The pure ash contains, per cent.:—

	K_2O.	Na_2O.	CaO.	MgO.	Fe_2O_3.	Mn_3O_4.	P_2O_5.	SO_3.	SiO_2.
I.	32·09	2 26	8·44	3·38	7·84	3·22	5 05	1·63	34·42
II.	38·87	1·83	29·04	3 59	4·44	1·21	7·29	4·56	10·21

The manurial value of the cupules differs very little for the two kinds, and is relatively small, owing to the low percentage of nitrogen.

The following analyses show the percentage composition of the dry matter of (1) the shells; (2) the seeds; and (3) the whole beech-nuts from trees grown in the Buntsandstein. 1000 of the beech-nuts contained 159·86 grams of dry matter, 105·82 grams of which belonged to the seeds, and 54·04 grams to the shells.

	Pure ash.	Nitrogen.
1. Shells	1·5160	0·4930
2. Seeds	3·9900	3·9400
3. Whole beech-nuts.....	3·1536	2·7747

The pure ash contained, per cent.:—

	K_2O.	Na_2O.	CaO.	MgO.	Fe_2O_3.	Mn_3O_4.	P_2O_5.	SO_3.	SiO_2.
1.	2·744	0·462	6·949	1·092	0·344	1·475	0·572	0·467	0·865
2.	14·597	0·243	4·301	4·180	0·320	1·824	11·291	2·221	0·159
3.	10·590	0·317	5·196	3·136	0·328	1·706	7·668	1·628	0·397

N. H. M.

Analytical Chemistry.

Bottle for Washing and Absorbing Gases. By F. A. KÜHNLENZ (*Zeit. anal. Chem.*, **28**, 608).—The gas bubbles passing through the liquid are caught by a series of glass bells, each of which has a short, straight tube through it to carry off the unabsorbed gas as soon as the bell becomes full, and these tubes are alternately on opposite sides of the bells, so as to retard the exit of the gas as much as possible.

M. J. S.

Detection of Free Chlorine in Hydrochloric Acid. By KUPFFERSCHLAEGER (*Bull. Soc. Chim.* [3], **2**, 134—136).—Pure concentrated hydrochloric acid diluted with one-fourth its volume of water does not attack granulated copper until heated at 200°, but slight traces of chlorine determine the solution of the metal in the cold, with consequent coloration of the acid.

Although pure hydrochloric acid has no action on phosphorus, in the presence of free chlorine an action obtains, and the solution produced gives a coloration and precipitate with ammonium molybdate.

T. G. N.

Action of Sulphuric Acid on the Haloid Salts of the Alkalis in Presence of some Metallic Salts. By D. VITALI (*Chem. Centr.*, 1889, ii, 398—399; from *L'Orosi*, **12**, 225—229).—Although concentrated sulphuric acid liberates the halogen acids from their alkaline salts when salts of the heavy metals are absent, this does not always take place if certain of the latter are present. If, for instance, sulphuric acid is added to a chloride in presence of an excess of cupric sulphate, anhydrous cupric chloride is precipitated.

The study of several reactions of this nature has led the author to recommend them as a means of distinguishing between chlorides, bromides, and iodides of the alkalis. If a little of a solution containing a chloride or bromide is evaporated to dryness, and one or two drops of concentrated sulphuric acid containing cupric sulphate in solution added, a yellow coloration is indicative of the presence of a chloride, whereas bromides cause a deep violet coloration; both colours are discharged on adding water. In the case of an iodide, iodine is liberated, and if cupric sulphate is present, the mixture becomes black, and *cuprous* iodide is formed, which remains as a white precipitate on adding water. The liberated iodine may be separated by shaking with chloroform. These latter reactions serve to distinguish iodides from bromides. If after adding a sulphuric acid solution of cupric sulphate to a bromide the mixture is shaken with ether, the latter becomes grass-green. Nickel salts alone cause a yellow coloration with sulphuric acid, which is not altered in presence of chlorides or bromides, but iodides cause a brown coloration with nickel sulphate and sulphuric acid; the solution contains free iodine, but no precipitate.

Both ferric and ferrous salts cause a beautiful, blood-red coloration with alkaline bromides and strong sulphuric acid; this disappears on addition of water.

Gold salts produce a cherry-red coloration under these circumstances, changing to yellow on addition of water.

Cobalt salts dissolve in concentrated sulphuric acid with a violet coloration, which changes to peach colour on addition of bromides, whilst chlorides cause a passing blue coloration at the junction of the liquids, the whole becoming peach-coloured on shaking.

J. W. L.

Estimation of Sulphur in Organic Compounds. By W. M. BURTON (*Amer. Chem. J.*, **11**, 472—474).—A modification of Sauer's method (compare this Journal, 1873, 939). The substance to be examined is burned in a combustion tube arranged in the manner recommended by Sauer, and the products of combustion are collected in excess of a standard solution of potash; the excess of potash is ascertained by titration with standard sulphuric acid, the indicator used being tropæolin OO, which is not sensitive to carbonic anhydride, or to alkaline sulphites. The sulphuric acid solution contained 0·015312 gram per 1 c.c, and the potash solution was roughly equivalent to this; accurate results were obtained.

The amount of potash neutralised by the sulphurous anhydride evolved during the combustion is a measure of the sulphur in the substance examined. A slightly diminished pressure is maintained in the tube during the experiment, and at its conclusion any gases left are swept out by a current of air or oxygen. A figure of the apparatus is given in the paper. It is evident that this method cannot be used in the case of compounds containing phosphorus, arsenic, or any of the halogens. C. F. B.

Simultaneous Estimation of Sulphur and Carbon. By L. Prunier (*Compt. rend.*, **109**, 904—906).—The substance is mixed with 80 to 100 times its weight of pure crystallised potassium permanganate, and the combustion is conducted as with cupric oxide. The evolved gas is passed through a solution of potassium permanganate; all the sulphur and carbon remain in this solution, or in the combustion tube. The contents of the tube are treated with water and filtered through asbestos; all the sulphur passes into solution. Half the filtrate is heated with hydrochloric acid, and the sulphur precipitated as barium sulphate in the usual way. The remainder is boiled for a long time with sulphuric acid, care being taken that excess of permanganate is present, and the evolved carbonic anhydride is absorbed in the usual way. Any carbon in the insoluble portion is oxidised in a similar manner. The permanganate must be free from nitrates, chlorates, and other substances which would interfere with the estimation of the carbon. C. H. B.

Titration of Small Quantities of Gases in Mixtures. By P. Behrend and H. Kast (*Dingl. polyt. J.*, **270**, 423—435).—The authors have examined Bunte's process for estimating volumetrically small quantities of gases in mixtures by means of Bunte's gas burette. The volume of gas employed is only about 100 c.c. The method is applicable to the estimation of hydrogen sulphide, ozone, and sulphurous anhydride. For the determination of hydrogen sulphide, a solution of iodine is used which contains 1·134 grams of iodine in 1 litre, so that 1 c.c. = 0·1 c.c. of hydrogen sulphide. 100 c.c. of the gaseous mixture is measured off into the burette, the remainder of the water in the measuring tube then run out to the lower mark of the same, and iodine solution added gradually, with constant shaking, until the mixture assumes a yellow tint. The turbidity formed owing to the separation of sulphur assists in determining the end of the reaction, which may be still further aided by introducing a few drops of thin starch paste, previously treated with sodium hydrogen carbonate, into the burette. The authors have employed this method for the determination of hydrogen sulphide in a mixture of this gas with coal gas, the results being checked gravimetrically by passing a weighed volume of the gas through an acetic acid solution of lead acetate and again weighing. The results, which are tabulated in the paper, show a mean difference of 0·04 per cent. between the two methods. The process has also been used in order to ascertain the rate of formation of hydrogen sulphide at various stages during the carbonisation of coal, the samples of gas being taken from the ascension pipes. The coals employed were: Bohemian lignite, Saar coal, and Tyne Boghead Cannel. The results show that the first two kinds of coal give off the maximum amount of hydrogen sulphide immediately after the retorts have been charged, whilst in the case of the English coal, the maximum formation of gas takes place 35 minutes after charging.

In order to determine ozone in oxygen containing this gas, a measured volume (90 or 100 c.c.) is treated in the gas burette with an excess of potassium iodide solution (about 7 grams of a solution containing 17 grams of iodide in 100 c.c.) and dilute sulphuric acid. The iodine thus separated is then titrated with standard sodium thiosulphate, and from the quantity of iodine found that of the ozone is calculated. D. B.

Action of Sulphides on Chloral and Chloroform. By PRUNIER (*J. Pharm.* [5], **20**, 385—390).—The author deals with the reactions involved in Baudrimont's proposed application of chloral for the detection of alkaline sulphides and hydrosulphides. In aqueous solution, the monosulphide gives a brownish-red coloration or precipitate, whilst the hydrosulphide gives a white precipitate. It is necessary that the chloral should be in excess, and the solution should remain slightly acid or at least neutral to litmus, the condition which obtains when the sulphide is added to excess of chloral. J. T.

Estimation of Nitrogen in Ammonium Magnesium Phosphate. By P. MAISSEN and E. ROSSI (*Chem. Cent.*, 1889, ii, 611—612, from *L'Agric. pratica*, **3**, 430—432).—A specimen of this salt contained 5·40 per cent. of nitrogen as determined by Dumas' method. When distilled, however, with excess of magnesia in water, only 4·113 to 4·598 per cent. of nitrogen could be obtained, or by protracted distillation up to 4·772 per cent., and finally, when the distillation was proceeded with, until Nessler's reagent showed the absence of ammonia in the distillate, up to 5·25 per cent. of nitrogen was found to pass over. If, on the other hand, the phosphate is dissolved in hydrochloric acid and the solution neutralised with magnesia, 5·382 to 5·412 per cent. of nitrogen passed over with the first two-thirds of the liquid. Boussingault has drawn attention to this stability of the ammonium magnesium phosphate when boiled with excess of magnesia; and, since in the estimation of ready formed ammonia in manures this becomes of importance, the author recommends that such substances should be first acidified with hydrochloric acid and then rendered alkaline with magnesia. J. W. L.

Jodlbauer's Modification of Kjeldahl's Method for the Estimation of Nitrogen in Nitrates. By A. DEVARDA (*Chem. Zeit.*, 13, 388—389).—With regard to the Jodlbauer method, it is pointed out:—1. That it is very good for the estimation of the total nitrogen in manures, but for nitrate manures, even when all precautions are taken, it cannot compare with the author's evaporation method as regards accuracy and simplicity; 2. That the use of a mixture of sulphuric acid, phenol, and phosphoric acid instead of phenol and sulphuric acid, is not altogether an advantage; 3. That with 0·5 gram of a nitrate the results are no better with than without cooling, but in the presence of much organic matter, cooling is advisable during nitration; 4. That by adding sulphuric acid at the same time as the phenol-sulphuric acid rather lower results are obtained than by adding the sulphuric acid subsequent to the nitration with phenolsulphuric acid. D. A. L.

Detection of Nitrous Acid in Saliva. By L. ILOSVAY DE N. ILOSVA (*Bull. Soc. Chim.* [3], 2, 388—391).—See this vol. p. 278.

Quantity of Nitric Oxide produced in the Combustion of Nitrogenous Organic Compounds with Copper Oxide. By F. KLINGEMANN (*Ber.*, 22, 3064—3069).—The author has made a large number of experiments with the object of ascertaining the quantity of nitric oxide which is produced in the combustion of nitrogenous organic compounds with copper oxide.

Frankland and Armstrong's method for determining nitrogen (and nitric oxide) was employed (compare this Journal, 1868, 109).

The results, which are given in tables, show that the quantity of nitric oxide produced is independent of the relative quantity of nitrogen in the compound; hydrazine-derivatives, for example, although containing a large proportion of nitrogen give little or no (generally 0 to 1·0 per cent.) nitric oxide, whilst azines and glyoxalines, in spite of the small proportion of nitrogen which they contain, yield very considerable quantities (generally 5 to 10 per cent.) of nitric oxide. Nitro-compounds give very variable (from 0 to 5 per cent.) quantities of nitric oxide; picric acid yields 6 per cent.

F. S. K.

Estimation of Phosphoric Acid in Slags. Formation of Tetrahydrated Ferric Phosphate. By G. ARTH (*Bull. Soc. Chim.* [3], 2, 324—327).—In eliminating by means of nitric acid the residual hydrochloric acid from slag, which had been treated with the latter reagent to remove silica, a probable source of error is described by the author, insomuch as a tetrahydrated ferric phosphate, $Fe_2(PO_4)_2 + 4H_2O$, is precipitated as a yellow, granular powder. This differs from the normal ferric phosphate resulting from the precipitation of a ferric salt by disodium phosphate in not suffering dehydration at 110°. It may be artificially produced by evaporating a solution of ferric chloride (4 mols.) and disodium phosphate (1 mol.) with an excess of nitric acid; as the solution becomes syrupy, an abundant separation of this phosphate occurs. T. G. N.

Analysis of Natural Phosphates. By H. Lasne (*Bull. Soc. Chim.* [3], **2**, 313—324).—The author states that all natural phosphates contain calcium fluorophosphate, CaF_2,Ca_3PO_4, and describes at length his method for estimating all the constituents of these minerals. T. G. N.

Estimation of Hypophosphites. By F. Moerk (*Chem. Centr.*, 1889, ii, 553; from *Amer. J. Pharm.*, **61**, 326).—The solution of sodium hypophosphite is oxidised with bromine (4 mols. of hydrogen bromide being formed by the oxidation of each molecule of hypophosphite). The solution is boiled to expel the excess of bromine, and excess of calcium chloride is added, each molecule of sodium dihydrogen phosphate liberating two molecules of hydrogen chloride. The solution is finally titrated with alkali, phenolphthaleïn being used as indicator; each molecule of hypophosphite being equivalent to 6 mols. of potassium hydroxide. It is to be noted that the author does not take into account the loss of hydrogen bromide which would occur when boiling off the bromine. J. W. L.

Detection and Estimation of Alkaline Hydroxides in Presence of Alkaline Carbonates. By L. Dobbin (*J. Soc. Chem. Ind.*, 7, 829—830).—This method is based on the fact that a solution of potassium mercuric iodide mixed with even a large quantity of a solution of potassium or sodium carbonate remains quite colourless on the addition of ammonium chloride, whilst an abundant brown precipitate is produced on the addition to this mixture of a few drops of alkaline hydroxide solution. For use as a qualitative test for alkaline hydroxide, a very delicate reagent is prepared in a short time by taking a small quantity of a solution of mercuric chloride, adding potassium iodide until the red precipitate just redissolves, and then adding a drop of ammonium chloride solution; whilst for quantitative estimation a standard ammonium chloride and double iodide solution is employed, the alkali to be estimated being used in a sufficiently dilute solution to produce a yellow coloration only, the intensity of which is then compared in narrow, flat-bottomed tubes (smaller than those usually employed for performing Nessler's test) with a standard solution of sodium hydroxide, in like manner to the mode of estimating ammonia in dilute solution by means of Nessler's reagent. The method is inapplicable to solutions containing sulphides, as the darkening due to the formation of mercuric sulphide interferes with the yellow coloration. D. B.

Volumetric Estimation of Sodium Carbonate and Hydroxide in Commercial Caustic Soda. By H. Gombel (*Chem. Zeit.*, **13**, 696).—The following method has given good results:—The quantity of acid required for neutralisation is ascertained by a preliminary experiment, and a quantity of standardised hydrochloric acid less than this is placed in a flask along with some phenolphthaleïn, the desired quantity of the solution of the soda under examination is dropped in, the whole diluted, and titrated cold until colourless. Poirrier blue is then added, and the titration in the cold continued until the liquid is dark blue. The first titration gives the amount of hydroxide; the second, half the quantity of carbonate present.

D. A. L.

Estimation of Zinc in Manganiferous Flue Deposits. By E. JENSCH (*Chem. Zeit.*, **13**, 465, 726—727).—The customary method of estimating zinc in flue deposits is to dissolve in hydrochloric or sulphuric acid, oxidise with potassium chlorate or nitric acid, remove the excess of oxidising agent, and titrate the zinc by Schaffner's method with sodium sulphide in the ammoniacal solution, from which the iron and alumina have been removed. If previous to oxidation the acid solution is evaporated to a syrup, mixed with dilute acid, precipitated with ammonia, and oxidised by two or three hours contact with hydrogen peroxide, then not only is the excess of hydrogen peroxide much more readily got rid of than the chloride, &c., but also all the manganese, as well as the iron and alumina, is precipitated from solution. The author shows by numerous comparative experiments and analyses that in the other method the manganese was held in solution, and although it was gradually deposited, yet even after 168 hours, only 70 per cent. of it had separated, and in all the various analyses the missing manganese was found in the precipitate produced in the titration of the zinc, making the results too high.

D. A. L.

Use of Double Pyrophosphates in the Electrolytic Estimation and Separation of Metals. By A. BRAND (*Zeit. anal. Chem.*, **28**, 581—605).—Most of the metals, when their solutions are mixed with an excess of sodium or ammonium pyrophosphate, form soluble double pyrophosphates, and the solutions of these are not precipitated by ammonia or ammonium carbonate. The ammoniacal liquids so obtained are peculiarly suitable for electro-deposition. Nickel, cobalt, iron, and zinc are very satisfactorily deposited from solutions of the double pyrophosphates mixed with ammonium carbonate. Cadmium requires the presence of an abundant excess of ammonia. Metals which form peroxides behave differently. Manganese is deposited by a feeble current from a solution of manganese sodium pyrophosphate as peroxide, adhering firmly to the anode. It may be washed with distilled water (not with alcohol), ignited over the blowpipe, and weighed as manganoso-manganic oxide. Copper is best precipitated from a solution of the pyrophosphate in excess of sodium pyrophosphate, but this method presents no advantages over the use of an acid solution. For silver, the pyrophosphate solution acidified with nitric acid may be used, but it is in no way preferable to the cyanide solution. The mercuric double salt dissolved in ammonia or ammonium carbonate yields good results; mercurous salts must first be oxidised. Tin cannot be satisfactorily estimated by the electrolysis of the double pyrophosphates. Stannous solutions are easily reduced, but part of the salt oxidises at the anode, and the stannic salt produced requires a very strong current for its electrolysis; even then the results are low. Chromic salts are converted into chromic acid when electrolysed. If nickel or cobalt is present together with the chromium, it is completely precipitated; should, however, the solution contain chromic acid at the outset, neither nickel nor cobalt can be thrown down. Iron also is reduced at first, but when chromic acid begins to appear the reduction ceases, and a reddish-yellow precipitate containing iron and pyrophosphoric acid appears at the cathode.

Lead and thallium cannot be precipitated from alkaline solutions without the formation of peroxide on the anode. In acid solutions this does not occur, but the rapid oxidation of the metal prevents an exact estimation. Bismuth is best thrown down from a solution containing ammonium oxalate. The acid bismuth solution is mixed with four or five times as much sodium pyrophosphate as is necessary for the formation of the double salt, then ammonium carbonate is added just to alkaline reaction, and then 3 to 5 grams of ammonium oxalate. Traces of peroxide are deposited on the anode. They are removed by adding a little oxalic acid towards the end of the operation. Antimony, although quantitatively deposited from a pyrophosphate solution mixed with ammonium carbonate, does not adhere firmly to the cathode.

Manganese may be separated from nickel, cadmium, zinc, and mercury by electrolysing a solution of the double salt mixed with 15 per cent. of concentrated ammonia. The manganese is deposited as peroxide on the anode, whilst the other metals adhere to the cathode. If iron or cobalt is present, a basic salt is deposited with the manganese. Manganese can be separated from metals which can be deposited from an acid solution, such as copper, cadmium, and mercury, by electrolysing such a solution containing pyrophosphoric acid, when the manganese remains dissolved as manganic pyrophosphate, and can subsequently be thrown down from the washings after concentration, reduction with oxalic acid, and addition of ammonia. The separation of manganese from iron and cobalt may be effected after the addition of ammonium oxalate to the pyrophosphate solution, as under these circumstances no manganese is thrown down as long as any ammonium oxalate remains undecomposed. Cadmium can be separated from zinc, iron, nickel, and cobalt by electrolysing a solution acidified with sulphuric acid. If manganese also is present, sodium pyrophosphate must be added before throwing down the cadmium.
M. J. S.

Separation of Copper from Cadmium. By J. H. KASTLE (*Amer. Chem. J.*, 11, 503–504).—It is proposed to precipitate the copper with metallic iron, the author preferring this to the method commonly used in qualitative analysis, which he thinks should be avoided by young students, as it involves the use of potassium cyanide. The filtrate from bismuth, if seen by its blue colour to contain copper, is acidified with nitric acid and evaporated to dryness. The residue is ignited until the nitrates are decomposed, and when cool treated with a few drops of hydrochloric acid; the solution is diluted and filtered into a test-tube, iron wire is added, and the whole heated at 80° in a water-bath. The copper is precipitated as a red deposit on the iron, and cadmium, if present, may be detected in the colourless solution by the yellow precipitate which it gives with hydrogen sulphide.
C. F. B.

Analysis of Organic Substances containing Copper. By J. WALKER (*Ber.*, 22, 3246—3247).—The analysis of copper salts of β-diketones and other substances containing the group $\cdot CO\cdot CH_2\cdot CO\cdot$, is attended with some difficulty, as they are slightly volatile, and if treated with nitric acid frequently explode. The author obtains good results by placing a weighed quantity of the salt in a Rose's crucible, and subjecting it to the action of a current of hydrogen sulphide in the cold. After 15—20 minutes, the crucible is heated to drive off the liberated ketone or its decomposition-products, the current of hydrogen sulphide is then stopped, and hydrogen passed over the heated cupric sulphide until it is converted into cuprous sulphide, in which form it is weighed. An estimation requires 1½ hours. H. G. C.

Estimation of Iron by means of Potassium Permanganate in Hydrochloric Acid Solutions. By C. REINHARDT (*Chem. Zeit.*, 13, 323—325).—After some tentative experiments, the following method was adopted:—½ to 1 gram of the finely pulverised and dry material is ignited until all the carbon or sulphur is expelled; it is then dissolved in 25—30 c.c. of hydrochloric acid, sp. gr. 1·19, warmed, and reduced by gradually adding stannous chloride solution to slight excess. 60 c.c. of mercuric chloride solution is added to remove the excess of stannous chloride, and the whole mixed with about 1½ litres of water containing 60 c.c. of a manganous sulphate solution containing free phosphoric and sulphuric acids and previously reddened with permanganate; then the iron is titrated with permanganate until a pink colour appears. The standard permanganate contains 6 grams per litre, the mercuric chloride 50 grams per litre, and the stannous chloride is made by dissolving 30 grams of tin free from iron in hydrochloric acid, filtering, and making up to 1 litre with moderately dilute hydrochloric acid, whilst for the manganous sulphate solution a mixture of 1000 c.c. of phosphoric acid, sp. gr. 1·3, mixed first with 600 c.c. of water, and then with 400 c.c. of sulphuric acid, sp. gr. 1·8, is poured into a solution containing 200 grams of crystalline manganous sulphate dissolved in a litre of water with the addition of a little dilute sulphuric acid, and the whole is made up to 3 litres. Special stopper arrangements for preserving the solutions are described. D. A. L.

Macro- and Micro-chemical Iron Reactions. By S. S. ZALESKI (*Zeit. physiol. Chem.*, 14, 274—282; compare Abstr., 1886, 1054).—The importance of iron both in animal and plant life and the many important questions still unsettled in regard to it are pointed out. Before those can be investigated, however, it is important that we should have at hand reactions by which iron can be recognised in the tissues themselves. Observations on vegetable tissues are still wanting, but the reactions found most suitable for animal tissues and organs are those with potassium thiocyanate and hydrochloric acid, or with potassium ferrocyanide or ferricyanide and hydrochloric acid. The method adopted is the following:—A small piece of the tissue is allowed to remain for 24 hours in 65 per cent. alcohol, and then transferred for another 24 hours to 96 per cent.

alcohol, to which a few drops of yellow ammonium sulphide has been added. The piece of tissue becomes greenish, not only on the surface, but throughout its thickness, the intensity of the colour varying with the amount of iron present. It is finally transferred for a short time to absolute alcohol coloured with ammonium sulphide in order to complete the process of dehydration. Sections may then be cut with a microtome or by the hand. The sections are first soaked in 65 per cent. alcohol, and subsequently in a 1 per cent. solution of potassium ferrocyanide or ferricyanide for 24 hours, or for two or three days in potassium thiocyanate dissolved in 96 per cent. alcohol. The sections are then placed in 1 to 2 per cent. hydrochloric acid in 96 per cent. alcohol for 24 hours, then in absolute alcohol, and finally mounted permanently; or the whole piece of tissue may be soaked in these reagents successively before the sections are made. Whole embryos, or even small animals, may be similarly stained in bulk.

W. D. H.

Estimation of Iron in Blood. By L. LAPICQUE (*Bull. Soc. Chim.*, [3], 2, 295—297).—Blood (2 grams) is warmed in a flask with pure sulphuric acid (3 c.c.), a few drops of nitric acid are added, and after slight heating the liquid is diluted with water and boiled for a few minutes; to the cooled liquor after dilution to 40 c.c. with distilled water, 10 c.c. of a 20 per cent. solution of ammonium thiocyanate is added, and the amount of iron present is ascertained by means of Duboscq's colorimeter. T. G. N.

Estimation of Nickel by Precipitation as Sulphide. By A. LECRENIER (*Chem. Zeit.*, 13, 431; 449—450).—The precipitation of nickel as sulphide by ammonium sulphide is not complete when the latter contains any polysulphides. The author now finds that by using 2 vols. of a 10 per cent. solution of sodium sulphite to 1 vol. of ammonium sulphide solution and heating on a water-bath, the polysulphides disappear in a few minutes; but even this solution only produces complete precipitation of nickel as sulphide when the solutions do not contain less than 0 1 gram of nickel to 200 c c. of water. The complete precipitation of the nickel by this colourless ammonium sulphide may be ensured even from very dilute solutions by adding ammonium carbonate, chloride, or acetate, &c. Ammonia prevents the precipitation of nickel sulphide, either partially or entirely according to the strength of the solutions, therefore with certain concentrations, colourless solutions may be obtained containing both a nickel salt and ammonium sulphide. With ammoniacal solutions, it is therefore advisable to boil off the greater part of the ammonia and to neutralise the rest with carbonic anhydride, or the ammonia may be neutralised by an acid and the solution made alkaline by adding ammonium carbonate. For analysis, the nickel sulphide is dissolved in aqua regia and determined electrolytically.

The author considers the retention of nickel sulphides in solution is due to the formation of an ammonium thionickelate, in support of which view he adduces the following facts:—

1. In the absence of oxidising influences, ammonium sulphide

decolorised by mercury completely precipitates nickel sulphide from solutions of any dilution. 2. Pure ammonium hydrosulphide (free from ammonia) saturated with sulphur dissolves nickel sulphide completely, probably indicating the formation of a higher sulphide of nickel, and although sodium sulphite prevents the solution of nickel sulphide, yet a solution of the latter in ammonium polysulphide is not precipitated by boiling with the former. Therefore when once the higher sulphide has formed and combined with the ammonium sulphide, the sodium sulphite cannot decompose it; ammonium thiostannate behaves in a similar manner. D. A. L.

Volumetric Estimation of Chromium in Chrome-iron Ore.—By C. Reinhardt (*Chem. Zeit.*, **13**, 430).—For estimating chromium in chrome-iron ore volumetrically, the author, after fusing with a mixture of soda-lime and potassium chlorate, dissolves in water, adds hydrochloric acid, or sulphuric acid if much manganese is present, warms and reduces with a measured quantity of ferrous sulphate (25 grams per litre) solution, and titrates back, using the permanganate and manganous sulphate previously recommended (this vol., p. 296), the end reaction being violet in this case. D. A. L.

Analytical Examination of Water for Technical Purposes. By A. H. Allen (*J. Soc. Chem. Ind.*, **7**, 795—806).—The author contends that although Clark's process for determining the hardness of water gives constant and fairly accurate results when applied to certain waters of moderate hardness, it gives misleading results when applied to hard water, highly magnesian water, or waters outside the general run of those met with in the south of England. In such cases the soap test must be abandoned in favour of other methods which furnish the information required more accurately, such for instance as boiling down the water to a small bulk with sodium carbonate, filtering and washing the precipitate, dissolving it in standard acid, and titrating back with standard alkali and methyl-orange. The result represents the total calcium and magnesium very closely, and may be expressed in terms of calcium carbonate. By titrating the original water with standard acid and methyl-orange, an estimate of the earthy carbonates (temporary hardness) can be obtained in a few minutes. The author gives many valuable analyses of special waters, the results of which furnish the strongest proofs of the untrustworthy nature of the soap test. In the remaining part of the paper the author discusses at some length the question of stating the results of the analysis of waters, which in his opinion should depend on circumstances. For technical purposes, grains per gallon seems to be the most generally convenient mode of expression, although in the case of feed waters it is often useful to add another table showing pounds per 1000 gallons. With regard to the method of recording acids and bases in combination as salts, a more regular and generally accepted practice is desirable. In the case of sulphates the author is in favour of expressing all the calcium as $CaSO_4$, or at any rate all which is in excess of that required to form carbonate, assuming of course that the sulphates are present in excess. The combined carbonic anhydride should as far as possible be expressed in the form of calcium carbonate. D. B.

Estimation of Alkalis in Water. By F. Muck (*Zeit. anal. Chem*, 28, 628).—A rough method in use consists in converting all the bases into sulphates and deducting from the gross weight that of the silica and the calcium and magnesium sulphates. The water is evaporated to dryness, and the residue is moistened with alcohol containing about three drops of concentrated sulphuric acid per c.c. The alcohol is then set on fire and burnt off, when, if the quantity of acid added is sufficient, the residue will appear damp, and acid fumes will be given off. In the contrary case, the residue will remain dry and will require a repetition of the treatment with the acid alcohol. In this way the quantity of acid is very conveniently adjusted. The final ignition with ammonium carbonate is performed as usual. M. J. S.

Estimation of Methoxyl. By R. Benedikt and A. Grüssner (*Chem. Zeit.*, 13, 872—873).—The authors describe and illustrate an apparatus which answers well for the estimation of methoxyl by Zeisel's method. A distilling flask serves for the reaction, carbonic anhydride being conducted to the bottom by a tube passing through a cork in the neck, the side tube bends upwards and terminates in a neck, into which is fitted, by a cork, the end of an upright tube which continues to a series of three bulbs, one above another; the first (lowest), of 30 c.c. capacity, is connected with the second, 80 to 100 c.c. capacity, by a tube projecting well into the latter, whilst a tube starts from the bottom of the second and terminates in a downward bend about midway in the third bulb, which has the same capacity as the second; above these three bulbs there is another, but much smaller bulb, and then a long tube, bent twice at right angles, passing downwards into the absorption apparatus consisting of a distilling flask connected by its side tube, which is bent downwards for the purpose, with a second flask. When in operation, the three bulbs are surrounded by a condenser, the second and third being charged by means of a wash-bottle with amorphous phosphorus and water; water at 70° is caused to circulate in the condenser, and by means of the bulbs the water and almost all the hydriodic acid run back into the reaction flask, the iodine is washed out, and the methyl iodide and carbonic anhydride pass on to the absorption apparatus. By retaining the condenser at 89°, isopropyl iodide has been successfully carried to the absorption flasks. D. A. L.

Estimation of Glycerol. By T. Morawski (*Chem. Zeit.*, 13, 431).—About 2 grams of glycerol is weighed into a crucible containing from 50—60 grams of lead oxide, and sufficient alcohol is added to permit of the mass being well mixed; it is dried in a vacuum water-oven and then heated at 120—130° to constant weight. The results differ by 0·5—0·6 per cent. on an average, and judging from a table of numbers obtained by various means, this method gives results agreeing fairly well with numbers obtained by combustion, &c.

D. A. L.

Estimation of Glycerol in Crude Glycerol. By J. Lewkowitsch (*Chem. Zeit.*, **13**, 659).—The author has already found the Benedikt-Cantor acetin method (Abstr., 1889, 748) effective, and now gives results, confirming that view, obtained with crude glycerols of various origins; moreover, from these results he recommends the adoption of the method in all cases where a more or less pure crude glycerol is obtained in course of analysis, as, for instance, in the glycerol estimations in fats or in wine or beer analyses. The author has estimated the glycerol in the fat of Sawarri nut, obtaining 88·48 and 88·29 per cent. of pure glycerol; the method does away with the waiting for drying, and also the ash determinations. The author neither considers nor has he found the lead oxide method (Morawski, preceding abstract) trustworthy for crude glycerols, at least in its present form.

D. A. L.

Examination of Commercial Carbolic Acid and of Disinfectant Powders made therefrom. By R. Williams (*J. Soc. Chem. Ind.*, 7, 826—828).—Most of the commercial carbolic acid examined by the author was found to contain little or no phenol, but consisted of cresols and still higher homologues. For the estimation of the water in carbolic acid, the distillation method is the most accurate. In the case of carbolic acid powders, the percentage of tar acids may be determined by the following process devised by the author, which is said to be simple in execution, yield accurate results, and to be applicable to a large number of samples at the same time:—600 grains of the sample is placed in a stoppered bottle, and digested for one or two hours with 3000 grains of strong alcohol, the mixture being shaken frequently. It is then passed through a double filter, after which two-thirds of the whole is transferred to a 10-oz. porcelain basin. 300 grains of a 10 per cent. solution of sodium hydroxide is now added, and the mixture evaporated until all the alcohol has been expelled. The residue is transferred to a long, narrow tube, holding 1000 grains, and carefully graduated into 500 divisions. 100 grains of hydrochloric acid is added, and the liquid saturated with salt. After mixing well and allowing to cool to 15°, the volume of tar acids is read off. As the sp. gr. of these acids usually lies between 1·04 and 1·05, their approximate weight may be ascertained by adding one-twentieth to the volume found.

D. B.

Percentage Glucosometer. By A. W. Gerrard (*Lancet*, 1890, **1**, 15—16).—This instrument is designed to enable medical practitioners to determine rapidly by means of Fehling's solution the percentage of dextrose in diabetic urines. It consists of a pair of burettes, clasped by a pair of swinging arms supported on an upright brass stand; the burettes can be moved at will, so as to be brought over a dish containing 10 c.c. of boiling Fehling's solution diluted with water. The burettes are graduated in degrees which correspond with percentages of dextrose in a urine diluted to 20 volumes with water. The instrument indicates percentages between 1 and 10; and the two burettes are of different sizes, one thin and narrow for high percentages, the other of larger capacity for low percentages. The saving of time to the busy practitioner thus accomplished is obvious.

W. D. H.

Analysis of Sugars. By E. JUNGFLEISCH and L. GRIMBERT (*Compt. rend.*, **109**, 867—870).—The authors have previously shown (Abstr., 1889, 479) that feeble acids do not affect the rotatory power of levulose, but that strong acids produce considerable variations, the effect being greater when the levulose is formed by inversion in presence of the strong acid than when the latter is added to levulose previously prepared. This action of the strong acids introduces serious errors into Clerget's inversion method for the analyses of sugars, and the use of acetic acid for producing inversion has been adopted by some chemists

The authors find that although alkaline acetates have no influence on inversion by strong acids, they prevent complete inversion by acetic acid, even when the latter is used in large excess. Alkaline citrates, formates, lactates, and tartrates, and zinc and lead acetates, produce a similar effect, but calcium acetate is much less injurious. Salts of the strong monobasic acids do not affect inversion by acetic acid. Normal salts of bibasic acids interfere when they contain monad metals, but not when the metals are dyad. Acid salts of strong polybasic acids do not interfere, and some of them, like the acid sulphates and acid oxalates, can themselves produce inversion. C. H. B.

Estimation of Raffinose in Raw Sugar. By T. BREYER (*Chem. Zeit.*, **13**, 559—560).—50 c.c. of the solution for polarisation, containing 26·048 grams per 100 c.c., is mixed with 5 c.c. of hydrochloric acid, sp. gr. 1·182, in a 50—55 c.c. flask, which is then placed in a water-bath, along with a similar flask filled with water, and with a thermometer in it; the heat is regulated so that this thermometer registers 68—69° for five minutes, five minutes being allowed for it to reach this temperature. The solution is then quickly cooled, and removed to the polarising room; after some hours, the flask is filled to the mark, decolorised with dry animal charcoal if necessary, and polarised in a cylinder with a tube for the thermometer attached. The apparent amount of saccharose can be calculated by Clerget's formula from the polarisation before and after inversion and the thermometer readings. In the absence of substances reducing Fehling's solution, and with a difference of 0·5 or above from the direct polarisation indicating the presence of some other optically active substance, the actual amount of saccharose can be calculated by a formula given in the paper, which is a combination of Clerget's and Creydt's formulæ. The difference between the number so found and the direct polarisation may be assumed to be due to a definite quantity of raffinose, which may be calculated. It is shown that neither differences in concentration nor in temperature, within certain limits, will affect Creydt's constants for the inversion of raffinose solutions, but if greater refinement is required, a formula embodying the necessary corrections is given. D. A. L.

Detection of Rye-Meal and Bran in Wheat-Meal and Bran. By F. BENECKE (*Landw. Versuchs.-Stat.*, 36, 337—366).—The method proposed by the author is based on the fact that whilst the ripe rye-corn of nearly every description contains a blue colouring matter, that of wheat does not (with the exception of one unimportant variety). To determine whether wheat-bran is free from rye-bran, or whether rye-bran is very much adulterated with wheat-bran, the product is so finely ground as to pass through a millimetre sieve; the meal is then sifted off through fine muslin, and the remaining bran (about a teaspoonful) rubbed with ether, until the ether is made only slightly turbid. It is then washed into a beaker with ether, the ether poured off, and olive oil added. It is then examined by a microscope magnifying from 100 to 200 times. To find how much rye-bran is mixed with wheat-bran, the relation of coloured to colourless particles in 100 units of surface is determined. It is possible to detect the presence of rye-bran without a microscope by putting the olive-oil containing the bran on a glass plate over a white surface.

The following method was found to be the easiest and most trustworthy for the determination of rye-meal in wheat-meal:—100 grams of the meal is put into a pear-shaped vessel (500—600 c.c. capacity), which is then two-thirds filled with chloroform. The whole is well shaken, so as to distribute the meal equally, and the vessel nearly filled with chloroform, again shaken, and allowed to settle. The dirt and dust settle first, and after about 24 hours a further separation takes place. With rye- and wheat-meal, the gluten settles to the bottom, whilst the other constituents, especially the starch, form a solid, floating mass. Between the sediment and the floating portion is a more or less clear, yellow chloroform solution. The differences in colour of the sediments and floating portions from the two kinds of meal is very striking, and is shown as well as that of various mixtures, in coloured tables. For instance, the colour of the residue from rye-meal of poorest quality is dark olive-green, and the floating portion light-brown; with wheat of best quality, the colours are brownish-yellow and almost white respectively. A further difference is that the amount of sediment with rye-meal of worst quality is far greater than that of the best wheat-meal. The better kinds of meal give less sediment. Whilst the amount of sediment depends on the quality of the meal, the colour depends on its origin.

To detect with certainty the presence of 10 per cent. of rye-meal of best quality in wheat-meal of second quality, the floating portion is carefully stirred and washed out with chloroform; ether is then poured into the vessel, the sediment stirred up, washed into a dish, and allowed to settle; the ether is poured off, moderately strong acetic acid is added, and the whole boiled and stirred; wheat-meal so treated gives a yellowish-brown colour, rye a splendid, deep rose-red colour (shown in the table). The colours produced with various mixtures are also shown.

Adulteration of wheat-meal with rye-meal is less frequent than than that of rye with wheat; but the above method, owing to its trustworthiness and ease with which it is used, is of considerable value.
N. H. M.

Estimation of Cellulose. By G. LANGE (*Zeit. physiol. Chem.*, **14**, 283—288).—The method depends on the fact that cellulose remains unaltered after fusion with alkaline hydroxides.

10 grams of the material is mixed with 30—40 grams of an alkaline hydroxide and 30—40 c.c. of water in a retort which is heated at 140—180° for an hour; it is then cooled to 80°, and the contents of the retort washed out with hot water and finally with cold water into a beaker. The mixture is here acidified with dilute sulphuric acid, and again carefully made just alkaline with dilute sodium hydroxide, so that all substances precipitated by the acid enter into solution again with the exception of the cellulose; the precipitate is collected on a filter, weighed, incinerated, and the amount of ash deducted. The method gives very concordant results; they are a little higher than those obtained by F. Schulze's method (*Chem. Centr.*, 1857, 321).
W. D. H.

Valuation of Wine-lees. By P. BOESSNECK (*Chem. Zeit.*, **13**, 356—357).—Goldenberg's, Fresenius's, and v. Lorenz's methods are individually inaccurate for the estimation of total tartaric acid in wine-lees, but concordant results are obtained by a combination of the Goldenberg-Geromont and Fresenius methods. 10 grams of the finely-powdered wine-lees is digested for some hours, with frequent agitation, in 15 c.c. of hydrochloric acid, sp. gr. 1·1, and the same volume of water, and made up to 203 c.c.; it is then filtered, and 100 c.c. heated, made strongly alkaline with potash, and, after prolonged boiling, again filtered. The filtrate and washings are treated with hydrochloric acid until only feebly alkaline, evaporated to 20 c.c., and when cold treated with 5 or 6 c.c. of glacial acetic acid. After 10 minutes' warming, 100 c.c. of absolute alcohol is poured in, and in two hours' time it is filtered. The precipitate, consisting of all the tartaric acid of the lees as potassium salt, is washed free from acid with strong alcohol, and titrated at first to neutrality, and then, after boiling for some time, to the finishing point, using the artificially-prepared litmus-colouring matter, "azolitminum." Potassium hydrogen tartrate may be determined in the presence of gypsum by boiling with excess of antimonious anhydride and estimating the antimony in the filtrate containing the potassium tartrate as the potassium antimony salt; or the whole of the tartaric acid may be determined by treating the lees first with potassium oxalate to eliminate calcium, then boiling with antimonious anhydride and decomposing the potassium antimony oxalate with gypsum, finally estimating the antimony in the filtrate. The strength of the solution and the quantity of antimonious anhydride present influence the results. The use of litmus tincture in the v. Lorenz method is not approved of.
D. A. L.

Analysis of Argol. By N. v. LORENZ (*Chem. Zeit.*, **13**, 693—694; compare Abstr., 1888, 327, and preceding abstract).—The author criticises in detail Goldenberg's methods of estimating tartaric acid, and asserts their untrustworthiness, but upholds the efficiency of his own method; he experiences no difficulty in using litmus tincture as an indicator, and attributes the failure of other chemists to the use of litmus either of inferior quality or not prepared according to his directions. He regards the Grosjean-Warington and the Scheurer-Kestner processes as even less trustworthy for the purpose than the Goldenberg method. D. A. L.

The Fokker-Salkowski Method of estimating Uric Acid in Normal and Pathological Urines. By R. POTT (*Pflüger's Archiv*, **45**, 389—400).—Fokker's method of estimating uric acid was compared with Salkowski's; in some cases the two methods gave identical results, in others they did not; the highest percentage difference obtained was about 3. It was generally much less. The results were sometimes higher by one method, sometimes by the other. Such variations are not, however, regarded as very serious, and the cause of their occurrence is not apparent. The experiments were performed with normal and with various kinds of morbid urine, and the final conclusion is that Fokker's method of estimating uric acid is applicable to all kinds of urine. W. D. H.

Simplified Fat-extraction Apparatus. By J. T. CRAWLEY (*Amer. Chem. J.*, **11**, 507—508).—This consists of (1) a glass tube 4 cm. wide and 20 cm. long, drawn out at one end so as to pass through a rather large hole in the cork of a flask; (2) a large sized test-tube, fitting into the larger tube so as to reach within 3 cm. of the top; (3) a glass tube of about $\frac{1}{3}$-cm. bore, bent so that one end dips down to the bottom of the test-tube, whilst the other limb lies between the two tubes (1) and (2) with the other end reaching to the narrowed part of the outer tube. The upper part of (1) is connected with a condenser, and ether or alcohol is boiled in the flask, the substance under examination being placed in the test-tube. The vapour is condensed, and flows back into the test-tube, and when this is nearly full, capillary attraction draws the liquid through the syphon, and the contents of the test-tube with the extracted fats are syphoned off into the flask below. C. F. B.

Estimation of Fat in Sour Milk. By M. KÜHN (*Chem. Centr.*, 1889, ii, 303; from *Milch-Zeit.*, **18**, 561—562).—The sour milk is rendered just alkaline with aqueous potash (40 grams in 1 litre of water), thereby dissolving the casein. 10 grams of the alkaline milk is poured on to a mixture of 25 grams of ignited gypsum, 4 grams of precipitated calcium carbonate, and 2 grams of potassium hydrogen sulphate, dried, ground up, and extracted in a Soxhlet's extractor. The addition of potassium hydrogen sulphate prevents the slight excess of alkali from saponifying the butter fat, whilst the calcium carbonate neutralises the remainder of the potassium hydrogen sulphate.

J. W. L.

Rapid Estimation of Fat in Milk. By A. W. STOKES (*Chem. News*, **60**, 214—215).—The author finds the following method, suggested by W. Schmid, to be rapid and accurate. 10 c.c. of milk is pipetted into tubes partly graduated up to 50 c.c., hydrochloric acid is poured in roughly to the 20 c.c. mark, the mixture is boiled, not more than two minutes, with frequent shaking, until it turns brown (watered milks do not turn deep-brown, whilst condensed or sugared milks become almost black); then after about three minutes it is cooled, and the tube filled up roughly with ether to 50 c.c., corked, and shaken for half a minute. In five minutes' time, 20 c.c. of the ethereal solution is carefully pipetted off, evaporated. and the fat dried in an air-bath and weighed. The volume of ether left in the tube is read off, taking three-quarters of the stratum of caseïn, if any is present, as ether, and the fat calculated on the whole volume of ether, &c. The differences between the fat observed by this method and the fat calculated never reaches a tenth per cent. D. A. L.

Examination of Butter. By S. Salvatori (*Bied. Centr.*, **18**, 788; from *Staz. Sper. Agrar. Ital.*, **14**, 516—526).—Drouot's method for examining butter consists in melting it slowly, when, if the butter is pure, a clear liquid is obtained, the water and caseïn settling at the bottom; an artificial butter, on the other hand, remains turbid, and only becomes clear when heated much above its melting point. The author finds that the method is not always trustworthy, inasmuch as purified natural fats of all kinds, oleomargarin, and frequently natural butter give very clear liquids, natural butter being further characterised by a sediment; the latter, in artificial butters, is amorphous, and renders the liquid turbid as it settles slowly. Some melted samples of natural butter were also turbid, from the presence of drops of water. When natural is mixed with artificial butter, the addition of margarin or fat cannot be established with certainty.

N. H. M.

Rapid Method for the Analysis of Tallow. By H. Taffe (*Bull. Soc. Chim.* [3], **2**, 209—210).—Ordinary tallow, when titrated for free stearic acid, yields 3·6 per cent., whereas stearine candles of good quality yield 100 per cent.; olive oil yields 2·5 per cent. of free oleic acid.

The method consists in determining the acid factor for a solution of the fat in an already titrated olive oil by means of normal potash, using turmeric as an indicator. T. G. N.

Analysis of Wool Oils. By H. Horwitz (*Dingl. polyt. J.*, **271**, 29—30).—The materials used in the manufacture of woollen goods for imbuing the fibres intimately with oil are emulsions of liquid fats and aqueous alkaline solutions. Those examined by the author were mostly mixtures of olive and cotton-seed oils with solutions of ammonia and sodium hydroxide. As olive oil is often adulterated with mineral, rosin and drying oils, which have an injurious effect on the subsequent manufacturing operations, the author recommends the following process for the quantitative estimation of these adulterants:—1·5 to 2 grams of the oil is weighed in a closed vessel, and digested for some hours with alcohol and ether. The sodium hydroxide, which remains undissolved, is collected on a tared filter, dried at 100°, and weighed. One half of the filtrate is evaporated and dried at 100—120°, in order to obtain the fat, whilst in the other half the ammonia is determined by treating the solution with hydrochloric acid and precipitating with platinic chloride. The water is determined by drying another portion of the oil at 100—120°, weighing, and deducting from the weight the quantity of ammonia found. The following analysis is given as an example:—

Fat.	Sodium hydroxide.	Ammonia.	Water.
14·16	0·91	0·32	84·45

showing that for the preparation of the wool oil in question 14·16 parts of fat, 0·91 part of soda, and 84·77 parts of ammonia of sp. gr. 0·9983 had been used. D. B.

Examination of Commercial Oleïn for Linoleïc Acid. By K. Hazura (*Zeit. ang. Chem.*, 1889, 283—284; compare Abstr., 1887, 359, 798, 913; 1888, 816, 817, 1269, 1270; 1889, 374).—Olive oil contains chiefly oleïc acid, with a small quantity of linolic acid, $C_{18}H_{32}O_2$. On oxidising its alkaline solution with potassium permanganate, the products are *dihydroxystearic acid* (melting point 137°; almost insoluble in water and ether), *sativic acid*, $C_{18}H_{32}O_2(OH)_4$ (m.p. 173—175°; slightly soluble in water, insoluble in ether), and *azelaïc acid*, $C_9H_{16}O_4$ (easily soluble in water and ether). The acid of linseed oil consists mainly of *linolenic acid* and *isolinolenic acid*, $C_{18}H_{30}O_2(OH)_6$, with small quantities of oleïc and linolic acids. The solid products of oxidation are dihydroxystearic acid, sativic acid, azelaïc acid, and two hexahydroxystearic acids, $C_{18}H_{30}O_2(OH)_6$, namely, *linusic acid* (m.p. 203°; completely insoluble in ether, sparingly soluble in water), and *isolinusic acid* (m.p. 173°; soluble in water, but insoluble in ether).

50 grams of the oil is saponified with alcoholic potash, freed from the alcohol, and diluted to 1 litre. To the solution, which must be strongly alkaline, there is then added a litre of 5 per cent. solution of potassium permanganate. After an hour it is filtered; the filtrate is acidified with sulphuric acid, filtered, neutralised with potash, evaporated to 300 c.c., and again acidified, whereupon a second precipitate is obtained. The whole is then shaken with ether, when, if the precipitate dissolves, it consists of azelaic acid, and the oil was free from linoleic acid. If it does not dissolve, it is collected, crystallised once or twice from water or alcohol, and its melting point determined. If this is above 160°, linoleïc acid was certainly present. Less than 1 per cent. cannot, however, be detected. M. J. S.

Estimation of Fat in Poppy-cake. By P. Baessler (*Landw. Versuchs-Stat.*, 36, 367—372).—It was previously shown (Abstr., 1889, 321) that too low results are obtained when the fat of linseed-cake is determined after drying the substance at 100°, and experiments described in the present paper show that the same holds good with poppy-cake. For example, a sample of cake containing 7·54 per cent. of fat (when dried for 4 to 6 hours at 110° in a stream of hydrogen) lost 0·84 per cent when heated for two hours, 3·11 per cent. when heated for four hours, and 3·67 per cent. when heated for six hours at 100° in air; at 110° the loss was still greater. Determinations made after drying in a vacuum over sulphuric acid were also unsatisfactory, the results being in one case 1·10, and in another 0·31 too low.

With regard to the determinations of water, it is found that when the substance is heated at 100° in a stream of dry hydrogen and the water weighed, the results obtained are too high, owing to an oily substance being carried over into the absorption apparatus.

The best results, both with regard to water and fat, were obtained by heating the substance from two and a half to three hours at 90°.

N. H. M.

Estimation of Cotton-seed Oil in Lard. By Bockairy (*Bull. Soc. Chim.* [3], **2**, 310—313; compare this vol., p. 93).—The sp. grs. of the following substances at 50° are:—

Lard	0·889—0·8915	Ox-kidney fat......	0·8895
Rancid lard........	0·8895	Fresh cotton-seed oil	0·897
Oleostearine........	0·8885	Old „ „	0·896

and mixtures of cotton-seed oil with pure lard determine a proportionate rise in the density.

Hubl's iodine test does not give sufficiently accurate data with the crude mixtures, but the author finds that the iodine numbers given by the solid fatty acids separated from these mixtures are more satisfactory, and he is working on a process for this estimation.

T. G. N.

Iodine Absorption as a Test for Essential Oils. By H. W. Snow (*Pharm. J. Trans.* [3], **20**, 4; compare this vol., pp. 199, 200).—Determinations are given of the iodine absorptions of a number of essential oils. The process followed was Hubl's, but the author found that the absorption was usually not complete in less than 40 hours. The experiments have shown that although these iodine absorptions are not constant, they afford valuable indications in determining the purity of oils, and they may be directly employed for the detection of turpentine in oil of peppermint. R. R.

Detection of Ordinary Turpentine in Venice Turpentine. By E. Hirschsohn (*Arch. Pharm.* [3], **27**, 999—1000, from *Pharm. Zeit. Russ.*, **36**, 561).—The behaviour of turpentine towards ammonia not only affords a certain means of discriminating between the two kinds of turpentine, but up to a certain point serves to detect one variety in presence of the other.

A small quantity of ordinary turpentine treated with strong ammonia gradually mixes to form a milk; with Venice turpentine the liquid remains clear. If a glass rod is used to stir up the mixture, the Venice turpentine gradually becomes a semi-solid, colourless, opaque mass, whilst the liquid is only slightly turbid; ordinary turpentine, on the other hand, dissolves readily and forms a milky liquid, which after a short time sets to a jelly, especially when 5 parts of ammonia is added to 1 part of turpentine. Venice turpentine containing 50 per cent. of ordinary turpentine is readily disseminated through ammonia; the mixture sets after five minutes, and when placed in boiling water becomes clear; a mixture of 30 per cent. of ordinary turpentine behaves similarly, sets in about 10 minutes, and becomes clear on the water-bath; with 20 per cent., the mixture readily becomes milky, does not set, but becomes clear on the water-bath; mixtures containing less than 20 per cent., can only be detected by comparison with genuine Venice turpentine. Mixtures containing not less than 30 per cent. of ordinary turpentine can to some extent be detected by the use of 80 per cent. alcohol; on shaking up 1 part of turpentine with 3 parts of alcohol, Venice turpentine gives an almost clear solution, whilst with ordinary turpentine over half the quantity employed separates after a short time. J. T.

Estimation of Urea. By E. Pflüger and L. Bleibtreu (*Pflüger's Archiv.*, **44**, 1—116).—This is a series of six articles related one to the other The first two are by E. Pflüger alone, and relate to technical details, whilst the next four deal with the actual analyses, full details of which are given; the outcome of the whole is the comparison of three methods of urea analysis, Bunsen's method (compare Böhland, Abstr., 1889, 538), the method of heating with caustic alkali, and lastly the phosphoric acid method. Bunsen's method with Böhland's modifications, and with certain precautions fully detailed in the present communications, is one of the greatest possible accuracy. The alkali method is simpler, but yields somewhat less ammonia even if the heating is continued for six hours. The phosphoric acid method is far simpler than either, and although it gives somewhat higher results than Bunsen's method, is regarded as being sufficiently accurate for most purposes. The apparatus and reagents necessary are:—a Schlösing-Neubauer apparatus for the estimation of the preformed ammonia in urine; copper drying chamber of special construction, which is fully described; a distilling apparatus; solution of sulphuric acid, of such a strength that 1 c.c. corresponds with 0·001 gram of nitrogen, an equivalent solution of sodium thiosulphate; a 20 per cent. solution of potassium iodide, and a 4 per cent. solution of potassium iodate; a mixture of hydrochloric and phosphotungstic acids; phosphoric acid in crystals, or a strong solution of phosphoric acid. The method is briefly as follows:—1 volume of urine is mixed with 2 volumes of the acid mixture to remove "extractions;" this is allowed to remain for 24 hours, and filtered into a mortar (filtrate I). This is rubbed up with chalk until alkaline, covered with a glass plate until the blue colour disappears, and filtered (filtrate II); three burettes are filled with this filtrate and closed with good stoppers. Some of this filtrate serves for the estimation of preformed ammonia. 10 grams of phosphoric acid crystals is placed in each of four distilling flasks, and 15 c.c. of filtrate II added. The flasks are then placed in the oven and heated for three hours to a temperature of 230—260°. To each about 70 c.c. of sodium hydroxide of 1·3 sp. gr., and 600 c.c. of water are added, and the distillate received in a measured volume of the standard sulphuric acid, which is then treated with iodine and thiosulphate, and from the amount of this used the nitrogen from urea and ammonia is calculated; the ammonia is known, and can be subtracted from this. The average is thus taken of the four estimations. W. D. H.

In the same volume (pp. 273—300) is an article by Pflüger relating to the details and precautions necessary in the titration of acids and bases, especially of ammonia, by means of iodine and thiosulphate. W. D. H.

Analysis of Methylanilines. By H GIRAUD (*Bull. Soc. Chim.* [3], **2**, 142—144; compare Abstr., 1889, 1038).—The author objects to the process described by Reverdin and De la Harpe (Abstr., 1889, 1038), on account of the difficulty in procuring and of preserving absolute acetic anhydride, and recommends the employment of a 10 per cent. solution of this substance in dimethylamine, which is easily standardised by barium hydroxide, using phenolphthaleïn as an indicator. The analysis of a sample is thus conducted:—1 gram of the methylaniline is added to 10 c.c. of the above acetic anhydride solution, and allowed to remain one hour in contact, when the mixture is to be diluted with water and titrated; the difference in the two values for acetic anhydride determining the methylaniline present.

The author also states that the formation of nitro- and of nitrosonitrosamines in Nölting's process, noticed by the above-mentioned authors, is probably due to their employing too great an excess of nitrite. T. G. N.

Test for Antipyrin. By A. C. STARK (*Pharm. J. Trans.* [3], **19**, 949).—The green colour produced when a liquid containing antipyrin is added to sulphuric acid with which a little weak solution of potassium nitrate has been mixed, is a delicate and characteristic test. R. R.

Estimation of Cinchona Alkaloïds. By T. FAWSSETT (*Pharm. J. Trans.* [3], **19**, 914).—1 gram of the alkaloïd or salt is dissolved in just sufficient dilute sulphuric acid, and the solution is diluted to 600 c.c., in a cylindrical vessel at a temperature not much below 15°. Bromine-water, which has immediately before been standardised in the usual way, is run in in quantities of 5 c.c., the colour being allowed to disappear after each addition, until a permanent yellow tint is produced. The excess of bromine is estimated colorimetrically by determining the quantity of the bromine-water required to produce an identical tint in 600 c.c. of pure water contained in a similar vessel. The amount of bromine decolorised by the alkaloïd is easily calculated. It was found that the amount of bromine absorbed by each molecule of quinine, quinidine, and cupreine was 6 atoms; 4 atoms by a molecule of hydroquinine, 2 atoms by each molecule of cinchonidine cinchonine, and amorphous quinine. The average amount of bromine absorbed by 1 gram of various specimens of commercial sulphate of quinine was found to be 1·029 gram. The process gives constant and accurate results, the maximum error found by control experiments being only 0·008 gram of bromine. R. R.

Estimation of Alkaloïds in Coca Leaves. By V. D. MARK (*J. Pharm.* [5], **20**, 500; from *Pharm. Zeits. Russ.*, **28**, 1889, 349).—50 grams of the powdered leaves and 20 grams of calcined magnesia are moistened with a little water, dried at 60°, and exhausted with ether. The ether is removed by distillation, and the residue treated with 2 per cent. hydrochloric acid; after filtering, the filtrate is shaken with a little ether, just sufficient to remove the colouring matter; ammonia in excess is now added, and again ether. This last operation is repeated three times, employing 25 c.c. of ether each time. The ethereal liquids are mixed, and freed from the small quantity of water they may contain by the addition of some fragments of fused calcium chloride. Finally, the ether is removed by evaporation, and the residue dried and weighed. J. T.

Cinnamylcocaïne in Coca Leaves. By B. H. PAUL and A. J. COWNLEY (*Pharm. J. Trans.* [3], **20**, 166).—The amount of cocaïne in coca leaves cannot be determined by the amount of alkaloïd crystallisable from light petroleum, for the authors have found that the leaves contain also cinnamylcocaïne, which is similarly crystallisable. R. R.

Assay of Emetine in Ipecacuanha Wine. By T. P. BLUNT (*Pharm. J. Trans.* [3], **20**, 254).—This method depends on the fact that emetine removes mercuric iodide from its solution in potassium iodide, and that it is therefore possible to measure the amount removed by determining the solvent power of the liberated potassium iodide for mercuric iodide. Practically the method employed is to add a standard solution of mercuric chloride until a permanent precipitate is obtained.

50 c.c. of the wine is evaporated on the water-bath to 20 c.c., then 10 c.c. of Mayer's solution is added; the precipitate is allowed to settle, and the liquid passed through a dry filter. To the 25 or 27 c.c. of filtrate thus obtained, a centinormal solution of mercuric chloride is gradually added from a pipette until a faint permanent cloudiness is obtained. From 4 to 6 c.c. will be required, according to the amount of emetine present.

Mayer's solution is prepared by adding saturated mercuric chloride solution to 100 parts of a 10 per cent. solution of potassium iodide until there is a slight permanent precipitate, filtering, and making up to 200 parts with water. R. R.

Reactions of the Alkaloïds. By A. L. BROCINER (*J. Pharm.* [5], **20**, 390—392).—A test solution, prepared by dissolving 1 gram of potassium perrutheniate in 20 c.c. of pure concentrated sulphuric acid, gives the following reactions:—With *solanine*, the liquid slowly becomes red, the colour disappearing at a gentle heat. *Ononine* becomes reddish-brown immediately. *Chelidonine* gives a green coloration; with potassium sulphoniobate, this same alkaloïd becomes brownish-red. *Imperatorine*, obtained by Ossan from *Imperatoria ostruthium*, gives with the test solution a blue coloration which quickly becomes intense green. This reaction is very delicate with the perrutheniate, although the other alkaloids give the best results with the rutheniate.

Freshly prepared ammonium sulphouranate (1 gram of ammonium uranate in 20 c.c. of concentrated sulphuric acid) gives with *codeine* a blue coloration on gently heating; *imperatorine* gives a blue coloration which quickly disappears on heating; *morphine* gives a dirty-green on gently heating; and *chelidonine* slowly affords a green coloration. J. T.

Colouring Matter of Wines. By MONNET (*Bull. Soc Chim.* [3], 2, 144).—In contradistinction to the other metallic sulphides which remove the colouring matter from wines, arsenic sulphide yields the colour up to unacidified alcohol, and the violet substance obtained on evaporation of the tincture is soluble in alcohol, glycerol, etherised water, and slightly less so in ordinary water.

The residue obtained on evaporating the tincture yielded by the arsenic sulphide precipitate to alcohol, acidified with acetic acid, is blue and partly soluble in alcohol; whilst that similarly obtained by means of lead sulphide is insoluble in alcohol, and is not the normal colouring matter of wine, as it was deemed to be by Mulder and Maumené. T. G. N.

Detection of Alkanna Red in Wine. By J. HERZ (*Zeit. anal. Chem.*, 28, 637).—Alkanna red is very easily taken up from its solutions by amyl alcohol. On adding to the amyl alcohol solutions a few drops of olive oil or oil of almonds, and evaporating off the alcohol on the water-bath, the oily residue (after washing with water) has a fine red colour, which, on saponification, becomes a rich blue, or, if the alkanna used was old, a green. M. J. S.

Valuation of Indigo. By M. HÖNIG (*Zeit. ang. Chem.*, 1889, 280—283).—The reduction and oxidation methods for estimating the indigotin in indigo give results which are respectively much below and above the truth. The author prefers to weigh the indigotin after extraction with boiling aniline or nitrobenzene. For this purpose, about 0·5 to 0·8 gram of the indigo, finely powdered and dried at 100—110°, is well mixed with three or four times its bulk of ignited pumice in grains of about a cubic millimetre. The mixture is introduced into a small Zulkowski-Wolfbauer percolation apparatus, which is connected with an upright condenser and a flask containing 50 c.c. of dry aniline. On boiling the aniline the vapours pass to the upper part of the percolator, and, condensing, fall while hot upon the mixture. It is essential to a rapid extraction that the aniline should percolate through the mixture while as hot as possible; hence the necessity for avoiding the presence of pumice dust. When the extract no longer runs off blue, the apparatus is cooled, and the aniline adhering to the pumice is displaced by 95 per cent. alcohol, which is collected apart. The extracted mixture should be dried, broken down, and returned to the percolator, to be once more extracted with the aniline. The aniline solution is then concentrated to about 10 c.c., and after cooling is measured in order to make a correction of 1·3 milligrams per c.c. (2·1 milligrams if nitrobenzene has been used) for the solubility of indigotin in the cold. It is then mixed with five or six volumes of alcohol (that which had been used for washing the pumice), and the indigotin is collected on a tared filter, washed with alcohol as long as the washings have a brown colour, dried at 110°, and weighed. It is well to determine any ash it may contain, as particles of pumice may have passed through the plug of cotton-wool placed at the bottom of the percolator. M. J. S.

Lime in Tanning Materials. By M. PETROWITSCH (*Zeit. anal. Chem.*, **28**, 606—607).—In examining tanning materials, it is not usual to do more than determine the tannin, as they are rarely adulterated. The author has met with a specimen of valonia, which, when used for tanning, produced bluish-black stains, such as might be attributed to the presence of lime. The ash amounted to 6·36 per cent., which is 2½ times as much as in pure valonia; and the lime constituted 6·37 per cent. of the ash, being about twice as much as it should have been. From the sample there was easily picked out 0·815 per cent. of small pebbles, some of which were calcareous.

M. J. S.

Trichloracetic Acid as a Reagent for Albumin. By BOYMOND (*J. Pharm.* [5], **20**, 482—484).—Marsault, Languepin, and Patein have indicated the existence in some urines of a variety of albumin which is coagulated by heat, but which is redissolved by acetic acid. Trichloracetic acid precipitates this variety of albumin, and the author recommends the substitution of this acid for nitric acid in a process given by Patein for the examination of urine, in which the globulin is determined by the aid of magnesium sulphate, the sereïn (? serum albumin) in a second portion by boiling with the addition of a few drops of acetic acid, and in the filtrate from this portion, the new variety is precipitated by the addition of nitric acid and boiling.

J. T.

Determination of Caseïn. By H. AUBIOT and D. MONNIER (*Chem. Centr.*, 1889, ii, 521; from *Arch. sci. phys. nat. Genève*, **22**, 55—58).—Caseïn is precipitated by copper sulphate, the copper caseate being insoluble in excess of the reagent, whereas the analogous precipitates obtained with albumin and proteïn substances are soluble in excess of copper sulphate, the only other exception being globulin. In applying this fact to the quantitative determination of caseïn, 1 or 2 c.c. of milk is precipitated with 5 c.c. of a 5 per cent. solution of copper sulphate, the mixture warmed on the water-bath, with constant stirring, and, after cooling, the precipitate is filtered, washed with distilled water, alcohol, and ether, and weighed; from this weight, the weight of the mineral matter carried down with it is deducted. The latter was found to be usually 10 per cent.

J. W. L.

General and Physical Chemistry.

Studies in Chemical Optics with Reference to the Dissociation Theory. By M. Le Blanc (*Zeit. physikal. Chem*, **4**, 553—560).—The atomic refractions of the elements are subject to variations as yet unexplained, and hence in many cases, even when no double bond is present, the molecular refraction is not equal to the sum of the atomic refractions. Gladstone has already pointed out that in hydrogen chloride the hydrogen has apparently a greater refractive power than in hydrogen bromide, and the author finds that this is the case with other acids, the refractive power of hydrogen increasing with the dissociation of the acid, and hence decreasing with the concentration. The influence of dissociation on the refraction of salt solutions is also apparent, but is not of as definite a character.

H. C.

Spectra of Gases at Low Temperatures. By K. R. Koch (*Ann. Phys. Chem.* [2], **38**, 213—216).—The author finds that down to a temperature of −100° no change takes place in the spectra of air, oxygen, and hydrogen. Hence he concludes that the spectrum of the *Aurora Borealis* is not merely that of air at low temperature, since the lines in the first are of far greater intensity than those of the latter.

H. C.

Circular Polarisation of certain Tartrate Solutions. By J. H. Long (*Amer. J. Sci.* [3], **38**, 264—276; compare Abstr., 1889, 380).—The author has continued his investigation of the influence of inactive salts on the optical rotation of many tartrate solutions

Potassium Antimony Tartrate.—The rotatory power decreases with rise of temperature, but increases with the concentration of the solution; at 20° with a 2 per cent. solution $[\alpha] = 140·7°$, and with a 6 per cent. solution $[\alpha] = 141·4°$. It is reduced by addition of chlorides, nitrates, or acetates of ammonium or sodium, the effect increasing in the order given.

Thallium Tartrate, $2Tl_2C_4H_4O_6 + H_2O$.—In a 5 per cent. solution at 20° $[\alpha] = 4·758°$, but the rotatory power increases with the temperature. It is also increased by addition of sodium and potassium salts, the effect being greatest in the case of potassium carbonate; doubtless owing to the formation of some potassium tartrate.

Thallium hydrogen tartrate, $HTlH_4C_4O_6$, in a 1 per cent. solution at 20° has a rotatory power $[\alpha] = 12·02°$.

Thallium Sodium Tartrate, $TlNaH_4C_4O_6 + 4H_2O$.—The rotatory power decreases with the concentration; in a 5 per cent. solution of the hydrated salt at 20°, $[\alpha] = 9·065°$, in a 20 per cent. solution, $[\alpha] = 6·492°$. It increases, however, with the temperature; with a 10 per cent. solution of the anhydrous salt, $[\alpha] = 8·595°$ at 20°, and

9·490° at 28°. Sodium sulphate increases the rotatory power, but thallium sulphate reduces it.

Thallium Lithium Tartrate, $TlLiH_4C_4O_6 + H_2O$.—The rotatory power decreases rapidly with the concentration; in a 5 per cent. solution at 20°, [α] = 9·456°, and in a 20 per cent. solution [α] = 6·693°. Lithium salts increase the rotatory power, but thallium sulphate produces a marked reduction.

Thallium antimony tartrate, $TlSbOH_4C_4O_6 + H_2O$, is obtained in small crystals resembling the potassium salt by boiling antimony oxide with thallium hydrogen tartrate. The rotatory power decreases with the temperature; in a 2 per cent. solution, [α] = 100·443° at 20°, and 99·644° at 28°. The rotatory power is reduced by inactive salts, especially acetates.

Thallium Potassium Tartrate, $TlKC_4H_4O_6$.—The rotatory power decreases with the concentration, but increases with the temperature; in a 5 per cent. solution at 20°, [α] = 10·057°, in a 20 per cent. solution, [α] = 8·173°; in a 10 per cent. solution, [α] = 8·840° at 20°, and 10·072° at 30°. Potassium and sodium salts increase the rotatory power; thallium salts reduce it.

Thallium Ammonium Tartrate, $TlNH_4C_4H_4O_6$—The rotatory power decreases with the concentration, but the increase with the temperature is more rapid than in the case of the potassium salt; in a 5 per cent. solution at 20°, [α] = 10·032°, in a 20 per cent. solution, [α] = 7·563°.

Potassium Boro-tartrate, $KBOC_4H_4O_6$.—This salt retains water over sulphuric acid, and was, therefore, dried at 100°. The rotatory power increases markedly with the concentration, but decreases with the temperature; in a 5 per cent. solution at 20°, [α] = 58·101°, in a 20 per cent. solution, [α] = 68·287°; with a 10 per cent. solution, [α] = 59·055° at 20°, and 57·286° at 29°. Inactive salts and boric acid produce a considerable increase in the rotation, a result which is unexpected, because the rotatory power of the sodium and potassium salts is lower than that of the boro-tartrate. It seems that boric acid is liberated in the manner indicated by the equation $KBOC_4H_4O_6 + NaCl + 2H_2O = KNaC_4H_6O_4 + H_3BO_3 + HCl$, a supposition confirmed by the taste and reaction of the solution, and by the fact that a mixture of sodium potassium tartrate, boric acid, and hydrochloric acid has practically the same rotatory power. Boric acid probably acts on the alkaline tartrates forming complex compounds of high rotatory power analogous to those described by Gernez.

The effect of inactive salts is probably due to partial interchange of the bases, and observations of the rotatory power should afford evidence of the extent of such changes. Mixtures of the alkaline acetates and the antimony tartrates which show such a marked reduction in rotatory power are in a state of unstable equilibrium, and readily form precipitates after some time, or if heated. The optical properties of solutions in unstable equilibrium seem worthy of further investigation.

C. H. B.

Theory of the Voltaic Cell and of Galvanic Polarisation.

By E. Warburg (*Ann. Phys. Chem.* [2], 38, 321—344).—The author regards the polarisation of the electrodes and change in the E.M.F. of voltaic cells as being in great measure caused by the presence of absorbed air. Cells consisting of electrodes of the same metal in one and the same electrolyte, the air contained in which, however, varied at the two electrodes, were constructed and examined. Such cells the author terms air cells.

Air cells, the electrolyte of which is a salt of the metal forming the electrodes, have an E.M.F. which is small and decreases with the concentration of the electrolyte. With mercury electrodes, and some chloride as electrolyte, the E.M.F. is small; with a sulphate as electrolyte, the E.M.F. is very much greater. The author regards these air cells as a special form of Grove's gas battery, the active gas being oxygen. The oxygen combines with the metal of the electrode, some of which dissolves in the electrolyte, thus bringing about a difference in concentration at the two electrodes and causing a concentration current. This effect will of course be more marked in dilute than in concentrated solutions, and with mercury less in the case of chlorides than in that of sulphates, as the mercury is more readily dissolved by the latter. It is shown that when mercury is agitated in contact with a magnesium sulphate solution containing absorbed air, oxide is formed on the surface and some of it goes into solution.

This behaviour of air cells will of course be common to all other voltaic cells. Each electrode will become surrounded by a weak solution of a salt of its own metal, and the differences in concentration will cause a change in the E.M.F. of the cell. Hence a portion of the so-called polarisation current may be simply a concentration current.

H. C.

Measurement of the Internal Resistance of Batteries. By B. O. Peirce and R. W. Willson (*Amer. J. Sci* [3], 38, 465—468).—The method of alternating currents did not give satisfactory results when the poles of the battery were connected with a conductor of moderate resistance for an interval of less than $\frac{1}{10000}$ of a second, it being assumed that the E.M.F. of the battery was the same during this short interval as it was immediately before when the circuit was open. By means of a special apparatus, the poles of the battery could be connected with shunts of various resistances for any interval of time between 0·3 and 0·0001 of a second, and during this interval a condenser of suitable capacity was charged by connecting its poles with the poles of the battery, and then disconnecting them. The charge received by the condenser was afterwards measured by means of a ballistic galvanometer. No signs of fatigue in the battery were observed, and the results were the same whether the battery was shunted for 0·5 or 0·001 of a second. The values for the internal resistances of various cells measured in this way were always greater than the values obtained by the method of alternating currents, and in most cases there is a tendency for the internal resistance to decrease as the strength of the current which the cell is delivering increases.

C. H. B.

Theory of the Secondary Cell. By F. Streintz (*Ann. Phys. Chem.* [2], 38, 344—362).—The author, in conjunction with Aulinger

(*Ann. Phys. Chem.* [2], **27**, 178), formerly advanced the theory that the hydrogen plate is the seat of the decrease of the E.M.F. of the secondary cell; this is shown to be the case in the present paper by experiments on the charging and discharging of secondary cells, during discharge, the potential of the positive plate remaining practically constant and of a value to which that of the negative plate gradually approximates. In cells containing two negative plates and only one positive plate, each negative plate may be discharged and the potential brought to that of the positive plate, while the latter remains practically unaltered. In fact, the durability of the positive, in comparison with that of the negative plate, is very great.

The study of the effect of current density on the potential differences led to the discovery that lead has, in a very marked degree, the power of occluding hydrogen, the occlusion being apparently similar in character to that observed in palladium. H. C.

Maximum Polarisation of Platinum Electrodes in Sulphuric Acid. By C. FROMME (*Ann. Phys. Chem.* [2], **38**, 362—395).—In a former paper (Abstr., 1888, 390), the author has described experiments on the polarisation of platinum electrodes in sulphuric acid, and in continuation of this work he has now examined the polarisation of platinised platinum electrodes. The change in the amount of polarisation with the concentration of the acid was formerly found to take place in a most complicated manner, several maxima and minima occurring on the curve representing this change. With platinised electrodes, this is not the case; the change is found to be a very regular one, and the polarisation is almost independent of concentration. If the cathode alone be platinised, the change is also perfectly regular, but in this case the polarisation increases with the concentration. With only the anode platinised, however, irregularities are still observed in the polarisation in dilute solutions, but in concentrated solutions (from 20 per cent. acid) the polarisation is small and practically constant. This is explained by the fact that the platinising of the cathode decreases the polarisation in a dilute, but has very little effect in a concentrated solution, whereas platinising the anode very considerably decreases the polarisation in concentrated, and exercises practically no influence on dilute solutions. Hence the maxima of polarisation formerly observed with non-platinised electrodes are due to the cathode in dilute solutions, and to the anode in concentrated solutions, and when both electrodes are platinised these no longer occur. It would seem that the platinising of the cathode assists the formation of gas bubbles in the dilute acids, and the formation of secondary products, such as persulphuric acid and hydrogen peroxide, takes place at the anode with greater readiness when not platinised.

The above effects with platinised electrodes cannot be obtained by merely increasing the size of those formerly used. The maximum of polarisation is reached in a very much shorter time by platinised than by the other electrodes. With a platinised cathode in dilute solution, or a platinised anode in concentrated solution, the polarisation is found to be independent of the strength of the current. H. C.

Transfer of Ions in Fused and Solid Silver Iodide. By O. LEHMANN (*Ann. Phys. Chem.* [2], **38**, 396—402).—A microscopical examination of the behaviour of silver iodide on electrolysis, in which various cases are distinguished and minutely described. H. C.

Resistance of Electrolytic Cells. By H. R. SANKEY (*Proc. Roy. Soc.*, **45**, 541—543).—The author has examined the increase of resistance with decrease of current density in electrolytic cells, known as "transfer" resistance. A current of 2·7 milliampères was gradually increased up to 370 milliampères, with the result that as the current increased the resistance diminished, rapidly at first, afterwards more slowly. The current was now again decreased to 2·7 milliampères, when the resistance became smaller, but immediately began to rise. The current was now increased as before, with the result that the resistance again diminished, but more slowly than before. When the current had again reached 370 milliampères, the resistance was practically the same as on the first occasion, and the transfer resistance was small. The author considers that the "transfer" resistance is not due to a non-conducting layer formed on one or both electrodes, since, in this case, the resistance should increase as the current increases, and should be greater after the application of a strong current than before, but that it may be due to a molecular interaction at the junction of the electrodes with the electrolyte offering a greater resistance to weak currents than to strong. With weak currents, the "transfer" resistance diminished very rapidly as the temperature increased, becoming very small at 70°. H. K. T.

Electrolysis of Mixed Solutions. By O. LEHMANN (*Zeit. physikal. Chem.*, **4**, 525—531).—The author has examined microscopically the separation of two metals from their mixed solutions on electrolysis, in order to ascertain whether the metals would simply separate out side by side, form mixed crystals, or enter into chemical combination to form an alloy of definite crystalline structure and physical properties. From mixtures of zinc and stannous chlorides and cadmium and stannous chlorides, the metals appear to separate out side by side. The appearance of the separated metals in the first case seems to warrant the assumption that tin is more readily deposited on a tin, and zinc more readily on a zinc electrode. From a mixture of silver and mercury nitrates, silver and mercury are deposited separately, but some amalgam is also formed. H. C.

Voltaic Energy of Dissolved Chemical Compounds. By G. GORE (*Proc. Roy. Soc.*, **45**, 442).—The author has examined the voltaic energy of nearly 250 different solutions of salts by means of the voltaic balance (compare Abstr., 1889, 665). The solutions examined comprise compounds of elements with elements, elements with mono-, bi-, and tri-basic acids; acids of these three classes with each other; elements with mono-, bi-, and tri-basic salts; mono-, bi-, and tri-basic acids with all these classes of salts, and all these salts with one another. The general results of the investigation prove that "every electrolytic substance or mixture when dissolved in water

unites chemically in definite proportions by weight with every other such dissolved body." The present research has discovered nearly 250 such compounds.
H. K. T.

Dilatation of Salt Solutions. By N. A. Tchernay (*J. Russ. Chem. Soc.*, 21, 176—183; compare Abstr., 1889, 204, 330, 1101). The following table gives the dilatation of solutions of the chlorides:—

$HCl + 50H_2O \quad v_t = 1 + 0{\cdot}0000652t + 0{\cdot}000004355t^2$
$LiCl + 50H_2O \quad v_t = 1 + 557t + 4036t^2$
$NH_4Cl + 50H_2O \quad v_t = 1 + 746t + 3997t^2$
$NaCl + 100H_2O \quad v_t = 1 + 602t + 4825t^2$
$KCl + 100H_2O \quad v_t = 1 + 590t + 4407t^2$
$MgCl_2 + 100H_2O \quad v_t = 1 + 688t + 3922t^2$
$HCl + 25H_2O \quad v_t = 1 + 0{\cdot}0001515t + 3209t^2$
$NN_4Cl + 25H_2O \quad v_t = 1 + 1407t + 3649t^2$
$NaCl + 50H_2O \quad v_t = 1 + 1457t + 3758t^2$
$KCl + 50H_2O \quad v_t = 1 + 1239t + 3611t^2$
$RbCl + 50H_2O \quad v_t = 1 + 1267t + 3716t^2$
$MgCl_2 + 50H_2O \quad v_t = 1 + 1394t + 2892t^2$
$CaCl_2 + 100H_2O \quad v_t = 1 + 1085t + 3613t^2$
$BaCl_2 + 100H_2O \quad v_t = 1 + 1345t + 3537t^2$
$HCl + 12{\cdot}5H_2O \quad v_t = 1 + 2800t + 1650t^2$
$NaCl + 25H_2O \quad v_t = 1 + 2573t + 2393t^2$
$KCl + 24{\cdot}7H_2O \quad v_t = 1 + 2141t + 2588t^2$
$MgCl_2 + 25H_2O \quad v_t = 1 + 1941t + 1856t^2$
$CaCl_2 + 50H_2O \quad v_t = 1 + 1925t + 2647t^2$
$SrCl_2 + 50H_2O \quad v_t = 1 + 2204t + 2542t^2$
$BaCl_2 + 50H_2O \quad v_t = 1 + 2393t + 2456t^2$
$HCl + 6{\cdot}25H_2O \quad v_t = 1 + 4460t + 2125t^2$
$NaCl + 12{\cdot}5H_2O \quad v_t = 1 + 3640t + 1237t^2$

Here, as in the case of nitrates, some of the solutions exhibit an analogous dilatation by heat, although the relation of the number of salt-molecules to that of the water-molecules is not the same; for example, potassium and sodium chlorides with $100H_2O$, and lithium and ammonium chlorides with $50H_2O$, show the same dilatation.

The same regularity is observed in the case of the dilatation coefficients (δ), the increment of the coefficient with increasing temperature being larger for KCl and NaCl solutions than for solutions of HCl, LiCl, and NH_4Cl, even in the case of different concentrations. This shows that the physical and chemical processes (dissociation) follow different laws for each group of solutions, so that the molecular constitution of the salt hydrates of both groups must be different. The values are:—

$NaCl + 100\ H_2O \quad \delta = 0{\cdot}0000602 + 0{\cdot}0000096t$
$KCl + 100\ H_2O \quad \delta = 590 + 88t$
$HCl + 50\ H_2O \quad \delta = 652 + 87t$
$LiCl + 50\ H_2O \quad \delta = 557 + 81t$
$NH_4Cl + 50\ H_2O \quad \delta = 746 + 79t$

$$
\begin{array}{llllrlr}
NaCl & + & 50 & H_2O & \delta = & 0{\cdot}0001457 + & 0{\cdot}0000075t \\
KCl & + & 50 & H_2O & \delta = & 1239 + & 72t \\
HCl & + & 25 & H_2O & \delta = & 1515 + & 64t \\
NH_4Cl & + & 25 & H_2O & \delta = & 1407 + & 61t \\
NaCl & + & 25 & H_2O & \delta = & 2573 + & 47t \\
KCl & + & 24{\cdot}7 & H_2O & \delta = & 2157 + & 48t \\
HCl & + & 12{\cdot}5 & H_2O & \delta = & 2800 + & 33t \\
NaCl & + & 12{\cdot}5 & H_2O & \delta = & 3640 + & 24t \\
HCl & + & 6{\cdot}25 & H_2O & \delta = & 4460 + & 04t
\end{array}
$$

A similar relation is found to hold in the case of the dilatation coefficients of $CaCl_2$, $SrCl_2$, $BaCl_2$ solutions on the one hand, and those of $MgCl_2$ on the other, the first showing a dilatation analogous to that of a solution of $MgCl_2$ containing only half the amount of water-molecules, and the increment of dilatation with rising temperature is smaller for $MgCl_2$ solutions than for those of $CaCl_2$, $SrCl_2$, $BaCl_2$ solutions, thus :—

$$
\begin{array}{llrlrlr}
CaCl_2 & + & 50H_2O & \delta = & 0{\cdot}0001925 + & 0{\cdot}0000053t \\
SrCl_2 & + & 50H_2O & \delta = & 2204 + & 51t \\
BaCl_2 & + & 50H_2O & \delta = & 2393 + & 49t \\
MgCl_2 & + & 25H_2O & \delta = & 1941 + & 37t \\
SrCl_2 & + & 100H_2O & \delta = & 1085 + & 72t \\
BaCl_2 & + & 100H_2O & \delta = & 1345 + & 71t \\
MgCl_2 & + & 50H_2O & \delta = & 1394 + & 56t
\end{array}
$$

There are two types of salt solution : the one expanding more, the other less, in the same molecular concentration. To the first type belong the chlorides of Na, K, Rb, Ca, Sr, Ba ; to the second type those of H, Li, NH_4, and Mg. Supposing that the dilatation depends on the relation between the salt-molecules and the water-molecules, the author concludes that the solutions of the second type contain only half the number of molecules that those of the first type do. The molecules of $MgCl_2$ in solution are therefore at least Mg_2Cl_4 derived from the type H_4Cl_4, those of $CaCl_2$ being simple and derived from H_2Cl_2. But as the solutions of $MgCl_2$, HCl, LiCl, and NH_4Cl show an analogous dilatation, they must all correspond with the type H_4Cl_4 ; whilst, for the same reason, those of $CaCl_2$, KCl, NaCl must belong to the type H_2Cl_2. There may be some relation between this and J. Thomsen's hypothesis that the solution of hydrogen chloride contains $H_2Cl{\cdot}OH$. B. B.

Heat of Formation of Potassammonium and Sodammonium. By JOANNIS (*Compt. rend.*, **109**, 965—967).—The compounds (this vol., p. 209) were formed in a glass vessel which could be closed by a stopcock, and the vessel was immersed in the calorimeter and the stopcock opened. The compound dissociated, and the ammonia escaped through a serpentine tube also immersed in the calorimeter. The quantity of heat absorbed under these conditions is equal to the heat of formation of the compounds from the alkali metal and gaseous ammonia at atmospheric pressure.

NH_3 gas + Na solid = NH_3Na solid...... develops +5·2 Cals.
NH_3 liquid + Na solid = NH_3Na solid.... „ +0·8 „

NH_3 gas + K solid = NH_3K solid........ develops +6·3 Cals.
NH_3 liquid + K solid = NH_3K solid..... „ +1·9 „

It is evident that when these compounds take part in reactions, and the ammonia escapes without producing secondary changes, the effect will be practically the same as that of the alkali metal alone; but if the ammonia takes part in the reaction, these derived ammonias will act more energetically than the sodium or potassium which they contain. C. H. B.

Thermochemical Data respecting Succinic and Isosuccinic Acids. By S. Tanatar (*J. Russ. Chem. Soc.*, 21, 183—188).—The thermochemical data obtained by the author give, in combination with other data obtained by previous investigators, the following results:—

Heat of formation of potassium and sodium succinates—

$C_4H_6O_4$ (solid) + 2KOH (solid) = $C_4H_4K_2O_4$ (solid) + $2H_2O$ (solid) + 45,215 cal.

$C_4H_6O_4$ (solid) + 2NaOH (solid) = $C_4H_4Na_2O_4$ (solid) + $2H_2O$ (solid) + 38,483 cal.

The heat of formation of sodium isosuccinate—

$C_4H_6O_4$ (solid) + 2NaOH (solid) = $C_4H_4Na_2O_4$ (solid) + $2H_2O$ (solid) + 39,693 cal.

In aqueous solution the heats of formation of the succinates are—

$C_4H_6O_4$ + 2KOH = 25,653 cal.; $C_4H_6O_4$ + 2NaOH = 25,506 cal.

The corresponding values for the isosuccinates are—

$C_4H_6O_4$ + 2KOH = 27,354 cal.; $C_4H_6O_4$ + 2NaOH = 27,320 cal.

It is seen that the formation of sodium isosuccinate from the acid and sodium hydroxide is accompanied by the development of more heat than the formation of sodium succinate, not only in solution, but also in the solid state.

The heat of dissolution of succinic acid at 9·5° is $C_4H_6O_4 + 400H_2O = -6{,}381$ cal. The corresponding value for isosuccinic acid at 12° is $C_4H_6O_4 + 200H_2O = -4{,}097$ cal. Similar relations are observed in case of fumaric and maleïc acids, and again with itaconic and citraconic acids. B. B.

Heat of Combustion of Isodibutylene and Isotributylene. By Malbot (*Bull. Soc. Chim.* [3], 2, 481—482).—On fractionating the product of the action of zinc chloride on isobutyl alcohol (Abstr., 1889, 842), isodibutylene and isotributylene, distilling respectively at 110—113° and 178—181° under a pressure of 768 mm., are obtained. Their heats of combustion at 15° have the mean values: for isodibutylene 1252·5 cals., and for isotributylene 1858·9 cals.

T. G. N.

Relation of Volume, Pressure, and Temperature in the case of Liquids. By C. BARUS (*Amer. J. Sci.* [3], **38**, 407—408).—Experiments with alcohol, ether, paratoluidine, diphenylamine, paraffin, and thymol, and less complete experiments with other organic compounds, show that if temperature and pressure vary linearly at a mean rate of about 0·11° per atmosphere, there will be no change of volume. This holds good between 30° and 300°, and between 20 atmos. and 500 atmos., and therefore through a range of pressure six or seven times as large as that used by Ramsay and Young.

Other conditions being equal, the pressure necessary to solidify a substance is decidedly in excess of the pressure at which it liquefies again. The author has investigated this as a typical "lag" phenomenon, and has obtained data relating to paraffin, naphthalene, and palmitic and chloracetic acids.

At 185°, under a pressure of 20 atmos., water attacks lead glass so rapidly that in very fine capillary tubes the contents became opaque and solid in about an hour. During this action the compressibility of the water at 185° increased gradually and regularly to about three times its original value, and the isothermal volume of the silicated water decreased at least 13 per cent of the original volume.

In the case of mercury, the decrease in electrical resistance r and volume v through increased pressure between 0 and 400 atmos. were found to be proportional to each other.

C. H. B.

New Method of Determining Gas Densities. By J. P. COOKE (*Amer. Chem. J.*, **11**, 509—541).—The gases are weighed in a glass balloon of about 5 litres capacity and 570 grams weight. This is provided with two tubes, one reaching to the bottom of the balloon, the other attached to the top of its neck; these tubes are fitted with well-ground stopcocks. The balloon is filled with gas by placing it in a calorimeter, a thermometer in which indicates the same temperature as another placed in the external air, and passing into it a current of gas purified by passing successively through solutions of potash and of baryta, then up two long tubes placed at a slight inclination to the horizontal and containing strong sulphuric acid, and finally through two vessels containing phosphoric anhydride; a second vessel of phosphoric anhydride was found to be necessary, as the anhydride in the first became granular after a time, and failed to remove the last traces of moisture from the gas. In the case of carbonic anhydride, the potash and baryta solutions are of course dispensed with. In weighing the balloon, it was supended from one pan of a balance, and from the other was hung as a counterpoise another balloon of exactly equal volume. The wires by which these are suspended pass through holes in the floor of the balance-case, and the balloons hang in a sheet-metal chamber beneath, and are weighed only when a thermometer inside this chamber indicates the same temperature as another thermometer placed in the external air. Temperature readings were accurate to 0·01°, barometer readings to 0·1 mm.

The first thing was to ascertain the tare of the empty balloon. This was first done by a modification of Regnault's method. The balloon was filled with hydrogen, and then exhausted to a known pressure (1·40 mm.) and weighed. This weight, when corrected for the weight of residual hydrogen and for the contraction of volume consequent on exhausting the globe, gives the tare of the empty balloon. This tare was then ascertained by the following "chemical method." The balloon was filled with carbonic anhydride and weighed. One of the stopcocks was then opened, and the gas sucked, by means of a Bunsen pump, through the following series of absorbing vessels: a bulb containing potash soluion, a U-tube containing soda-lime, a U-tube containing phosphoric anhydride, a third U-tube containing glass beads with a few drops of strong sulphuric acid to indicate any sucking back (this tube was not weighed), and lastly a bulb containing 50 c.c. of normal barium hydroxide solution. Finally by opening the second stopcock, a current of air was drawn through the purifying apparatus, in order to sweep all the rest of the carbonic anhydride out of the balloon into the absorbing vessels. The potash bulb, soda-lime tube, and phosphoric anhydride tube were weighed separately before and after the experiment, and the amount of baryta-water neutralised was determined by titration with oxalic acid; elaborate corrections were also made to reduce the weighings to a vacuum. The total gain in weight gives the weight of carbonic anhydride contained in the balloon, and this, when subtracted from the weight of the balloon when full of carbonic anhydride, gives the tare of the empty balloon. This was found to be 2·5573 by Regnault's, 2 55703 by the chemical method, each number being the mean of three closely agreeing experiments.

The balloon was now filled with purified air and with hydrogen at the atmospheric temperature and pressure, and its weight ascertained, three experiments being made in each case; its weight when full of carbonic anhydride is already known. (The hydrogen was obtained from an electrolytic generator, the carbonic anhydride from marble and hydrochloric acid.) By subtracting from these weights the tare of the empty balloon, the weights of the different gases which fill the globe are ascertained, and from these numbers the density of hydrogen was calculated to be 0·06958 using Regnault's, and 0·06962 using the chemical method of determining the tare, the density of air being taken as unity. For carbonic anhydride the density is 1·52856 (air = 1), or 21·971 (hydrogen = 1) by Regnault's method, and by the chemical method 1·52854 or 21·957 respectively. And further, using Regnault's number (1·10562) for the density of oxygen referred to air, and his own numbers for hydrogen, the author calculates, as the mean of three experiments, that the density of oxygen (hydrogen = 1) is 15·891 by Regnault's, or 15·882 by the chemical method. Lord Rayleigh obtained the number 15·884.

The author regards his results as showing that the atomic weight of oxygen (H = 1) is decidedly less than 16. He points out that, as compared with hydrogen, the density of oxygen is slightly, and that of carbonic anhydride considerably greater than the halves of their respective molecular weights, and this is what one would expect, having regard to the fact that at the atmospheric temperature oxygen is considerably, and carbon anhydride very much nearer its critical point than hydrogen is at that temperature. Finally, the author expresses his approval of the provisional system of atomic weights which assumes O = 16 as its basis. C. F. B.

Formulæ for Calculating the Molecular Volumes of Organic Compounds. By W. LOSSEN (*Annalen*, **254**, 42—83).—The molecular volume of a compound $C_nH_mO_p$ if of the fatty series is given by the formula $10{\cdot}45n + 5{\cdot}225m + 10{\cdot}45p \pm \frac{1}{4}(n-2)^2 \pm 1{\cdot}5\mu$, if of the aromatic series by $10{\cdot}45n + 5{\cdot}225m + 10{\cdot}45p + \frac{1}{4}(n-4)^2 \pm 1{\cdot}5\mu$, where μ denotes the number of hydrogen-atoms necessary to convert an unsaturated into a saturated compound. With the aid of these formulæ, the author has calculated the molecular volumes of 407 organic compounds, and in only 97 cases or 24 per cent. are the calculated within 2 per cent. of the observed values. The author therefore concludes that it is impossible, taking account of every known influence, to express the molecular volume by any general formula that shall serve for all compounds. Results which are in good agreement with the observed may however be obtained from the expressions $(10{\cdot}24 \pm x0{\cdot}5)(n + p) + (5{\cdot}12 \pm x0{\cdot}25)m \pm \frac{1}{4}(n-2)^2 + 1{\cdot}4\mu$, where x may vary between 0 and 1 for the different homologous series, but is constant for the members of one and the same series.

H. C.

Vapour-pressure of Aqueous Solutions. By R. EMDEN (*Ann. Phys. Chem.* [2], **38**, 447—453).—A reply to a paper by Tammann on the same same subject (Abstr., 1889, 668), in which the accuracy of the author's own experiments and of Babo's law is upheld.

H. C.

Determination of the Molecular Weight from Vapour-pressure Reductions. By E. BECKMANN (*Zeit. physikal. Chem.*, **4**, 532—552).—The author describes various modifications which he has made in the present methods for determining the reduction of the vapour pressure of a solution by any dissolved substance, with the view of making this method of determining molecular weights of general use in the laboratory. The chief of those are those introduced for the purpose of accurately determining the boiling points of solutions, and from the rise in the boiling point of the solvent the molecular weights of the dissolved substances. A thick platinum wire sealed into the bottom of the vessel serves to conduct the heat to the solution, and overcomes the difficulty arising from boiling with bumping. The bulb of the thermometer which must be placed in the liquid is surrounded with a layer of asbestos tied on with platinum wire, and in this way is effectually shielded from currents of superheated liquid, and gives a constant register of the temperature of the boiling solution. In order also to overcome as far as possible the effect of convection currents, the vessel is filled to about half the volume of the solution with glass beads. The vessel itself which contains the solution is provided with three tubular necks, through one of which passes the thermometer, through the second the end of the condenser tube, whilst the third serves for the introduction of the substance the molecular weight of which is being determined.

The calculation of the results is similar to that employed in the case of the reduction of the freezing point. A gram-molecule of substance dissolved in 100 grams of the solvent will raise its boiling point through t degrees, so that if the number of grams of substance in 100 grams of the solvent necessary to raise the boiling point 1° be determined, and this multiplied by t, the molecular weight will be obtained. The number t may either be directly determined from observations with a substance of known molecular weight, or, according to Arrhenius, $t = 0{\cdot}02T^2/W$, where T is the boiling point in absolute temperature, and W the heat of vaporisation of 1 gram of the solvent. H. C.

Cryoscopic Method of Determining Molecular Weights.

By J. F. Eykman (*Zeit. physikal. Chem.*, **4**, 497—519).—The author has determined the molecular reductions of the freezing points of a number of organic solvents from observations with compounds of known molecular weight, the apparatus used being that previously described (Abstr., 1889, 336). The results are tabulated and given in curve form. From the molecular reduction, the latent heat of fusion is calculated by means of Van't Hoff's formula, a correction being applied for that portion of the solvent which by crystallisation is removed from the sphere of action of the osmotic pressure. The calculated latent heats of fusion and the corrected molecular reductions of the solvents used are as follows:—

	Latent heat of fusion.	Molecular reduction.
Diphenyl	29·4	79·4
Diphenylmethane	27·1	65·6
Phenol	26·9	72·0
Parabromophenol	22·9	98·0
Paracresol	27·1	69·6
Thymol	27·9	73·9
Cetyl alcohol	34·3	59·7
Chloral alcoholate	27·0	74·4
Anethoil	27·9	61·2
Benzophenone	23·2	87·8
Phenylpropionic acid	24 8	82·6
Capric acid	40·6	44·7
Stearic acid	54·4	42·5
Stearin	47·3	49·2
Urethylane	48·5	43 0
Urethane	41·0	49·6
Acetoxime	41·4	52·9
Azobenzene	29·4	77·6
Paratoluidine	38·6	51·1

For diphenyl, thymol, azobenzene, and urethane the latent heats of fusion were also directly determined, the numbers obtained being 28·5, 27·5, 29, and 40·8. H. C.

Dissociation of Substances in Solution. By D. MENDELÉEFF *J. Russ. Chem. Soc.*, 21, 198—202).—Van't Hoff's highly interesting paper, "Lois de l'équilibre chimique dans l'état dilué gaseux ou dissous" (1886), has attracted general interest to those values of *i* which are found from the osmotic pressures, from the isotonic coefficients, from the freezing temperatures, and from the vapour-pressures of dilute solutions. Ostwald and Arrhenius have given a new method of determining the same value of *i* from the electric conductivity of weak solutions, but as soon as Arrhenius, Planck, and Ostwald, in 1888, attempted to explain the deviation of *i* from unity for electrolytes by the assumption that the compounds in solutions dissociate to free electrolytes, Mendeléeff began to doubt the correctness of this hypothesis, which assumes (1) that conducting solutions have a constitution different from that of non-conducting solutions; (2) that in solutions of the first kind the value of *i* is larger than the unit, on account of the presence of free ions, and (3) that in non-conducting solutions there is no such dissociation, and, therefore, $i = 1$.

The phenomena of dissolution are, in a great many cases, identical in both kinds of solutions, and the assumption of free ions is very different from the very probable and satisfactory explanation given by Clausius as to there being a certain degree of interchange of atoms between the molecules of dissolved substances. The author does not agree with the hypothesis of free ions, as, after a continued study of solutions, he considers the phenomena to be most satisfactorily explained by the assumption that dissociated systems always exist, not only of the dissolved compounds, but also of their definite liquid hydrates, similar to melted crystallohydrates ($CaCl_2,6H_2O$, for example), or of unstable hydrates like those of Wroblewski, Roozeboom, &c. (See Mendeléeff's work "On Solutions, &c., 1877.")

The assumption of dissociation and of a reciprocal decomposition of molecules of the hydrates formed in solution does, according to the author, satisfy the claims by which Arrhenius, Planck, and Ostwald are bound to assume free ions in solutions. The author shows, by the discussion of the depression of the freezing point, that differences in the value of *i* for different compounds may be explained without assuming free ions in solutions. He shows, first, that the molecular depression dm (d being the depression for 1 gram of a substance with the mol. wt. m, dissolved in 100 grams of water) of the anhydrous salt in weak solutions will be equal to the molecular depression of any hydrate of the same salt. Let a definite hydrate with nH_2O be assumed. The depression for 1 gram of the anhydrous salt being d, for 1 gram of the hydrate (d_n), it will be as many times smaller than d as m is smaller than $m + n\,18$ if the solution be a weak one, that is $d_n = \frac{dm}{m + n18}$. If the solution be concentrated, then for 1 gram of the hydrate in 100 grams of water, $d_n = \frac{dm}{m + n18} \div \left(1 - \frac{0\,18n}{m + 18n}\right)$. In dilute solutions the divisor $1 - \frac{0{\cdot}18n}{m + 18n}$ will be nearly equal to 1, and, therefore, for such solutions, $d_n = \frac{dm}{m + 18n}$. The molecular depression of the hydrate will therefore be $= \frac{dm}{m + 18n}(m + 18n)$, or $= dm$, that is, equal to the molecular depression of the anhydrous salt. A dilute solution of the anhydrous salt (m) or that of the hydrate ($m + 18n$) will give the same i, for this is equal to the molecular depression divided by 18·5, as shown by Van't Hoff (*loc. cit.*, p. 24).

For $MgSO_4$ the isotonic coefficients, as well as the molecular depression, give $i = 1{\cdot}04$, from which $dm = 1{\cdot}04 \times 18{\cdot}5 = 19{\cdot}24$, and $d = 0{\cdot}160°$. According to the formula $d_n = \frac{dm}{m + 18n}$, for the hydrate $MgSO_4 + 7H_2O$ ($n = 7$) $d_n = 0{\cdot}078°$. De Coppet and Rüdorff have shown that the depression of such a solution is proportional to the amount of the heptahydrated (not anhydrous) salt dissolved, namely, 1 gram $= 0{\cdot}072$—$0{\cdot}073°$, which, calculated as above, gives $i = 0{\cdot}96$. This number differs very little from the value 1·04, calculated for the depression 0·078°, or $i = 1$. The value of i is, within the limit of error, identical for weak solutions of both $MgSO_4$ and $MgSO_4,7H_2O$, and the same will be the case for $MgSO_4,10H_2O$.

As, for dilute solutions, the same value of i is obtained both for anhydrous and for hydrated salts, the author concludes that neither the determination of osmotic pressures, nor of isotonic coefficients, nor of the vapour-pressure of weak solutions, nor of the molecular depression, nor of the electrolytic conductivities, will show whether the value of i, obtained by means of them, refers to anhydrous compounds or to hydrates (or generally to compounds formed with the solvent).

These methods cannot show the degree of hydration of the substance dissolved in water, and they cannot contradict the hypothesis which assumes the existence of particular dissociated hydrates in aqueous solutions. If there is a possibility and need of explaining the variation of i by means of dissociation, it would be better, prior to assuming a dissociation of MX in solution to $M + X$, to inquire whether, in solutions of salts MX, the action of the water does not give rise to molecules $MOH + HX$, or whether the hydrates $MX(n + 1)H_2O$ may not dissociate into the hydrates $MOHmH_2O + HX(n-m)H_2O$, or directly the hydrates $MXnH_2O$ into separate molecules. Such an hypothesis, in connection with that of the interchange of atoms between molecules, explains sufficiently the identity of i, obtained by different methods, as well as its variation for different substances. Before going further than Van't Hoff, it is necessary to investigate exactly (1) how the value of i changes with varying concentration for compounds giving different values for i, and (2) whether the values of i remain far from integers (for example, for $CaCl_2$, $i = 2{\cdot}5$, for alums, $i = 4{\cdot}5$, &c.) for varying temperatures and concentrations. B. B.

Supersaturated Solutions. By A. POPILITZIN (*J. Russ. Chem Soc.*). See p. 333.

Rate of Chemical Change. By G. GORE (*Proc. Roy. Soc*, **45**, 440—442).—This is a continuation of the author's experiments on the use of the voltaic balance for determining the rate of chemical change in solution (compare Abstr., 1889, 665) Two solutions were examined: one containing equivalent quantities of chlorine and potassium iodide, the other equivalent quantities of potassium chloride and iodine. The general results of the investigation are, that the first solution is very unstable and loses energy, partly while being mixed, and to a further extent after a time, the change not being complete after a lapse of six days at a temperature of 12°. The second solution is nearly, but not quite, stable, as it increases slightly in voltaic energy after a time. The two solutions ultimately acquire a composition represented by 0·23 part of potassium iodide, 74·49 parts of potassium chloride, 126·8 parts of iodine, and 0·0497 part of chlorine.

The rate of change did not seem to be affected by daylight, but two minutes' ebullition had as much effect in altering the composition of the first solution as an interval of six days at the ordinary temperature. With the first solution, the loss of energy on mixing is greater the greater the concentration of the constituents. The loss was also greater when the chlorine solution was added to the iodide solution than when the reverse order of mixing was adopted. The colours of the solutions were in accordance with the above observations, that of the first solution being light, and gradually becoming darker, that of the second undergoing no appreciable change.

The "voltaic balance" method can be used in measuring the rate of change in liquids already mixed. It is simpler and more sensitive than thermochemical or colorimetric methods, and can be used for colourless liquids. H. K. T.

Determination of Affinity Coefficients. By M. CONRAD and C. BRUCKNER (*Zeit. physikal. Chem.*, **4**, 631—657; see this vol., p. 4).—The authors have studied the action of the alkyl oxides of sodium and potassium on the chlorides, bromides, and iodides of organic radicles. The relation between the coefficients obtained is found to depend on the nature of the alkyl oxide and of the halogen, but is independent of the metal. Thus, for the ethoxide of sodium or potassium the relations between the affinity coefficients, that of the propyl compound being in each case taken as unity, are as follows:—

	Propyl.	Ethyl.	Allyl.	Benzyl.
Cl..................	1	—	65·70	126·5
Br..................	1	3·24	61·34	120·1
I..................	1	2·85	54·34	93·95

The coefficients of the other groups approach that of the propyl as the atomic weight of the halogen with which they are associated increases.

If, however, the action of the potassium salt be compared with that of the sodium salt, the former is found to have the greater activity, for, setting that of potassium ethoxide in each case at 100, that of sodium ethoxide becomes for allyl chloride 79·0, and for benzyl chloride 88·4.

The comparative activities of chlorine, bromine, and iodine, putting that of the iodide in each case as 1000, are shown by the following numbers:—

	Iodide.	Bromide.	Chloride.
Propyl	1000	473	7·63
Allyl	1000	532	9·23
Benzyl	1000	604	10·28

Methyl bromide shows an exceptional behaviour, and is found to have an activity greater than that of the iodide. H. C.

Increase in Chemical Energy at the Free Surface of Liquid Substances. By W. SPRING (*Zeit. physikal. Chem.*, 4, 658—662).—The author shows, by various experiments, that there exists at the free surface of any liquid a layer which possesses a superior chemical activity to that of the rest of the liquid. For instance, if a prism of calcspar be immersed to about half its length in hydrochloric acid, the action at the surface is so vigorous that in a short space of time the prism is cut in two, and the lower half sinks in the acid. No satisfactory explanation for these facts can be given. H. C.

Chemical Energy at the Surface of Liquids. By J. BECHHOLD (*Zeit. physikal. Chem.*, 5, 68).—The phenomena observed by Spring (preceding abstract) are explained by the author on the assumption that the liquid at the surface on dissolving some of the crystal becomes denser and sinks in the solution down the sides of the crystal, thus protecting the lower portion from the action of the solvent, and also making way for fresh quantities of the latter at the surface. If in the calcspar experiment the upper portion of the prism be coated with wax, and the whole then immersed vertically in the acid, the prism will now be cut in two at the boundary of the wax coating, although this is far below the surface of the liquid. H. C.

Isomorphism. By J. W. RETGERS (*Zeit. physikal. Chem.*, 4, 593—630; compare Abstr., 1889, 931).—This paper contains a study of the isomorphism of the nitrates of the alkali metals and of silver by means of the specific gravities of the mixed salts. The nitrates of ammonium, potassium, thallium, and silver crystallise in the rhombic system, those of sodium, lithium, rubidium, and cæsium in the hexagonal system. Sodium and silver nitrates form an isodimorphous series, hexagonal crystals being formed containing as much as 52·57 per cent. of silver nitrate, and rhombic crystals containing up to 0·8 per cent. of sodium nitrate from mixed solutions of the two salts. Isodimorphism is also observed with mixtures of the other nitrates, although not quite to as marked a degree as in the above example. The author concludes from this that, although a salt may crystallise in some stable form, it is capable of existing in an indefinite number of unstable modifications, and that polymorphism, far from being the exception, is probably the rule for all solid chemical substances. H. C.

Inorganic Chemistry.

Apparatus for Distillation under Reduced Pressure. By H. Gautier (*Bull. Soc. Chim.* [3], 2, 675).—To the base of a wide glass tube, smaller tubes are fused in such a way that by the rotation on an upper accurately-ground tube carrying the delivery tube of the condenser, the latter may be successively approximated to their upper orifices and several flasks be filled without vitiating the vacuum. T. G. N.

Colour and Spectrum of Fluorine. By H. Moissan (*Compt. rend.*, 109, 937—940).—Fluorine in small quantities seems to be colourless, but when examined in a platinum tube 50 cm. in length, with plane ends of colourless fluorspar, it is seen to have a distinct greenish-yellow colour, paler than that of chlorine and decidedly yellower. A column of the gas 1 metre in length shows no definite absorption bands.

If a small quantity of water is introduced into the tube containing the fluorine, it is decomposed with formation of hydrogen fluoride and ozone, the latter having the deep indigo-blue colour described by Hautefeuille and Chappuis.

Salet compared the spectra of silicon fluoride and silicon chloride and described the spectrum of fluorine as consisting of five lines in the red. The author employed a platinum tube closed by transparent stoppers of fluorspar and provided with sparking wires of platinum and of gold. He examined the spectra when the tube was filled with air and when it was filled with fluorine, making observations with both the gold and platinum electrodes, and he also examined the spectra of hydrogen fluoride, silicon fluoride, and phosphorus trifluoride. The lines common to all these spectra are regarded as the lines due to fluorine, and their wave-lengths are as follows:—*very faint*, 749, 740, 734; *faint*, 714, 704, 691, 687·5, 685·5, 683·5; *strong*, 677, 640·5, 634, 623. Salet gives the wave-lengths of two feeble lines as 692 and 686, and of three strong lines as 678, 640, 623.

The spark spectrum of hydrogen fluoride contains several very broad and indistinct bands in the orange and the violet, but their wave-lengths could not be determined. C. H. B.

Formation of Ozone during Rapid Combustion. By O. Loew (*Ber.*, **22**, 3325—3326).—Ilosvay comes to the conclusion (*Bull. Soc. Chim.* [3], **2**, 360—377) that ozone is never formed during rapid combustion. The author has clearly obtained the odour of ozone when a rapid current of air was blown across the upper part of a flame. This is especially noticeable with a Bunsen burner. Thann and Schnauss have made similar observations (*Jahresb.*, 1870).

L. T. T.

Composition of Water. By Lord Rayleigh (*Proc. Roy. Soc.*, **45**, 425—430).—This paper is a continuation of the author's researches on the relative densities of hydrogen and oxygen (compare Abstr., 1888, 643). Various attempts were made to obtain lighter hydrogen than hitherto, especially by means of aluminium in alkaline solution, but without success. The gas was also purified by absorption with palladium so as to free it from nitrogen, but the hydrogen was no lighter than before. In the author's previous researches, the composition of water was determined by combining the ratio of densities with that found by Scott (Abstr., 1888, 411) for combination by volume. In this paper, experiments are described in which the combining proportions are determined by direct weighing. The gases were weighed in glass globes, from which they were exhausted by means of Sprengel pumps, first into a mixing chamber and thence into a eudiometer. The manipulative difficulties were very great, owing to the necessity of maintaining the gases in approximately equivalent proportions. When sufficient quantities of the gases had been pumped out, the flasks were again weighed, the (calculated) weight of the residual gas (generally oxygen) in the eudiometer being deducted from the weight of the gas taken. A mean of five experiments gave 15·89 as the atomic weight of oxygen after allowing for the effect of pressure on the glass globes (*loc. cit.*). This result is somewhat lower than the value (15·91) obtained from the relative densities of hydrogen and oxygen and Scott's combining ratio by volume. The residual gas (from 2000 c.c. of mixed gases) was analysed, and was found to contain 0·1 c.c. of nitrogen and 0·05 c.c. of carbonic anhydride. As these gases were probably contained in the oxygen, their effect is negligible. The water of combustion was examined for nitric acid with negative results.

H. K. T.

Thiosulphates. By A. Fock and K. Klüss (*Ber.*, **22**, 3310—3316; compare this vol., p. 210).—The authors have prepared the following thiosulphates:—$Sr_2S_2O_3 + H_2O$, $MgS_2O_3 + 6H_2O$, $NiS_2O_3 + 6H_2O$, $CoS_2O_3 + 6H_2O$, and $Fe_2S_2O_3 + 5H_2O$; the crystal measurements of the salts are given.

F. S. K.

Preparation of Nitrogen. By Berthelot (*Bull. Soc. Chim.* [3], **2**, 643—645).—Nitrogen obtained by the action of copper and ammonia solution on air is always contaminated by ammonia and traces of nitrite, which are best removed by passing the gas first through aqueous potash and then through sulphuric acid, the final traces of oxygen being absorbed by chromous chloride solution. The usual order is thus reversed, because sulphuric acid decomposes the nitrite to form traces of nitrogen dioxide, which are not absorbed by the potash. T. G. N.

Freezing Points of Arsenic Chloride and Stannic Chloride. By Besson (*Compt. rend.*, 109, 940—941).—Arsenic trichloride carefully purified from excess of chlorine solidifies at —18° with very considerable contraction, and crystallises in white, nacreous needles. If, however, the chloride is saturated with chlorine at 0°, the product does not solidify above —30°, but at this temperature it freezes with very great contraction. At —30° the arsenic chloride will absorb a much larger quantity of chlorine, yielding a yellow liquid which does not solidify at —60°. If this liquid, cooled to —50°, is thrown into water, a large volume of chlorine is liberated, and the solution contains arsenious acid and not arsenic acid; it follows that no arsenic pentachloride is formed. If liquid chlorine at —35° is brought in contact with arsenic chloride at the same temperature, and the temperature is allowed to rise slowly, the arsenic chloride melts, and the two liquids gradually mix by diffusion without any development of heat or any other evidence of combination.

Stannic chloride free from excess of chlorine solidifies at —33°, and forms small, white crystals. Like arsenic chloride, it absorbs large quantities of chlorine at a low temperature, with considerable increase in volume, and the freezing point of the solution is much lower than that of the stannic chloride. C. H. B.

Preparation of Boron. By H. C. C. Maisch (*Chem. Centr.*, 1889, ii, 905; from *Chem. tech. Centralanzeiger*, 7. 359—360, 369, 379).—The author has prepared boron by reducing anhydrous borax with magnesium powder: 8 grams of magnesium and 15 grams of borax are suitable proportions. J. W. L.

Reduction of Oxygen Compounds by Magnesium. By C. Winkler (*Ber.*, **23**, 44—57).—The exceptionally high heat of combustion of magnesium has led the author to examine the action of the powdered substance on the oxygen compounds of a large number of metals. In this paper the results are given so far as Mendeléeff's first group is concerned.

In the case of the alkali metals, the carbonates were employed as with the exception of lithium oxide, the oxides of these metals can only be obtained pure with difficulty, but in the other cases the oxides were used. Sufficient magnesium powder was added to combine with the whole of the oxygen present in the carbonate or oxide; the latter being carefully dried by ignition, and intimately mixed in a warmed mortar with the necessary quantity of magnesium powder. After making a preliminary examination with very small quantities, to ascertain the behaviour of the mixture on heating, a somewhat larger quantity was heated in a tube closed at one end, over the flame of an ordinary burner, or, if necessary, by a blowpipe.

Lithium.—The reaction takes place below a red heat, and is extremely violent; with 0·2 gram, an explosion takes place, and the tube is destroyed. With smaller quantities, the whole becomes red-hot, but the tube remains intact. The product has no metallic appearance, but evolves hydrogen when placed under water, and must therefore contain lithium.

Sodium.—The mixture becomes first black, and when a red heat is reached, a violent reaction takes place, a bright sodium flame issuing from the mouth of the tube, the interior of which becomes coated with a mirror of metallic sodium. Part of the mixture is ejected from the tube, whilst the residue consists of carbon and magnesia. The reaction does not succeed equally well in all cases. If freshly ignited magnesia be added, a mixture of magnesia, charcoal, and sodium is obtained, which decomposes water violently, and ignites the evolved hydrogen.

Potassium.—The reaction in this case proceeds much more quietly, no violent evolution of potassium taking place under any circumstances, and the temperature necessary to commence the reaction appears also to be lower than with sodium. The mixture is preferably heated in a porcelain boat in a current of hydrogen, the potassium condensing as a mirror on the cooler parts of the tube. The residue consists of magnesia and charcoal, and has only a slightly alkaline reaction, showing that the potassium is completely driven off. This method might perhaps be employed as a technical method for the preparation of potassium, but it has the disadvantage that no gas is formed to carry forward the potassium vapour, and the formation of the explosive compound of carbon monoxide and potassium is not avoided. The formation of this compound is due to the fact that two atoms of oxygen are more readily given off than the third, and if 1 mol. of potassium carbonate be heated with 2 atoms of magnesium, this compound and magnesia are the sole products; the author therefore concludes that it has the formula COK_2. If sufficient magnesium is present to combine with all the oxygen, the explosive compound is only formed when the mixture is heated gradually, and to a moderate temperature.

Potassium hydroxide is also readily reduced by magnesium, and in this case the above explosive compound cannot, of course, be formed. When the mixture is heated in a tube closed at one end, a somewhat violent reaction takes place, hydrogen being evolved, and a mirror of metallic potassium formed. If a few grams be heated in a current of hydrogen, the reaction is so violent as to become dangerous, but a mixture of 36 parts of potash, 24 parts of magnesium powder, and 56 parts of magnesia may be heated without any risk, the metal distilling over quietly, and a residue of magnesia remaining behind. The reaction might also be moderated by allowing the fused potash to flow on to heated magnesium bars. Either method would probably enable potassium to be obtained much more cheaply than at present.

Rubidium.—The carbonate of this metal behaves with magnesium in a manner very like that of potassium carbonate. Heated in a tube closed at one end, the reaction commences at a moderate red heat, and a mirror of metallic rubidium is obtained. The latter is also formed when the mixture is heated in a porcelain boat in a current of hydrogen. The residue, which also contains rubidium, decomposes water with violence, and takes fire in the air. Metallic rubidium is most readily prepared by this method.

Cæsium.—The mixture of cæsium carbonate and magnesium powder blackens on heating from separation of charcoal, but no metallic cæsium is obtained even in the blowpipe flame. Small quantities of potassium and rubidium contained as impurities are volatilised, so that it is thus possible to separate these metals from cæsium. The residue consisted of unaltered magnesium, magnesia, charcoal, and cæsium oxide.

Copper.—Cuprous oxide is acted on by magnesium at a moderate heat, with a hissing noise, the mixture being partially ejected from the tube. The residue consists of a mixture of copper and magnesia. Cupric oxide and magnesium explode violently on heating, the tube being destroyed.

Silver.—Silver carbonate and magnesium unite with a slight explosion, the contents of the tube being ejected, but the tube remains intact. With silver oxide, the reaction is much more violent, and a loud explosion takes place.

Gold.—When aurous oxide and magnesium are heated, the former quietly decomposes into gold and oxygen, the magnesium taking no part in the reaction.

From these results it follows that the observation of Warren (this vol., p. 195) that magnesium does not reduce the alkalis and alkaline earths, is incorrect. With the exception of cæsium, all the alkali metals are reduced, the intensity of the reaction decreasing with the increase of atomic weight. In the sub-group the reverse is the case, the apparent exception in the case of gold being due to the instability of its oxide at high temperatures. H. G. C.

Some Properties of Sodium Perchlorate: Supersaturated Solutions. By A. POTILITZIN (*J. Russ. Chem. Soc.*, **21**, 258—274).—This salt was investigated by Serullas and by Penny, who found that it forms deliquescent, rhombic crystals (not rhombohedra, as quoted in *Gmelin-Kraut. Handb.*, ii, 1, 211). Potilitzin prepares sodium perchlorate from perchloric acid and sodium hydroxide prepared from sodium. After separating the ferric oxide and alumina, the salt is treated with an excess of perchloric acid, in order to destroy the chlorate and chloride, which are always present in traces. At the ordinary temperature, the salt $NaClO_4,H_2O$ crystallises in lanceolate prisms belonging to the rhombic system; it becomes anhydrous at 45—50°, and at or above 54° the anhydrous salt crystallises out from saturated solutions in the form of long, rectangular prisms. Neither kind of crystal is hygroscopic, but the weight of the anhydrous salt increases slightly on exposure to air. The same anhydrous salt separates out from supersaturated solutions at the ordinary temperature. A supersaturated solution contains not only the anhydrous, but also the hydrated salt, as seen from the fact that the solution solidifies on contact with a crystal either of the hydrated salt, or of the anhydrous salt the surface of which has been converted into the hydrated salt by plunging it for a short time into water. The crystals of the anhydrous salt alone do not cause crystallisation, but dissolve in a supersaturated solution.

The author discusses the different views on supersaturated solutions, and shows that the mechanical theory of heat alone (Coppet) does not explain why certain salts form supersaturated solutions whilst others do not. Again, Shtcherbatcheff's view, that the supersaturation of a solution is due to the formation of a lower hydrate having a greater solubility, does not explain the existence of supersaturated solutions of anhydrous salts. The third view, according to which a supersaturated solution is one of the anhydrous salt, is of older date, and has been defended especially by Nicol (Trans., 1887, 389, &c.). The author shows that this hypothesis is not in accordance either with the change of specific gravity which takes place on dissolution and on dilution of solutions; with thermal data connected with the formation of hydrates and the dissolution of hydrated, dehydrated, and anhydrous salts; with the colour phenomena occurring on dilution or change of temperature; or with the change in the coefficients of refraction and other properties of salt solutions. The author shows that the values of the heats of formation of chlorides in solution from R_2O or RO and $2HCl$ are not identical, as assumed by Nicol, but that the largest value (27,900 cal.) corresponds with calcium chloride, which, according to Rüdorff, exists in solution as $CaCl_2,6H_2O$. Nicol's views do not explain the existence of solutions of anhydrous salts and of such substances as sulphur. The author shows that, in accordance with Mendeléeff's views on solutions in general, the supersaturated solutions of salts undoubtedly contain the salt in the state of several (probably of all possible) hydrates, as well as in the form of the anhydrous salt; the relative quantity of these changing with varying dilution and temperature. Such solutions can be formed only by the substance forming compounds which are either isomeric or of different composition, and differ in their solubility and crystalline form. B. B.

Allotropic Silver. By M. C. Lea (*Amer. J. Sci.* [3], 38, 237—240 and 241).—The three allotropic forms of silver previously described (this vol., p. 210) are merely the most stable forms amongst a very large number. Modifications were also obtained the body colours of which were blue, many different shades of green, red, yellow, and purple. In one case a soluble modification yielding an intense yellowish-brown solution was obtained, but on addition of sodium phosphate this changed to bright scarlet, and afterwards decolorised with separation of a purple precipitate, and the latter became bluish-green when washed on the filter.

Blue allotropic silver is very stable, and may be kept in the moist state for a long time without undergoing any change, but the gold-coloured modification always tends to pass into normal grey silver, especially in presence of the mother liquor or of water. The change is produced even by friction of the particles of the dried substance with one another. Both modifications evolve oxygen with hydrogen peroxide.

Both the blue and the golden modifications are attacked by substances which have little action on normal silver. Not only solutions of the halogens, and chlorinating or brominating mixtures, but also alkaline sulphides, potassium permanganate and ferrocyanide, and phosphorous acid produce brilliant blue, green, red, or purple colorations when brushed over dry films of the allotropic silver. Auric, stannic and platinic chlorides do not give these colour reactions, and the haloïd salts of the alkalis also give no colours but convert the allotropic silver into normal silver.

Pure preparations of the blue allotropic silver are converted into the yellow modification by the action of light (compare *loc. cit.*), and afterwards, if the exposure is continued, into grey normal silver.

If a small crystal of iodine is placed on a film of allotropic silver, it produces brilliantly coloured interference rings. C. H. B.

Darkened Silver Chloride not an Oxychloride. By M. C. Lea (*Amer. J. Sci.* [3], **38**, 356—361).—Pure silver chloride was fused and poured into refined petroleum, in which it solidified. When exposed to light under the petroleum, the silver chloride immediately blackened, and the author regards this result as proof that darkened silver chloride does not contain oxygen, and therefore is not an oxychloride.

Pure silver reduced by means of cadmium was heated nearly to redness, and whilst very hot was dropped into petroleum. A small quantity of iodine was then added, and as it dissolved in the petroleum it combined with the silver, until after some time no free iodine remained, and the silver had been converted into a black photo-iodide, which from the conditions of its formation could not be an oxy-salt.

Any satisfactory theory must explain the period of so-called induction when silver chloride is exposed to light, and the fact that the decomposition of the silver chloride is incomplete even after prolonged exposure. According to the author, the period of induction corresponds with the formation of an almost colourless photochloride (Abstr., 1888, 1), which is much more sensitive than the normal chloride, and rapidly darkens after it has once been formed. The decomposition of the silver salt is limited by the reconversion of the subchloride or photochloride into normal chloride by the chlorine liberated from the adjacent particles of chloride which are acted upon by light.

Peculiar Crystalline Alloy of Copper, Tin, and Lead. By A. French (*J. Soc. Chem., Ind.*, **8**, 36—37).—This crystalline alloy was found within a cavity in the bottom of a cupola furnace, which was being put off after having been used for lead-smelting. The crystals form plates, and flat, lengthy, four-sided prisms. They resist atmospheric oxidation, and are not affected by strong sulphuric or hydrochloric acids. Hot nitric acid attacks them, but there are smaller crystals amongst them which resist this action. Analysis gave—

Pb.	Cu.	Sn.	Sb.	Fe.	Si.	S.	Insoluble in HNO_3.	Total.
66·89	11·32	10·22	3·70	0·75	2·09	0·53	4·50	100·00

D. B.

Ternary Alloys. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc*, **45**, 461—481).—If tin, lead, and zinc are melted together and left at rest in a fused condition, no separation takes place if the proportion of tin exceeds a certain amount, but if the quantity of tin is less than this, the alloy separates into two layers, like certain mixtures of alcohol, ether, and water, each layer consisting of a ternary alloy of the above three metals. The authors have examined the nature of this separation, and the composition of the alloys under different conditions. The method of experiment consisted in maintaining the fused mixture at a temperature of 600—700° for some hours, care being taken to avoid convection currents, and analysing the two layers, which were usually quite distinct. In order to obtain separation, the proportion of tin must not exceed ⅜ths by weight of the whole. The heavier alloy consists of a saturated solution of zinc in lead containing tin, the lighter consists of a saturated solution of lead in zinc containing tin. The two alloys always correspond with two conjugate points on the solubility curves of zinc in lead-tin, and of lead in zinc-tin. The tin does not distribute itself equally in the two alloys, except when present in a particular proportion, which varies with the ratio of zinc to lead. With less tin than this, the lighter alloy takes up the excess of tin; with more, the heavier takes up the excess. Consequently an indefinite number of mixtures may be prepared in which the heavier alloy will always be the same, the lighter alloy varying in composition, whilst in another set the lighter alloy will remain constant, the lower varying. In the absence of tin, lead dissolves zinc forming an alloy containing 1·24 per cent. of zinc, and zinc dissolves lead forming an alloy containing 1·14 per cent. of lead.

H. K. T.

Compounds of Vanadic Pentoxide with Sulphuric Acid. By L. MÜNZING (*Chem. Centr.*, 1889, ii, 908—909).—In a critical essay on the various compounds of vanadic and sulphuric acids, said to have been prepared by several workers, the author considers that the anhydrous compounds which Fritsche and Ditti claim to have prepared are not obtainable, and that their yellow or orange compound is identical with that of Berzelius. Gerland's octohedral compound, $V_2O_5,3SO_3$, is identical with Berzelius's brown compound.

Mineralogical Chemistry.

Occurrence of Hydrogen Sulphide and Sulphur in the Stassfurt Salt Deposits. By E. PFEIFFER (*Arch. Pharm.* [3], **27**, 1134—1137).—In a new shaft sunk near Güsten, compact anhydrite was passed through at a depth of 105 to 133 metres; the salt clay was also regularly and compactly deposited, but at its contact with rock-salt it was permeated by strings of crystallised sulphur as thick as the finger. E. Reichardt first explained such an occurrence of sulphur, ascribing it to the action of decomposing vegetable matter collected on the shores of the ancient sea, which decomposing substances in contact with anhydrite caused the separation of sulphur and the formation of hydrogen sulphide, whilst the lime set free was converted into calcium chloride by the action of magnesium chloride, magnesia being deposited. The free magnesia is detectable in the salt clay, and the calcium chloride in the secondary product tachydrite. The occurrence of sulphur in these deposits affords some confirmation of Reichardt's view of the origin of the gaseous hydrocarbons so frequently found in quantity in the cavities of the carnallite deposits, which he also ascribes to the decomposition of vegetable matter.

J. T.

Native Lead from Pajsberg, Sweden. By A. HAMBERG (*Zeit. Kryst. Min.*, **17**, 253—263).—Native lead, in distinct crystals, has recently been found at the Harstigen mine, near Pajsberg, in Wermland. It occurs only in open cavities, not filled in with calcite. The forms observed on the crystals collected by the author were: O, $\infty O\infty$, ∞O, $2O2$, $5O$, $\infty O4$. An analysis of the lead crystals failed to indicate the presence of any other element. The sp. gr. was found to be 11·372. The author is of opinion that the lead has been reduced by arsenious acid, as arsenic compounds, especially arsenates, are of frequent occurrence in the Wermland mines. B. H. B.

Fluorspar, Opal, Amber, and Diamond. By G. F. KUNZ (*Amer. J. Sci.* [3], **38**, 72—74).—The author describes some crystals of fluorspar found in a cave in Archæan limestone at Macomb, St. Lawrence Co., New York. The cave contained at least 15 tons of the mineral, the crystals being simple cubes of a uniform, light, sea-green colour. The author also describes specimens of a very remarkable amber from an unknown locality in Southern Mexico. The colour is a rich golden-yellow, and the mineral exhibits fluorescence similar to that of uranine. A specimen of fire opal was found near John Davis River, Oregon. It is the first opal found in the United States that exhibits colour. In conclusion, the author notes that a small diamond is said to have been found in Russel Co., Kentucky.

B. H. B.

Artificial Copper-bismuth-glance. By R. SCHNEIDER (*J. pr. Chem.* [2], **40**, 564—573; compare Abstr., 1889, 354).—One gram of finely powdered potassium bismuth sulphide, K_2S,Bi_2S_3, prepared by fusing powdered bismuth (1 part) with potassium carbonate (6 parts) and sulphur (6 parts), is put into a flask (50—60 c.c.), which is then filled with a feebly ammoniacal solution of 0·235 gram. of cuprous oxide in hydrochloric acid, and well shaken. After 8 or 10 days the solution becomes colourless, and a nearly black powder settles down; this is a mixture or compound of cuprous sulphide, bismuth sulphide, potassium sulphide, and bismuth trioxide; it is put into a flask which is filled with a mixture of equal quantities of fresh hydrosulphuric acid and dilute hydrochloric acid (1:20), and well shaken. The resulting powder is found to have the same composition as copper-bismuth-glance, and when it is fused assumes the light-grey colour and crystalline fracture of the natural mineral. Its specific gravity at 15° is 6·10, that of the natural mineral being

5·137—5·263 according to Weisbach, and 6·23—6·38 according to Frenzel.

Copper-bismuth-glance is also artificially obtained by fusing cuprous sulphide with bismuth sulphide (equal mols.). It is thus evident that the rational formula of this mineral is Cu_2S,Bi_2S_3.

By passing hydrogen sulphide through a mixture of cuprous chloride (3 mols.) with bismuth trichloride (2 mols.), and fusing the precipitate formed, artificial copper-bismuth ore (Wittichenite), $3Cu_2S,Bi_2S_3$, is obtained. A. G. B.

Metallurgical Products from the Mechernich Lead Works.

By A. Brand (*Zeit. Kryst. Min.*, 17, 264—268).—Some crystals from the Mechernich lead furnaces were examined by the author, and two types are described in detail. The crystals of the first type were flat, triangular, and irregular, and exhibited a perfect metallic lustre and steel-grey colour. They were found to be twinned octahedra of the regular system, and to give on analysis the following results:—

S.	Cu.	Pb.	Fe.	Total.
18·43	49·73	18·47	13·41	100·04

This is evidently an isomorphous mixture of Cu_2S, Fe_2S, and PbS. A mineral crystallising in the regular system with the composition $2PbS + Cu_2S$ (cuproplumbite) is known, as are also regular crystals of artificially prepared copper-glance. This metallurgical product is consequently chiefly of interest on account of its crystallising in the regular system in the presence of so much iron as Fe_2S.

The crystals of the second type appear to be distinct octohedra. Analysis gave the following results:—

Sb.	Pb.	Cu.	Ni.	Co.	Fe.	S.	Total.
32·80	19·32	41·25	4·60	0·48	0·27	0·66	99·38

This the author considers to be an isomorphous mixture of NiSb,PbS and Cu_2S,PbSb, and Cu_6Sb. B. H. B.

Preparation of Crystallised Iron Disulphide (Iron Pyrites).

By E. Glatzel (*Ber.*, 23, 37—40).—Iron pyrites may be artificially prepared by the action of phosphorus pentasulphide on ferric chloride. For this purpose, a mixture of ferric chloride (50 grams) and phosphorus pentasulphide (25 grams) is carefully heated in a retort as long as thiophosphoryl chloride distils over rapidly, and then strongly heated until the evolution ceases entirely. On cooling, a greyish-white mass is formed under a crust of unaltered ferric chloride and phosphorus pentasulphide, which may readily be detached. The mass is then treated with water, which removes ferrous chloride, and the residual mixture of iron pyrites and lighter impurities sifted and washed to remove the latter. The reaction is represented by the equation—

$$6FeCl_3 + 2P_2S_5 = 3FeCl_2 + 3FeS_2 + 4PSCl_3.$$

The iron pyrites thus obtained forms microscopic, sharply-developed crystals, consisting of pentagonal dodecahedra or cubes, or combinations of these, and also combinations of the pentagonal dodecahedron and octohedron. The yield is very good, but considerable quantities are lost in the washing process. H. G. C.

Minerals from the Tyrol and other Localities. By H. v. Foullon (*Jahrb. f. Min.*, 1889, ii, Ref. 414—420; from *Jahrb. k.k. geol. Reichsanst.*, 38, 1—33).—This memoir is divided into nine heads. The first deals with the minerals found at Hall, in the Tyrol, the minerals described being galena, breunerite, and bloedite. Of the last two, a number of analyses are given. The second section is devoted to a description of the brucite which occurs with carbonates of calcium, magnesium, and strontium at the Steinpass, near Imst, in the Tyrol. The specimen examined so closely resembled gurhofian, that the author was induced to examine that mineral from Gurhof, Windhof, and Altenberg. The results of the analysis of the specimen from Windhof showed it to be composed of 4·80 per cent. of serpentine, 89·00 per cent. of calcium and strontium carbonate, 3·89 per cent. of magnesium carbonate, and 1·48 per cent. of magnesium hydrate. A product of the alteration of serpentine so rich in lime is remarkable, and it would be of interest to know whether other serpentines when altered actually yield magnesium hydrate.

The remaining sections deal with (3) realgar from Wolfsberg, in Carinthia; (4) minerals from Truskawiec, in Galicia; (5) minerals from Közép-hegy, near Rosenau, in Upper Hungary; (6) quartz from Bereghszász, (7) siderite in the opal of Nagy Laáz, in Hungary; (8) similarity of the Japanese and Greek glaucophane rocks; and (9) similarity of the eruptive rocks of the province of Karassi, in Asia Minor, and those of Schemnitz, in Hungary. B. H. B.

Plattnerite from Idaho. By H. A. Wheeler (*Amer. J. Sci.* [3], 38, 79).—The author notes a new occurrence of plattnerite (lead dioxide) from one of the lead mines of the Cœur d'Alêne district, Idaho. The specimen was irregular, massive, and of an iron-black colour, with a chestnut-brown streak. The hardness is 5 to 5·5, and the sp. gr. 9·411. Analysis gave the following results:—

PbO_2.	SiO_2.	Fe_2O_3.	Total.
96·63	1·62	1·12	99·37

The percentage of lead is 83·69. This rare mineral is called a doubtful species in Dana's System of Mineralogy (compare next abstract). B. H. B.

Plattnerite from Idaho. By J. D. Hawkins and E. N. Hawkins (*Amer. J. Sci.* [3], 38, 165—166).—Two analyses of plattnerite from a mine near Wallace, Shoshone Co., Idaho. The results were as follows:—

<table>
<tr><th>PbO₂.</th><th>ZnO.</th><th>SiO₂.</th><th>Al₂O₃.</th><th>Fe₂O₃.</th><th>Total.</th></tr>
<tr><td>90·99</td><td>0·07</td><td>2·68</td><td>0·28</td><td>5·69</td><td>99·71</td></tr>
<tr><td>91·03</td><td>0·07</td><td colspan="2">3·00</td><td>5·86</td><td>99·96</td></tr>
</table>

The sp. gr. of the powdered mineral is 7·25, which seems to be more in accordance with the sp. gr. of massicot (8·0) than with that given by Wheeler (preceding abstract). The specimen was found in a fissure vein in quartzite, and appears to be a direct alteration from galena.
B. H. B.

Urao (Natural Soda). By T. M. Chatard. (*Amer. J. Sci.* [3], **38**, 59—64).—The salts described by the author were obtained by the spontaneous solar evaporation of the water of Owen's Lake, California, and consequently are regarded as minerals. The urao of Venezuela, analysed by Boussingault, is an almost theoretically pure salt, showing only a small loss of water and a trifling increase of sodium hydrogen carbonate. The existence of a native sodium sesquicarbonate, $Na_2CO_3,2NaHCO_3+3H_2O$, to which the name of trona has been given, rests on an analysis by Klaproth, and to this mineral the numerous published analyses of natural sodas have been referred. A recalculation of these analyses shows that none of them agree with this formula, but that the salts were uraos, with a widely varying excess of one or the other of the two carbonates. Additional proof was afforded by the fact that the artifical salt produced by Winkler's method was a urao with an excess of sodium hydrogen carbonate. Thus, there is no such salt, either natural or artificial, as sodium sesquicarbonate, but the true salt has the formula $Na_2CO_3,NaHCO_3 + 2H_2O$, although the presence of an excess of sodium hydrogen carbonate may occasionally give results approaching the composition of a sesquicarbonate. The five salts of which analyses are appended were obtained from Owen's Lake. Nos. 1 and 2 are from the same specimen, and were formed in an artificial ground vat, No. 1 being well crystallised and translucent, sp. gr. 2·1473, and No. 2 the undissolved portion of the first product. No. 3 was formed on a branching grass-root. No. 4 is from a small lagune on the east side of the lake. No. 5 was formed in a vat which was dug in the beach, and allowed to fill with permeating water from the surrounding soil.

	1.	2.	3.	4.	5.
Insol. inorganic.	0·02	0·22	2·92	0·40	4·10
Insol. organic ..	—	—	0·14	0·12	0·27
SiO_2	—	0·10	0·05	0·09	0·04
CaO	—	—	—	0·06	—
MgO..........	—	—	—	0·02	—
K_2O		—	—	trace	—
Na_2O..........	40·99	41·26	40·22	40·08	39·36
Cl............	0·19	1·57	2·73	0·21	1·83
SO_3	0·70	0·79	0·76	0·63	0·84
CO_2	38·13	37·00	35·24	37·50	35·10
H_2O	20·07	19·62	18·31	19·94	18·58
Total	100·10	100·56	100·37	99·05	100·12
O = Cl	0·04	0·35	0·61	0·05	0·41
	100·06	100·21	99·76	99·00	99·71

Each of these samples is urao, differing very slightly from the theoretical figures—

Na_2CO_3.	$NaHCO_3$.	H_2O.
46·96	37·17	15·93

A series of experiments was undertaken in order to determine the conditions under which urao is formed. In no case, no matter what the relative proportions of the salts might be, was any other mixed carbonate but urao obtained. It is therefore remarkable that this salt, which seems to be the natural form of sodium carbonate, should either not be mentioned in treatises on the sodium salts, or be confounded with another which does not appear to exist at all.

B. H. B.

Kaliborite, a new Boron Mineral. By W. FEIT (*Chem. Zeit.*, **13**, 1188).—In the mines at Schmidtmannshall, near Aschersleben, not only are boracite, pinnoite, and stassfurtite found in the upper layers of the kainite, but there is also another mineral present, in fragment, either quite pure or associated with the above minerals. Disregarding the 1 to 2 per cent. of sodium chloride it contains, it has the following composition:—

K_2O.	MgO.	B_2O_3.	H_2O.
6·48	12·06	57·46	24·00 = 100

from which is deduced the complex formula—

$$K_4Mg_9B_{48}O_{83} + 39H_2O, \text{ or } 2K_2B_6O_{10} + 9MgB_4O_7 + 39H_2O.$$

This new mineral is called *kaliborite;* its sp. gr. is 2·05, and superficially it resembles pinnoite, but its fracture resembles that of kieserite, and, like the latter mineral, it falls to powder under water; this is attributed to the solution of the small proportion of sodium chloride which probably acts as a cement The powder consists of microscopic, colourless, sharp-edged granules, clear as water, but on which crystalline faces cannot be detected. The mineral is slightly soluble in water yielding an alkaline solution, but is not decomposed by it; it dissolves readily when warmed with mineral acids. Before the blow-pipe, it fuses with difficulty to a colourless glass.

It is suggested that kaliborite is formed from pinnoite, the strong potash solutions in the mine abstracting magnesium and introducing potassium, for although laboratory experiments have failed to produce kaliborite by soaking pulverised pinnoite in saturated solutions of potassium chloride, yet under the conditions in the earth it may be probable, and a fragment was found consisting of pinnoite grown on boracite, a portion of the former being covered over with a layer of the new mineral, 2 to 10 mm. thick.

D. A. L.

Descloizite from new Localities. By W. F. HILLEBRAND (*Amer. J. Sci.* [3], **37**, 434—439).—The author gives the three following analyses of descloizites from new localities in America:—

	PbO.	CuO.	FeO.	ZnO.	V_2O_5.	As_2O_5.	P_2O_5.	H_2O.	Cl.	SiO_2.	CaO.	MgO.	K_2O.	Na_2O.	CO_2.	Total.
I.	55·93	1·15	0·70	15·94	20·80	0·32	0·27	4·37	—	0·18	0·10	0·06	—	—	—	99·82
II.	56·01	1·05	0·07	17·73	20·44	0·94	0·26	2·45	0·04	1·01	0·04	0·03	—	—	—	100·07
III.	57·00	11·21	trace	4·19	19·79	1·10	0·19	2·50	0·07	0·80	1·01	0·04	0·10	0·17	0·82	98·99

No. I is a friable, uncrystallised material, from Mayflower Mine, Beaverhead Co., Montana It has a dull-yellow to pale-orange colour. and consists chiefly of a vanadate. The percentage of water is double that required by descloizite, $R_2(OH)VO_4$; but this is not considered sufficient cause for separating the mineral from descloizite, although the close agreement of water-determinations made on different samples appears to indicate the correctness of the formula

$$2[R(OH)VO_4] + H_2O.$$

No II, from the Commercial Mine, Georgetown, New Mexico, is one of the most interesting occurrences of descloizite known, because of the extreme brilliancy of colouring of the mineral. It varies from yellow through all shades of orange-red to deep reddish-brown.

No. III was found in the Lucky Cuss Mine, Tombstone, Arizona, as an incrustation on quartz. Its colour is brown, its hardness 3·5, and its sp. gr. 5·88. The low total in the analysis is probably owing to a loss of zinc. There can be no doubt that the general formula for this vanadate is that of descloizite. It closely resembles the descloizite of Penfield (Abstr., 1884, 24), the cupro-descloizite of Rammelsberg (Abstr., 1885, 731), and perhaps the tritochorite of Frenzel (Abstr., 1882, 473). The specific identity of all these substances seems highly probable, and it might be well to designate them by some distinctive name. For this purpose *cupro-descloizite* is the most suitable.

B. H. B.

Pharmacolite from the Vosges. By E. JANNETAZ (*Jahrb. f. Min.*, 1889, ii, Ref. 409; from *Bull. Soc. fran. min.*, 11, 212—215).—The crystals found at Sainte-Marie-aux-mines, Vosges, are, as usual, grouped radially. They have a sp. gr. of 2·535, and, after subtraction of 0·70 per cent. of silica and 0·35 per cent. of ferric oxide, gave on analysis the following results:—

As_2O_5.	P_2O_5.	CaO.	MgO.	H_2O.	Total.
51·05	0·30	24·54	0·50	24·00	100·39

B. H. B.

Silicic Acids. By G F. BECKER (*Amer. J. Sci.* [3], 38, 154—157) —The silicic acids usually assumed to be necessary to account for the natural silicates are orthosilicic acid, H_4SiO_4, metasilicic acid, H_2SiO_3, polysilicic acid, $H_4Si_2O_8$, and disilicic acid, $H_2Si_2O_5$. Groth, however, has shown that polysilicic acid may be regarded as a combination of $H_2Si_2O_5$ and H_2SiO_3, thus reducing the number of acids to three. If disilicic acid is, as Groth suggests, a constituent of the alkaline felspars, it is remarkable that it is not of more frequent occurrence independently, for whilst polysilicates are amongst the most abundant minerals found, disilicates are represented only by petalite and milarite. The author proposes to simplify the series of acids in another way, namely, by regarding H_2SiO_4 and $H_4Si_3O_8$ as forming $4H_2SiO_3$, an hypothesis which is supported by the fact that both of the constituents are very abundant in nature. There are, too, grounds in the behaviour of the silicates favourable to this view of their constitution. It remains to be considered how disilicic acid is to be regarded. This the author regards as a polysilicic acid from which orthosilicic acid has been removed, a process represented by $3H_4Si_3O_8 - H_4SiO_4 = 4H_2Si_2O_5$. The constitution of petalite and milarite appears to be insufficiently established, and it is not necessary to assume for them an acid not known to exist elsewhere.

B. H. B.

New occurrence of Gyrolite. By F. W. Clarke (*Amer. J. Sci.* [3], **38**, 128—129).—A mineral, lining crevice veins in the New Almaden quicksilver mine in California, locally supposed to be white fluorspar, is found by the author to be gyrolite, having the following composition:—

H_2O.	SiO_2.	$Al_2O_3 + Fe_2O_3$.	CaO.	K_2O.	Na_2O.	F.
14·60	52·54	0·71	29·97	1·56	0·27	0·65

The gyrolite is obviously not perfectly pure, but it agrees approximately with the formula $Ca_2Si_3O + 3H_2O$. B. H. B.

Artificial Magnesia Mica. By K. v. Chroustschoff (*Zeit. Kryst. Min.*, **17**, 303; from *Tschermak's min. Mitth.*, **9**, 55).—An artificially prepared glass, having approximately the composition of a basalt free from felspar and poor in iron, was pulverised and melted in a platinum crucible with the constituents of an iron-magnesia mica, amorphous silicic acid, and a mixture of potassium silicofluoride, sodium fluoride, and aluminum fluoride. The product of the melting consisted of brown tablets of mica, spinel, and glass. The mica (I) and spinel (II) gave on analysis the following results:—

	SiO_2.	Al_2O_3	Fe_2O_3.	FeO.	MnO.	MgO.	K_2O.	Na_2O.	F.	Total.
I.	39·11	18·09	2·17	8·55	trace	21·02	7·23	1·74	1·65	99·56
II.	—	63·15	4·19	10·82	—	22·85	—	—	—	101·01

B. H. B.

Barytic Felspars from Sweden. By L. J. Igelström (*Jahrb. f. Min.*, 1889, ii, Ref. 409—410; from *Bull Soc. fran. Min.*, **11**, 263—264). —At the Sjö Mine, Örebrö, a red felspar, resembling the hyalophane of Jacobsberg, occurs in association with garnet, specular iron ore, hausmannite, rhodonite. On analysis, the results given under I were obtained:—

	SiO_2.	Al_2O_3.	FeO + MnO.	BaO.	MgO.	CaO.	$K_2O + Na_2O$.	Total.
I.	61·90	15·80	5·00	9·58	1·30	0·40	6·02	100·00
II.	54·15	29·60	—	1·26	1·52	1·00	12·47	100·00

The second analysis, II, is that of a white felspar optically resembling albite, but much more basic. It occurs in association with rhodonite and calcite.
B. H. B.

Andesine from Bodenmais. By M. Schuster and H. v. Foullon (*Zeit. Kryst. Min.*, **17**, 300; from *Jahrb. k.k. Geol. Reichsanst.*, **37**, 219).—Analysis of this felspar gave the following results:—

SiO_2.	Al_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	Fe_2O_3.	S.	Total.
59·22	25·88	7·08	0·28	0·54	6·79	0·96	0·03	100·78

This composition is that of the mixture of albite and anorthite represented by the formula Ab_7An_4. The optical properties of the felspar are intermediate between those of the mixtures Ab_2An_1 and Ab_3An_2. The angle, for instance, made by the direction of extinction with the edge formed by the faces 0P and $\infty\breve{P}\infty$ on a cleavage plate taken parallel to 0P is $-1° 47'$, the corresponding angles in the mixtures Ab_2An_1 and Ab_3An_2 being $-0° 35'$ and $-2° 12'$ respectively.
B. H. B.

Cossaïte from the Upper Susa Valley. By G. Piolti (*Jahrb. f. Min.*, 1889, ii, Ref. 428; from *Atti Acc. Sci. Turin*, **23**, 7).—This mineral occurs interbedded in lime mica schists. It is of an apple-green colour, and easily yields a white powder. It looks as if it were amorphous, but under the microscope is seen to be composed of a number of small plates. Thin sections polarise very distinctly, and the mineral is seen to be anisotropic and biaxial. Its hardness is 2·5, and its sp. gr. 3·07. Analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	Li_2O.	Na_2O.	K_2O.	H_2O.	Total.
46·49	40·68	2·68	trace	4·75	1·33	4·57	100·50

According to Dana, cossaïte is identical with paragonite. The author, however, regards this mineral as cossaïte, and is of opinion that cossaïte should not be classed as onkosin, but as a member of the mica group.
B. H. B.

Epidote and Muscovite. By H. v. Foullon and V. Goldschmidt (*Zeit. Kryst. Min.*, **17**, 299—300; from *Jahrb. k.k. geol. Reichsanst.*, **37**, 1).—Analysis I gives the composition of epidote from a coarse-grained glaucophane schist from the island of Syphnos; Analysis II that of pale-green muscovite from the glaucophane schist of Syra:

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Ignition.	Na_2O.	H_2O.	Total.
I.	40·23	23·74	11·95	0·50	20·49	0·72	2·35	—	—	99·98
II.	49·34	23·69	6·84	—	1·25	2·97	4·40	0·78	10·74	100·01

B. H. B.

Aegirine. By J. Machado (*Zeit. Kryst. Min.*, **17**, 304, from *Tschermak's min. Mitth.*, **9**, 318).—The augite from the coarse-grained nepheline syenite of Barriero, Minas Geraës, Brazil, proved to be aegirine, having the following composition:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	K_2O.	Na_2O.	Ignition.	Total.
51·60	1·92	26·29	4·20	4·25	1·15	1·05	8·89	0·56	99·91

This represents a mixture of $3NaFeSi_2O_6$, $1Na_2Al_2SiO_6$, $2CaFeSi_2O_6$, and $2CaMgSi_2O_6$. B. H. B.

Inesite, a Manganese Silicate from Dillenburg. By A. SCHNEIDER (*Zeit. Kryst. Min.*, **17**, 298—299; from *Jahrb. preuss. geol. Reichsanst*, 1888, 472).—At Nanzenbach, near Dillenburg, manganese ore is mined in a contact-vein between clay-slate and diabase, the ore being chiefly manganese silicate in amber-yellow masses. This silicate is a mixture similar to klipsteinite. Besides this ore and manganite, psilomelane, wad, pyrites, native copper, and anthracite occur. At the sides of the vein. a new mineral, *inesite* (from ἶνες, muscles), has been found in radiated masses of a reddish colour. It has a hardness of 6, and gave on analysis—

SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	H_2O.	Total.
43·92	0·29	0·69	37·87	8·40	0·33	9·22	100·72

Taking into account the fact that the mineral is slightly altered, the most probable formula appears to be $(MnCa)(MnOH)_2Si_3O_8 + H_2O$. The crystals are asymmetrical, the axial ratio being $a : b : c = 0·9753 : 1 : 1·3208$; $\alpha = 92° 18'$, $\beta = 132° 56'$, $\gamma = 93° 51'$. The mineral most closely resembling it is the hydro-rhodonite of Engström, but this, although containing the same amount of silica, contains less manganese oxide and more magnesia. B. H. B.

Peridotite from Arkansas. By J. C. BRANNER and R. N. BRACKETT (*Amer. J. Sci.* [3], **38**, 50—59).—This rock, which extends over an area of 2400 feet by 1600 feet, occurs in association with palæozoic and cretaceous rocks, and is shown by the coloured geological map accompanying the memoir to be of eruptive origin. The eruption took place at the close of the cretaceous period. The specific gravity of a comparatively unaltered variety was found to be 2·728 to 2·651, whilst that of a highly decomposed variety was 2·317. The latter is traversed by veins of barytes and serpentine. The rock is rendered porphyritic by crystals of olivine and brownish-yellow mica. The olivine is almost always altered into serpentine, and then frequently exhibits trichites of magnetite. The ground-mass consists of augite, perovskite, and magnetite. Enstatite and titaniferous iron are absent, and garnet is of rare occurrence. The rock contains 0·89 per cent. of titanic anhydride. B. H. B.

Porphyrite Bosses in New Jersey. By J. F. KEMP (*Amer. J. Sci.* [3], **38**, 130—134).—The author describes, with the aid of a map, the eruptive rocks in the north-western portion of New Jersey. There are eight exposures in all. The rocks are to be classed with the porphyrites according to the types systematised by Rosenbusch, and might be termed biotite-augite-porphyrite. They agree with the porphyrites of Thuringia in composition, structure, and alteration-products. The author gives the following analyses of the rock from two localities (1 and 2) and of the biotite (3):—

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	P_2O_5.	Ignition.	Total.
1.	40·47	11·86	17·44	16·80	3·10	4·21	1·90	—	3·60	99·38
2.	31·80	18·78	15·20	14·60	3·32	5·07	1·10	0·95	8·10	98·92
3.	34·61	15·74	8·52	trace	20·03	17·14	trace	—	2·80	98·84

The sp. gr. of No. 1 is 3·102, that of No. 2 is 2·939. The former effervesced, the latter did not. Alteration consequently lowers the specific gravity. B. H. B.

New Meteorite from Mexico. By J. E. WHITFIELD (*Amer. J. Sci.* [3], **37**, 439—440).—The author describes a mass of meteoric iron weighing 33 kilos., found on La Bella Roca, a peak of the Sierra de San Francisco, in the State of Durango. The date of its discovery and the name of the finder are unknown. The composition of the metallic portion is as follows:—

Fe.	Ni.	Co.	P.	S.	C.	Total.
91·48	7·92	0·22	0·21	0·21	0·06	100·10

On one side of the meteorite there are large, deep pittings, greater in diameter just below than immediately at the surface. Remains of a substance that evidently originally filled the cavities proved to be troilite having the composition—

NiS.	FeS.	Fe.
2·13	85·27	9·37

The exposed portions of the troilite were greatly decomposed, and gave on analysis—

NiS.	FeS.	Fe_2O_3.	H_2O.
2·07	37·51	37·8	19·85

The deep pittings were probably formed by the removal of troilite nodules while the mass was hot, and by the subsequent weathering. Nodules of troilite occur throughout the mass, but the pittings have been formed only on the front side of the meteorite. Thin sections of the meteorite, when etched, show Widmannstättian figures and dark diagonal bands of troilite. B. H. B.

Meteorite from Mighеї, Russia. By S. MEUNIER (*Compt. rend.*, **109**, 976—978).—This meteorite fell on June 9th, 1889, at Mighеї, in the south of Russia. It is a dark, greenish-black, friable, earthy substance which soils the fingers and paper; sp. gr. at 12° = 2·495. In thin sections under the microscope it is almost entirely opaque, with small crystalline nuclei consisting chiefly of magnesian pyroxene with some peridote. It contains 0·867 per cent. of a very fine magnetic substance consisting almost entirely of iron with a little nickel, and there are also a few grains of pyrrhotine; 85·167 per cent. of the meteorite is soluble in acids, and has sensibly the composition of peridote, SiO_2, 36·21; MgO, 34·91; FeO, 26·48 = 97·60. The inorganic part of the insoluble portion has the composition—

SiO_2.	MgO.	FeO.	CaO.	Al_2O_3.	Mn and Cr oxides.	
58·42	28·04	10·99	3·04	1·12	traces	= 101·61

The meteorite contains 4·72 per cent. of organic matter which, when heated to redness in a current of hydrogen, splits up into carbon and a small quantity of a bituminous substance with a powerful odour. If the meteorite is heated with alcohol, it yields 0·056 per cent. of a yellow resin very similar to the kabaite of Wöhler.

When the meteorite is treated with water, it yields a colourless, limpid solution which has an odour of amber, and contains a small quantity of organic matter, but it also contains some inorganic substance, amounting to 1·728 per cent. of the meteorite, which with barium chloride, gives a heavy, white precipitate, and with silver nitrate a brilliant red, curdy precipitate insoluble in nitric acid. In contact with the mother liquor, it is partially converted into colourless, hyaline, highly refractive crystals; when exposed to light, it rapidly blackens. The exact nature of this substance has still to be determined. C. H. B.

New Meteorite from Chili. By F. v. SANDBERGER (*Jahrb. f. Min.*, 1889, ii, Mem., 173 -180).—The author describes a meteorite found at Carcote, in Chili. It was originally mistaken for silver ore. The main portion of the mass is of a light-grey to whitish colour, and is as hard as quartz. The specific gravity of the mass, after removal of nickel-iron, was found to be 3·466. In addition to minute grains of chrome-iron ore, the meteorite contains grains of two distinct silicates. A portion, 0·476 per cent., of the meteorite was soluble in distilled water, and gave on analysis—

CaO.	MgO.	SO_3.	KCl, &c.
33·83	8·40	27·52	30·25

Hydrochloric acid dissolved the silicate which formed 38·88 per cent. of the mass. This consisted of colourless grains which behaved like olivine under the microscope, and which gave on analysis—

SiO_2.	MgO.	FeO.	Al_2O_3.
38·35	35·83	25·28	0·54

This is the composition of an olivine fairly rich in iron. The second silicate formed 40·73 per cent. of the meteorite. It gave on analysis—

SiO_2.	Al_2O_3.	FeO.	MgO.	CaO.	Na_2O.	K_2O.
57·43	5·20	10·07	20·36	2·85	3·35	0·74

This is obviously an alkali-bearing compound of the diopside group. a mineral which has hitherto but rarely been met with. Black grains of chrome-iron ore disseminated throughout the meteorite form but 1·39 per cent. of the mass. The troilite, which forms 5·83 per cent. of the mass, is not distinguishable from ordinary magnetic pyrites. The nickel-iron gave on analysis—

Fe.	Ni + Co.	Mn.	Cu + Sn.	P.
87·08	8.85	1·44	0·60	2·03

This is similar to the composition of the nickel-iron from the meteorite of Deesa. As the alteration-products contain the same elements in equal proportions, the ferric oxide, nickel oxide, and manganese oxide may be calculated as metal. This gives 8·36 per cent. of the mass, which with 1·66 per cent. of unaltered nickel-iron, represents 10·02 per cent. of the meteorite. Minute quantities of the rhabdite of G. Rose also appear to be present. The most remarkable substance, however, occurring in this meteorite is dull-black, has great hardness (9), is not attacked by acids, and consists exclusively of carbon. In one place it forms a segregation 3 mm. in breadth, and appears to be black diamond. Other carbonaceous matter is present, but has not been accurately estimated. The results of the investigation are of considerable interest, as this meteorite represents a new type for Chili—a country in which numerous meteorites have been found. Similar meteorites are, however, known in other districts. Thus, this meteorite resembles the Alfianello meteorite which fell on February 15, 1883, and probably also that of New Concord, Ohio.

B. H. B.

Organic Chemistry.

Arrangement in Space of the Atoms in the Molecule of Carbon Compounds containing Nitrogen. By A. Hantzsch and A. Werner (*Ber.*, **23**, 11—30).—At the present time a certain number of geometrically isomeric compounds are known in which the isomerism cannot be explained in the same manner as in the case of fumaric and maleïc acids (Abstr., 1888, 35). The compounds in question are the isomeric mono- and di-oximes of benzil, the two benzaldoximes, the two ethyl hydrogen oximidosuccinates, the modifications of the hydroxamic acids, and lastly the two isomeric parazoxytoluenes, and trinitroazotoluenes.

In order to explain the existence of isomeric benzil mono- and di-oximes, Auwers and V. Meyer assume that Van't Hoff's second hypothesis (according to which isomeric compounds of the general formula  $\begin{matrix}R_1\\R_1\\R_2\end{matrix}{>}C—C{<}\begin{matrix}R_1\\R_1\\R_2\end{matrix}$ cannot exist) does not hold true in all cases, but that under certain conditions, three geometrically isomeric compounds of such a formula may be obtained (these Abstr., 1888, 549, 597). The existence of two isomeric benzaldoximes has been explained by Beckmann (Abstr., 1889, 608) on the assumption of a different structure of the oximido-group in the two compounds, but Goldschmidt considers this explanation to be incorrect (this vol., p. 253).

An examination of the above compounds shows that all of them contain one or more nitrogen-atoms. The authors point out that up to the present time geometrical considerations concerning the arrangement of the atoms in the molecule have been for the most part confined to the carbon-atom, and it therefore appeared to them that an application of the same principles to the nitrogen-atom might lead to an explanation of the above cases of isomerism, without making any modification of Van't Hoff's second hypothesis.

The following consideration forms the starting-point of the theory proposed. If Van't Hoff's first hypothesis, that "the valencies of the carbon-atom are equally distributed in space, and correspond to the corners of a regular tetrahedron inscribed in a sphere," be accepted, it is manifest that in the cyanogen compounds, and in those rings of carbon- and nitrogen-atoms in which all three valencies of the latter are combined with carbon, these valencies cannot lie in the same plane as the nitrogen-atom. This is expressed generally as follows:—

The valencies of the *triad* nitrogen-atom do not *necessarily* lie in the same plane as the nitrogen-atom itself.

From this consideration is deduced the hypothesis that "in certain compounds the valencies of the nitrogen-atom are directed towards the corners of an irregular tetrahedron, the nitrogen-atom itself occupying the fourth corner."

On this hypothesis the nitrogen-atom may be in a certain sense represented as a tetrahedron, and, therefore, when a nitrogen-atom is united by two of its valencies either to a carbon-atom or to a second nitrogen-atom, we may have cases of isomerism similar to that of fumaric and maleic acids. Thus a compound of the formula $XY\!:\!C{=}N{\cdot}Z$ should exist in two forms,

$\begin{array}{l}X{\cdot}C{\cdot}Y\\ \ \ \ \|\\ \ \ \ N{\cdot}Z\end{array}$

and

$\begin{array}{r}X{\cdot}C{\cdot}Y\\ \|\ \ \ \\ Z{\cdot}N\ \ \ \end{array}$

, the compound $X{\cdot}N{=}N{\cdot}Y$ in two forms,

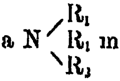
$\begin{array}{l}N{\cdot}X\\ \|\\ N{\cdot}Y\end{array}$

and

$\begin{array}{r}N{\cdot}X\\ \|\ \ \ \\ Y{\cdot}N\end{array}$

.

It would further follow from this hypothesis that compounds of the formula

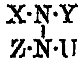


$N\begin{array}{l}\diagup R_1\\ -R_1\\ \diagdown R_3\end{array}$

might possibly exist in optically isomeric forms, and that isomeric hydrazines of the formulæ

$\begin{array}{l}X{\cdot}N{\cdot}Y\\ \ \ \ |\\ U{\cdot}N{\cdot}Z\end{array}$

and



$\begin{array}{l}X{\cdot}N{\cdot}Y\\ \ \ \ |\\ Z{\cdot}N{\cdot}U\end{array}$

might also be obtained. Such compounds are not, however, at present known.

According to this theory, the above-mentioned special cases of isomerism receive the following explanation:—

Benzaldoxime can exist in the two following forms,

$\begin{array}{l}H{\cdot}C{\cdot}Ph\\ \ \ \ \|\\ \ \ \ N{\cdot}OH\end{array}$

and

$\begin{array}{l}\ \ \ \ H{\cdot}C{\cdot}Ph\\ \ \ \ \ \ \ \ \|\\ HO{\cdot}N\end{array}$

; sufficient data are, however, not available to show which formula corresponds with benzaldoxime, which with isobenzaldoxime.

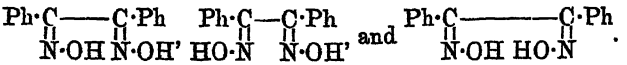
Benzilmonoxime can exist also in two forms,

$\begin{array}{l}Ph{\cdot}C{-}C{\cdot}Ph\\ \ \ \ \ \ \|\ \ \ \ \|\\ \ \ \ \ \ O\ \ \ N{\cdot}OH\end{array}$

and

$\begin{array}{l}Ph{\cdot}C{-\!-}C{\cdot}Ph\\ \ \ \ \ \ \|\ \ \ \ \ \ \ \ \|\\ \ \ \ \ \ O\ \ HO{\cdot}N\end{array}$

. *Benzildioxime* should exist in three forms:



$$\begin{matrix}\mathrm{Ph{\cdot}C} & — & \mathrm{C{\cdot}Ph}\\ \| & & \|\\ \mathrm{N{\cdot}OH} & & \mathrm{N{\cdot}OH}\end{matrix},\quad \begin{matrix}\mathrm{Ph{\cdot}C} & — & \mathrm{C{\cdot}Ph}\\ \| & & \|\\ \mathrm{HO{\cdot}N} & & \mathrm{N{\cdot}OH}\end{matrix},\ \text{and}\ \begin{matrix}\mathrm{Ph{\cdot}C} & — & \mathrm{C{\cdot}Ph}\\ \| & & \|\\ \mathrm{N{\cdot}OH} & & \mathrm{HO{\cdot}N}\end{matrix}.$$

This agrees well with the facts, two benzilmonoximes and three dioximes being known. The third formula probably represents the γ-dioxime, as that compound yields an anhydride so readily; the β-dioxime, which is the most stable, has probably the second formula, whilst the α-dioxime, which in its properties is intermediate between the other two, has probably the first formula. If these assumptions are correct, the first formula given above for the benzilmonoximes must represent the α-monoxime, and the second the γ-monoxime.

Ethyl Hydrogen Oximidosuccinates.—The two isomeric compounds will be represented by the formulæ  $\begin{matrix}\mathrm{COOEt{\cdot}C{\cdot}CH_2{\cdot}COOH}\\ \|\\ \mathrm{N{\cdot}OH}\end{matrix}$ and  $\begin{matrix}\mathrm{COOEt{\cdot}C{\cdot}CH_2{\cdot}COOH}\\ \|\\ \mathrm{HO{\cdot}N}\end{matrix}$.

Lossen's substituted hydroxamic acids may also be regarded as geometrical isomerides, having the general formulæ  $\begin{matrix}\mathrm{C_xH_y{\cdot}C{\cdot}OH}\\ \|\\ \mathrm{HO{\cdot}N}\end{matrix}$ and  $\begin{matrix}\mathrm{C_xH_y{\cdot}C{\cdot}OH}\\ \|\\ \mathrm{N{\cdot}OH}\end{matrix}$, but matters are here more complicated, as these tautomeric compounds may exist in desmotropic modifications.

Trinitroazotoluenes.—These two compounds receive the formulæ  $\begin{matrix}\mathrm{N{\cdot}C_6H_3Me{\cdot}NO_2}\\ \|\\ \mathrm{N{\cdot}C_6H_2Me(NO_2)_2}\end{matrix}$ and  $\begin{matrix}\mathrm{N{\cdot}C_6H_3Me{\cdot}NO_2}\\ \|\\ \mathrm{C_6H_2Me(NO_2)_2{\cdot}N}\end{matrix}$.

The Parazoxytoluenes are represented in a similar manner as follows:  $\mathrm{O}<\begin{matrix}\mathrm{N{\cdot}C_7H_7}\\ |\\ \mathrm{N{\cdot}C_7H_7}\end{matrix}$ and  $\begin{matrix} & \mathrm{N{\cdot}C_7H_7}\\ \mathrm{O}< & |\\ \mathrm{C_7H_7}— & \mathrm{N}\end{matrix}$.

To this theory the objection may be possibly raised, that if these considerations were correct the number of such isomerides would be extremely large, whereas, in reality, only a very limited number are known. In answer to this the authors point out that only a very small number of the theoretically possible geometrical isomerides of carbon compounds have been as yet obtained; and that, further, such geometrical isomerides as are here described can, according to the theory, only be formed when the three valencies of the nitrogen-atom are not in the same plane as the atom itself, and it is quite possible that in a large number of instances this condition may not be fulfilled, in which case the number of isomerides corresponding with those discussed above would be greatly diminished. Experiments are now being made to see whether, under any circumstances, optical isomerides of ammonia or hydrazine derivatives can exist.

H. G. C.

Sulphur Compounds in Raw Petroleum and in Petroleum Residues. By C. F. MABERY and A. W. SMITH (*Ber.*, 22, 3303—3305). —Ohio petroleum contains considerable quantities of sulphur compounds which are present in the largest proportion in the portions boiling between 200 and 300°. The sulphur compounds can be extracted by treatment with concentrated sulphuric acid and, on neutralising the diluted acid solution with lead carbonate (or lime) and evaporating, a salt separates from the solution. When this salt is distilled with steam, the sulphur compounds collect in the receiver in the form of a light yellow oil; this product, which contains 14·97 per cent. of sulphur, was distilled under a pressure of 100 mm. and the following fractions collected:—

Fraction..	80—90°	100—105°	135—140°	150—155°	185—190°
Sulphur..	none	18·23	15·52	16·44	14·21

The fractions boiling above 100° all contained sulphides, but thiophen compounds and mercaptans were absent in every case; those of lower boiling point gave crystalline precipitates with an alcoholic solution of mercuric chloride, whilst the higher fractions gave oily compounds which subsequently solidified when kept or recrystallised from benzene. They all combine with bromine with explosive violence. The fraction boiling at 80—90° combined with bromine, yielding a heavy oil which seems to have the composition $C_{17}H_{14}Br_2$. All the fractions boiling below 135° combined with hydrobromic acid yielding oily products.

Analyses of the mercury compounds showed that the sulphur compounds present are ethyl, propyl, and butyl sulphides.

F. S. K.

Derivatives of Diallyl. By G. CIAMICIAN (*Ber.* **22**, 3326).—A reply to Wagner's note (this vol., p. 223).

Cyanogen Monosulphydrate. By R. ANSCHÜTZ (*Annalen*, **254**, 262—264).—Pure cyanogen monosulphydrate (flaveanwasserstoff) $C_2H_4N_2S$, can be obtained by passing hydrogen sulphide and excess of cyanogen into alcohol and recrystallising the dark-coloured product from boiling chloroform. It forms pale yellow needles, begins to darken at about 80°, and melts at 87—90° with decomposition.

F. S. K.

Action of Ammonia on the Compounds of Mercuric Cyanide with Metallic Chlorides. By R. VARET (*Compt. rend.*, **109**, 941—944).—Aqueous ammonia added to an aqueous solution of mercuric chlorocyanide gives a white precipitate of mercurammonium chloride, NH_2HgCl, and the solution contains mercuric cyanide and ammonium chloride. It follows that mercuric cyanide has no influence on the action of ammonia on mercuric chloride. If zinc cyanide is added to the solution of mercuric chlorocyanide which has been mixed with excess of ammonia, the precipitate redissolves, and when the liquid is concentrated over potash, the compound $HgCy_2,ZnCy_2,HgCl_2,4NH_3$ separates in nodules.

The action of a solution of dry ammonia in absolute alcohol on dry mercuric chlorocyanide at a low temperature yields a precipitate of the composition $HgCl_2,3NH_3$, and the liquid, when concentrated over potash, yields prismatic needles of the compound $HgCy_2,2NH_3$. The compound $HgCl_2,3NH_3$ alters rapidly when exposed to air and is decomposed by water.

The action of dry ammonia on dry mercuric chlorocyanide at 70° yields a greyish-white compound, $2Hg_2Cy_2Cl_2,3NH_3$, which is decomposed by water and by aqueous ammonia, and when heated yields a blackish powder.

Mercuric zinc chlorocyanide, $HgCy_2,ZnCy_2,HgCl_2 + 6H_2O$, in an aqueous solution, yields with ammonia a white precipitate of zinc cyanide and mercurammonium chloride, soluble in excess. When treated with dry ammonia, it loses water and combines with 4 mols. of ammonia. When treated with aqueous ammonia, it dissolves and the solution yields small, crystalline nodules of the compound $HgCy_2,ZnCy_2,HgCl_2,4NH_3$, which is decomposed by water, loses ammonia when exposed to the air, and is only slightly soluble in cold alcohol or cold aqueous ammonia.

Mercuric cupric chlorocyanide dissolves in aqueous ammonia, and when the liquid is concentrated, it yields blue, prismatic needles of the compound $2HgCy_2,CuCl_2,4NH_3$, which can be heated at 100° without loss of ammonia, and is only slightly soluble in cold, aqueous ammonia, but is decomposed by water.

Mercuric chlorocyanide alone is decomposed by ammonia, but in presence of another metallic cyanide a triple compound is formed and the decomposition of the mercuric salt is prevented.

C. H. B.

New Method of Preparing Potassium Ferricyanide. By G. Kassner (*Chem. Zeit.*, **13**, 1701).—Recognising the unsatisfactory character of the methods employed for the conversion of potassium ferrocyanide into the ferricyanide, the author recommends the following:—

An aqueous solution of calcium plumbate is boiled with an alkaline carbonate; the precipitate, consisting of plumbic peroxide and calcium carbonate, converts ferrocyanide into ferricyanide. When carbonic anhydride is present to neutralise the base formed, the reaction is as follows:—$2K_4FeC_6N_6 + PbO_2(+ 2CaCO_3) + 2CO_2 = K_6Fe_2C_{12}N_{12} + K_2CO_3 + PbCO_3 (+ 2CaCO_3)$. The ferricyanide and potassium carbonate are dissolved out, and the mixture of lead and calcium carbonates is reconverted into calcium plumbate by igniting in the air. The process, the author argues, is economical, inasmuch as there is no loss of material, and it amounts simply to utilising the atmospheric oxygen; moreover the bye-products are valuable, *e.g.*, caustic alkalis from the decomposition of the plumbate, and therefore it ought to tend towards the technical application of potassium ferricyanide (compare next abstract).

D. A. L.

New Application of Potassium Ferricyanide. By G. Kassner (*Chem. Zeit.*, **13**, 1302, 1338, 1407).—The author has observed that when alkaline potassium ferricyanide and hydrogen peroxide are mixed, oxygen is evolved, the former being converted into ferrocyanide; the following equations explain the change:—$K_6Fe_2C_{12}N_{12} + 2KHO = 2K_4FeC_6N_6 + H_2O + O$ and $O + H_2O_2 = H_2O + O_2$. The quantity of alkali regulates the reaction; therefore the following is suggested as a method for preparing oxygen:—Potassium ferricyanide dissolved in a little water is mixed with 3 per cent. hydrogen peroxide in a flask furnished with a delivery tube and a tap funnel down which the potash is delivered as quickly as desired. 58 grams of ferricyanide and 100 c.c. of 3 per cent. hydrogen peroxide yield 2 litres of oxygen.

Alkaline carbonates also convert ferricyanide into ferrocyanide in the presence of hydrogen peroxide with the liberation of oxygen and carbonic anhydride, the carbonates being more active than the hydrogen carbonates. It is noteworthy that in these reactions there is no loss of valuable substance. Incidently it is noted that when ferricyanide is agitated and digested with about 20 per cent. potash and some milk of lime, oxygen is evolved, and the residue contains calcium hydroxide, some calcium carbonate, but no potassium ferrocyanide, inasmuch as the latter has become converted into a very sparingly soluble double ferrocyanide of potassium and calcium which adheres to the containing vessel. Potassium ferricyanide is to a great extent decomposed, when heated at 180° in a sealed tube with milk of lime and some potash, yielding ferric oxide, ammonia, potassium cyanide, and potassium ferrocyanide. D. A. L.

Ethereal Salts of Nitrous Acid. By G. Bertoni (*Gazzetta*, 18, 431).—In continuation of his previous investigations (compare Abstr., 1886, 217 and 975, 1887, 458), the author has now prepared the following compounds, using the methods already described:—

Butyl nitrite, $C_4H_9 \cdot NO_2$. A yellowish, mobile liquid of unpleasant odour. On inhalation, it produces the same symptoms as ordinary amyl nitrite. It is only very sparingly soluble in water, by which it is decomposed on prolonged contact, but dissolves in ether, chloroform, carbon bisulphide, &c.; it is insoluble in glycerol. It boils at 75° and its sp. gr. at 0° = 0·9114. It exhibits the general reactions of alcoholic nitrites.

Secondary butyl nitrite, $CHMeEt \cdot NO_2$, has the general properties of the alcoholic nitrites, and is insoluble in glycerol. It boils at 68°, and its sp. gr. at 0° = 0·8981.

Normal heptyl nitrite, $C_7H_{15} \cdot NO_2$, exhibits the same general reactions. It boils at 155°, and its sp. gr. at 0° = 0·8939. It is insoluble in glycerol. S. B. A. A.

First Oxide of the Pentahydric Alcohol from Diallyl Carbinol. By S. Reformatsky (*J. Russ. Chem. Soc.*, 21, 295—319).—In order to obtain a pentatomic alcohol, the preparation of which was attempted in vain by Saytzeff and by Dieff, the author first treated diallyl carbinol with hypochlorous acid, and then decomposed the chlorhydrin thus obtained by potash (this vol., p. 120); the potash was then saturated with sulphuric acid or carbonic anhydride, and the water removed by evaporation. The alcoholic extract of the residue thus obtained was fractionally precipitated with ether in order to remove the salts and other impurities, and the alcohol-ether solution evaporated, when it yielded, not the alcohol required, but its oxide (first anhydride), $C_7H_{11}(OH)_3O$, as a viscid, sweet oil, which partly solidified to a crystalline mass after being kept two years. It is soluble in water and alcohol, insoluble in ether, and cannot be distilled without decomposition even under reduced pressure. The same product was formed on decomposing the chlorhydrin with lead oxide.

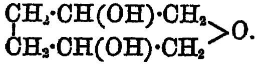
Dieff's triacetate was obtained by the action of acetic anhydride at 150°; the pentacetate and the pentabenzoate were also obtained in an impure condition. As regards the constitution of the anhydride in question, which is discussed by the author at some length, the conclusion is drawn that its formula is most probably:

$$CH(OH){<}\begin{matrix}CH_2·CH(OH)·CH_2\\CH_2·CH(OH)·CH_2\end{matrix}{>}O.$$

The analogy between the constitution of this anhydride and that of the glucoses is not complete, as aniline has no action on it.

B. B.

First Oxide of a Tetrahydric Alcohol from Diallyl. By S Reformatsky (*J. Russ. Chem. Soc.*, **21**, 320—326).—The author, on attempting to obtain a tetratomic alcohol from diallyl, by first converting it into the chlorhydrin, $C_6H_{10}(OH)_2Cl_2$, by means of hypochlorous acid, and then acting on this with potash, obtained only the same oxide, $C_6H_{10}O(OH)_2$, as Přibytek. This, however, is not converted into the alcohol by assimilation of the elements of water, as stated by Přibytek. After studying the acetate, and comparing the properties of the oxide with those of the pentatomic alcohol described in the preceding abstract, the author concludes that the substance in question has the constitution:



$$\begin{matrix}CH_2·CH(OH)·CH_2\\|\\CH_2·CH(OH)·CH_2\end{matrix}{>}O.$$

B. B.

Dehydration of Monhydric Alcohols. By A. Volkoff. (*J. Russ. Chem. Soc.*, **21**, 327—341).—From experiments on the dehydration of a series of saturated monhydric alcohols the author draws the following conclusions. Heating the alcohols to a high temperature alone (up to 253° and in some cases to 310°) does not give rise to dehydration, but it remains an open question whether this effect is not produced in some cases by heating to 400° or higher. On heating secondary and tertiary alcohols with a small quantity of methyl iodide, however, complete decomposition takes place, whereas primary alcohols are converted into simple ethers containing the radicle of the primary alcohol; one of the first phases of the reaction being the formation of the corresponding iodide. This conversion is either represented by the equation: $mC_nH_{2n+1}·OH + MeI = C_nH_{2n+1}I + Me·OH + (m-1)C_nH_{2n+1}·OH$, or the compound methyl ether is first formed together with hydrogen iodide, which in the second phase of the reaction gives the alkyl iodide:

$$(I)\ m(C_nH_{2n+1}·OH) + MeI = Me·O·C_nH_{2n+1} + (m-1)C_nH_{2n+1}·OH + HI$$

and

$$(II)\ (m-1)C_nH_{2n+1}·OH + HI = C_nH_{2n+1}I + (m-2)C_nH_{2n+1}·OH + H_2O.$$

The further progress of the reaction is dependent on the stability of the iodide formed under the conditions of the experiment, so that secondary and tertiary iodides are decomposed, yielding the hydrocarbons of the ethylene series and hydrogen iodide, whereas the primary iodides react with a molecule of the alcohol present in excess, forming the simple ether thus: $C_nH_{2n+1}I + C_nH_{2n+1}OH = (C_nH_{2n+1})_2O + HI$. The hydrogen iodide thus produced again gives rise to the formation of a fresh molecule of the iodide, and the reaction proceeds continuously in this way, until all the alcohol is converted, and at last free hydrogen iodide remains. The author is about to publish an account of similar experiments with unsaturated alcohols. B. B.

β-Inosite. By MAQUENNE (*Compt. rend.*, **109**, 968—970)—If heated at 160—170° with saturated hydriodic acid in presence of some red phosphorus, β-inosite yields a phenol which, when treated with iodine and potassium hydroxide, yields an insoluble iodo-derivative. The latter crystallises from alcohol or chloroform in slender, yellowish needles, soluble in alkalis, but insoluble in water and dilute acids. With nitric acid it yields trinitrophenol, and hence is identical with the product obtained from inosite under the same conditions. This result and the fact that it yields quinones on oxidation prove that β-inosite has the same formula as ordinary inosite. The absence of aldehydic or ketonic groups is proved by the absence of reducing power and the non-formation of any compound with phenylhydrazine acetate.

Hexacetyl-β-inosite, $C_6H_6(OAc)_6$, obtained by the action of acetic anhydride in presence of zinc chloride, could not be obtained in crystals. It is very fusible, and even volatile, dissolves in alcohol and ether, but is insoluble in water.

Hexabenzoyl-β-inosite, obtained by the action of benzoic chloride in presence of small quantities of zinc, crystallises from amyl alcohol in brilliant, white needles which melt at 253°, and are insoluble in most solvents in the cold, although somewhat soluble in hot amyl alcohol.

β-Inosite, in a 10 per cent. solution at 14·3°, has a rotatory power $[\alpha]_D = 65{\cdot}0°$, almost identical with that of β-pinite. It differs in the physical and chemical properties of itself and its derivatives from ordinary inosite, the quebrachite of Tanret, and the matezo-dambose of A. Girard.

It follows from these and the previous results that pinite is the mono-methyl ether of β-inosite, and is, therefore, isomeric with bornesite and quebrachite. C. H. B.

Rhamnodiazine. By B. RAÝMAN and O. POHL (*Ber.*, **22**, 3247—3249; compare Abstr., 1889, 485).—Rhamnodiazine is decomposed when boiled with methyl iodide in methyl alcoholic solution, yielding methylamine and brown, amorphous substances. It is decomposed by glacial acetic acid with liberation of rhamnose. A crystalline compound is obtained when rhamnodiazine is treated with hydrogen chloride in alcoholic solution, but it cannot be easily separated from the ammonium chloride, which is also formed in the reaction; it has probably the composition $C_{14}H_{22}N_2O_7,2HCl$.

When rhamnose, in alcoholic solution, is treated at the ordinary temperature with ethyl acetoacetate (1 mol.), and an amido-compound (2 mols.) such as aniline, toluidine, β-naphthylamine, or ethyl imidocrotonate, α-rhamnosamine is formed.

Rhamnodiazine probably has the constitution—

$C_5H_{11}O_4\cdot CH(N\vdots CMe\cdot CH_2\cdot COOEt)_2$. F. S. K.

Melitose. By BERTHELOT (*Bull. Soc. Chim.* [3], 2, 655—657; compare Abstr., 1886, 138).—Melitose (raffinose) obtained from cotton-cake separates from alcohol in small, hard, granular crystals, having the formula $C_{36}H_{64}O_{32} + 10H_2O$, but when crystallised from aqueous alcohol yields lamellar crystals of $C_{36}H_{64}O_{32} + 12H_2O$; the rotatory power being the same for both hydrates.

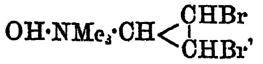
Good beer yeast determines the total fermentation of melitose; with feeble baker's yeast, a complete arrest of fermentation occurs after 48 hours, and a residue of carbohydrate amounting to 67—75 per cent. of the original melitose remains. In one instance, 100 parts of melitose, fermented with a feeble yeast, yielded carbonic anhydride, 15·6, alcohol, 16, and residual carbohydrates, 74·3 parts, of which 30 per cent. is reducing sugar.

The ferment probably causes a prior hydrolysis of melitose to a glucose and either a reducing saccharose or two glucoses, of which but one is reducing. T. G. N.

An Unfermentable, Dextrorotatory Constituent of Honey. By E. v. RAUMER (*Zeit. ang. Chem.*, 1889, 607—609).—Sieben has stated that the presence of starch-sugar in honey can be detected by means of its unfermentable dextrin, since, according to his experiments, honey contains no substance which could be mistaken for it. The author has, however, recently, examined a number of specimens of honey, including several which were unquestionably genuine, and they all, after fermentation, exhibited dextrorotation. Some of the active substance was prepared in a state of approximate purity by precipitation with alcohol and washing with ether. It appears to belong to the class of dextrins, and different preparations showed a specific rotatory power of 52° to 68°, which, by inversion, was diminished to about half. The reducing power of two different preparations was respectively 0·455 and 0·304 of copper for 1 part of substance: by inversion this was increased in the ratio of 2·7 : 1. After inversion the substance fermented completely, its rotatory power diminishing during the fermentation, but always remaining positive, whence it is inferred that lævulose is not present.

M. J. S.

Allyltrimethylammonium Compounds. By A. PARTHEIL (*Ber.*, 22, 3317—3324).—Weiss has described (*Chem. Centr.*, 1887, 1345) the tribromide, $C_3H_5Br_2\cdot NMe_3Br$, of this base. When this derivative is treated with alcoholic potash or fresh silver oxide, *bromallyltrimethylammonium bromide*, $C_3H_4Br\cdot NMe_3Br$, is formed. This salt crystallises in colourless prisms, soluble in water, alcohol, and warm chloroform, insoluble in ether, and melts at 165°. The *platinochloride* forms easily soluble, reddish-brown plates melting with decomposition at 220°; the *aurochloride*, sulphur-yellow crystals melting at 181°. With excess of bromine it yields *bromallyldibromide-trimethylammonium bromide*, $CHBr_2\cdot CHBr\cdot CH_2\cdot NMe_3Br$, which crystallises in colourless scales and melts at 156°. When the monobromo-bromide is further treated with alcoholic potash, *trimethyltrimethineammonium bromide*,  $NMe_3Br\cdot CH<\begin{matrix}CH\\ \|\\ CH\end{matrix}$, is formed, which is not soluble in chloroform, and yields the free *base* when digested with excess of alcoholic potash. The *aurochloride* forms yellow scales. No platinochloride could be obtained, as it was so easily reducible; the aurochloride deposited gold when boiled with water. When the bromide is treated with excess of bromine, it yields a *perbromide* crystallising in dark, yellowish-brown plates; when this is boiled with absolute alcohol, it is converted into the *base*



$$OH\cdot NMe_3\cdot CH<\begin{matrix}CHBr\\ |\\ CHBr\end{matrix},$$

crystallising in colourless needles, and melting at 187°. The *platinochloride* forms brownish-red plates melting at 232°, the *aurochloride*, citron-yellow plates melting at 193°. When boiled with silver nitrate, the bromide yielded the compound $C_3H_4Br_2\cdot NMe_3\cdot NO_3$.

When allyltrimethylammonium iodide is treated with hydriodic acid at 100°, *γ-moniodopropyltrimethylammonium iodide*, $C_3H_6I\cdot NMe_3I$, is formed. This crystallises in colourless needles soluble in water and alcohol, and melts at 151°. The *platinochloride*, $(C_3H_6I\cdot NMe_3Cl)_2,PtCl_4$, forms reddish-yellow needles, and melts with decomposition at 237°; the *aurochloride*, brownish-yellow scales, and melts at 135°. When boiled for some time with silver nitrate, the iodide yields γ-homocholine. Hydrobromic and hydrochloric acids, at about 160—170°, yield similar additive-products, but these were not obtained pure; the *platinochloride*, $(C_3H_6Cl\cdot NMe_3Cl)_2,PtCl_4$, crystallises in dark, brownish-red needles; the *aurochloride* in golden-yellow plates melting at 185°.

Hypochlorous acid forms two isomeric additive-products with allyltrimethylammonium chloride. The first yields a sparingly soluble *platinochloride*, $(OH\cdot C_3H_5Cl\cdot NMe_3Cl)_2,PtCl_4$, crystallising in yellow scales melting at 234—235°, and a moderately soluble *aurochloride*, crystallising in yellow plates, melting at 162°. When heated with silver oxide, the compound,  $NMe_3Cl\cdot CH\cdot CH<\begin{matrix}O\\ |\\ CH_2\end{matrix}$, is formed, which crystallises in yellowish-red, easily soluble, octohedral needles, and melts at 207°. The second isomeride forms an easily soluble *platinochloride*, crystallising in yellowish-red needles melting with decomposition at 225—226°, and an easily soluble *aurochloride* melting at 192°.

L. T. T.

Ketoaldehydes. By L. Claisen and L. Meyerowitz (*Ber.*, 22, 3273—3281; compare Abstr., 1889, 619).—*Formyldiethyl ketone* (*propionylpropionaldehyde*), $COEt\cdot CHMe\cdot COH$, is prepared by gradually adding a well-cooled mixture of ethyl formate (11 grams) and diethyl ketone (13 grams) to finely-divided sodium ethoxide (10·5 grams), covered with dry ether (10 parts). After keeping for 12 hours, the sodium-derivative (about 12 grams) is separated by filtration, dissolved in ice-cold water, the solution acidified with hydrochloric acid and the oil extracted with ether; the crude product is purified by distillation under reduced pressure (45—50 mm.). It forms colourless crystals, melts at about 40°, boils at 75—85° (45—50 mm.), and dissolves freely in water and the ordinary organic solvents. It has a peculiar odour, recalling that of the fatty aldehydes, and also that of ethyl acetoacetate. When exposed to the air, the crystals turn reddish-brown, and slowly deliquesce. In alcoholic solutions, ferric chloride produces an intense dark-violet coloration. When heated in small quantities, it distils without decomposition at 164—166°, under the ordinary pressure.

The *ammonium*-derivative, $C_6H_9O_2{\cdot}NH_4$, separates in colourless, very deliquescent crystals when ammonia is passed into an ethereal solution of the ketoaldehyde. The *copper* compound, $(C_6H_9O_2)_2Cu$, separates as a green precipitate when copper acetate is added to an alcoholic solution of the ketoaldehyde; it dissolves freely in alcohol and warm benzene, but on adding light petroleum to the benzene solution, it is reprecipitated in greyish-green needles melting at 167—168°. A compound, of the composition $C_{12}H_{14}N_2$, most probably methylethylphenylpyrazole, is formed when the ketoaldehyde is treated with phenylhydrazine; it is a colourless liquid with an odour of quinoline, boils at 282—284°, and has a sp. gr. = 1·0476 at 15°. This compound is isomeric with the propylphenylpyrazole prepared from methyl propyl ketone, ethyl formate, and phenylhydrazine (Abstr., 1885, 671).

Formylethyl phenyl ketone (*benzoylpropaldehyde*), COPh·CHMe·COH, is prepared from phenyl ethyl ketone, as described in the case of the preceding compound, but as the sodium-derivative of the ketoaldehyde cannot easily be separated by filtration, the whole of the product of the reaction is treated with ice-cold water; the supernatant ethereal solution then separated, the residual alkaline solution acidified with hydrochloric acid, and the precipitate recrystallised from dilute alcohol. The ethereal solution contains about 50 per cent. of the phenyl ethyl ketone employed; if this unchanged ketone is treated again with ethyl formate and sodium ethoxide, 51 grams of the ketoaldehyde can be obtained from 54 grams of the ketone. Formylethyl phenyl ketone crystallises from alcohol in slender, colourless needles, melts at 118—119°, and is readily soluble in alcohol, benzene, methyl alcohol, and ethyl acetate, and moderately easily in ether, carbon bisulphide, and hot water, but only very sparingly in light petroleum. In alcoholic solutions, ferric chloride produces a dark-violet coloration, and copper acetate an olive-green, crystalline precipitate. It dissolves freely, and without change, both in alkalis and in alkaline carbonates. The *anilide*, COPh·CHMe·CH:NPh, prepared by heating the ketoaldehyde with aniline at 150°, crystallises in colourless needles, melts at 132°, and dissolves freely in ether, but is reprecipitated on adding light petroleum.

Formylpropyl phenyl ketone (*benzoylbutaldehyde*), COPh·CHEt·COH, crystallises from hot dilute alcohol in colourless plates, melts at 86—87°, and shows the same behaviour with ferric chloride, copper acetate, alkalis, and alkaline carbonates as the preceding compound.

The *anilide*, $C_{17}H_{17}ON$, crystallises in colourless needles, melts at 120°, and gradually decomposes on keeping.

Formyldeoxybenzoin (*benzoylphenylacetaldehyde*), COPh·CHPh·COH, forms yellow crystals, melts at 110°, and is readily soluble in alkalis and moderately easily in alkaline carbonates. It gives a dark-violet coloration with ferric chloride, and a light-green copper-derivative with copper acetate.

Phenyl isopropyl ketone does not react with ethyl formate and sodium ethoxide; the behaviour of a ketone under these conditions may serve as a means of ascertaining its constitution by determining whether the carbonyl-group is in direct combination with a primary radicle on the one hand, or with a secondary or tertiary radicle on the other.

Experiments lately carried out seem to show that camphoraldehyde (Abstr., 1889, 619) has probably the constitution  $C_8H_{14}<\begin{matrix}C\!:\!CH\cdot OH\\ |\\ CO\end{matrix}$, and is not a true aldehyde; if this is really the case, the ketoaldehyde described above have probably an analogous constitution,

R·CO·CR:CH·OH. F. S. K.

Symmetrical Tetrabromodiacetyl. By H. F. KELLER (*Ber.*, 23, 35—37).—When diacetyl is treated with bromine in carbon bisulphide solution, the reaction does not, as previously stated (Abstr., 1889, 491), stop with the formation of a dibromo-derivative, but proceeds further, although somewhat slowly, the final product being *tetrabromodiacetyl*, $CHBr_2\cdot CO\cdot CO\cdot CHBr_2$. This crystallises from carbon bisulphide in large, transparent, yellow tablets, which melt at 95—96°. It strongly resembles in all its properties the tetrachlorodiacetyl obtained by Levy and Jedlicka (Abstr., 1888, 414; see also this vol., p. 232) by the action of hydrochloric acid and potassium chlorate on chloranilic acid. Like this compound, it dissolves in ether, chloroform, and benzene, forming a yellow solution, but gives a colourless solution in hot water, and is readily attacked by aqueous soda. It also unites with phenylhydrazine in alcoholic solution, forming a compound, $C_{16}H_{11}Br_2N_4O$, which crystallises from benzene in cinnabar-red, granular crystals. These become brown at 185°, and melt with decomposition at 190°.

The striking analogy between the tetrabromo-derivative and Levy and Jedlicka's compound, removes the last doubts as to the correctness of the constitution assigned to the latter substance. H. G. C.

Decomposition of Acetic Anhydride by Water. By N. MENSHUTKIN and M. VASILIEFF (*J. Russ. Chem. Soc.*, 21, 188—198).—The aim of the present investigation was to collect experimental material in reference to the hydration of organic anhydrides. The first member of the compounds in question is acetic anhydride, and the authors attempted to find the constant of velocity of its hydration. Although a great many experimental data are given in the form of tables, they are not suited for abstraction, and the result of the investigation is that the authors did not succeed in solving the problem in question, the difficulty being that the two substances do not mix in all proportions, and no solvent could be found which did not act either on the substances themselves or on the products of the reaction. In order to give a rough idea of some of the reactions of hydration, a table is given of the decomposition of acetic anhydride, acetamide, and ethyl acetate by 1 mol. of water at 100° under the same conditions. The experiments were made in the presence of acetic acid, however, for the reason stated above.

Substance.	Acetic anhydride $+ 1H_2O$.	Acetamide $+ 1H_2O$.	Ethyl acetate $+ 1H_2O$.
Acetic acid added..	11·86 p. c.	15·85 p. c.	11·45 p. c.
	Decomposition in percents.		
Time.			
1 min.	25·68	4·51	0·2
11 "	83·9	4·64	0·5
61 "	98·5	4·94	0·87
121 "	99·5	5·82	0·99
181 "	99·7	6·41	—

It is seen from an inspection of this table that acetic anhydride is almost completely decomposed after one hour; whereas the decomposition of acetamide is very small, and that of ethyl acetate has scarcely begun.

B. B.

γ-Amidobutyric Acid. By S. Gabriel (*Ber.*, **22**, 3335—3339).—Attempts to obtain the compound $C_8H_4O_2{:}N\cdot CH_2\cdot CH_2\cdot CH_2\cdot CN$ by the action of potassium or mercuric cyanide on bromopropylphthalimide proved fruitless. *γ-Bromobutyronitrile*, $CH_2Br\cdot CH_2\cdot CH_2\cdot CN$, was obtained by mixing 200 grams of trimethylene bromide with 60 grams of potassium cyanide in aqueous solution and enough alcohol to cause mixture of the layers, and then allowing the whole to remain for 14—16 hours at 40°. It is a heavy oil boiling at 205°. When this substance is heated at 150° with potassium phthalimide in molecular proportion, it yields the sought-for *γ-cyanopropylphthalimide*,

$$C_8H_4O_2{:}N\cdot C_3H_6\cdot CN.$$

This is also produced when γ-chlorobutyronitrile is substituted for the bromine-compound. It forms transparent, colourless, rhombic crystals melting at 80·5—81·5°. It is soluble in the usual solvents when hot. When digested for three hours with 27 per cent. hydrochloric acid, it is resolved into phthalic acid and *γ-amidobutyric acid*, $NH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot COOH$. The latter crystallises in snow-white scales soluble in alcohol and water, melts at 183—184°, and begins to lose water at the same temperature; if the heating is continued for some time at 200°, *pyrrolidone*,  $NH<\begin{matrix}CH_2\cdot CH_2\\ CO\cdot CH_2\end{matrix}$, is formed. This forms a colourless, fibrous, crystalline mass melting at 25—28°, and having an odour resembling that of acetamide. It is very soluble in water, the solution reacting neutral and yielding a crystalline *platinochloride* and *aurochloride*. When exposed to moist air, the crystals first deliquesce, and the liquid afterwards again solidifies to rhombic or hexagonal plates of the *hydrate* $C_4H_7NO + H_2O$, which melts at 35° and is isomeric, not identical with the acid.

γ-Amidobutyric acid is probably identical with Schotten's piperidinic acid (Abstr., 1883, 813). L. T. T.

Thio-derivatives of the Crotonic Acids. By W. Autenrieth (*Annalen*, **254**, 222—252).—*β-Thiophenylcrotonic acid*,  $\begin{array}{l}\mathrm{SPh{\cdot}C{\cdot}Me}\\ \quad\ \|\\ \mathrm{H{\cdot}C{\cdot}COOH}\end{array}$, is obtained when the sodium salt of chlorocrotonic acid (m. p. 94·5°) is treated with sodophenylmercaptide, as described by Escales and Baumann (Abstr., 1886, 878) in the preparation of β-thiophenylisocrotonic acid. The yield is almost quantitative. It melts at 157—158° yielding carbonic anhydride and β-thiophenylpropylene (b. p. 207—208°), identical with the compound obtained by Escales and Baumann. It is readily soluble in hot alcohol, ether, chloroform, and light petroleum, and in other respects behaves like the isomeride referred to above. The salts of the alkalis and alkaline earths are readily soluble in water. The *barium* salt, $(C_{10}H_9SO_2)_2Ba + H_2O$, crystallises in colourless plates or needles. The *silver*, *mercury*, and *lead* salts are amorphous.

β-Thioethylisocrotonic acid,  $\begin{array}{l}\mathrm{Me{\cdot}C{\cdot}SEt}\\ \quad\ \|\\ \mathrm{H{\cdot}C{\cdot}COOH}\end{array}$, prepared by treating β-chlorisocrotonic acid with sodioethylmercaptide, separates from alcohol in well-defined crystals, melts at 91—92° with evolution of carbonic anhydride, and is readily soluble in chloroform, ether, benzene, and light petroleum, but almost insoluble in boiling water. It gives a dark-green coloration when warmed with isatin and sulphuric acid, and behaves in other respects like the corresponding phenyl-compounds. The salts of the alkalis and alkaline earths are very readily soluble in water. The *silver* salt is readily soluble in water, but it is decomposed when the solution is boiled. The *barium* salt $(C_6H_9SO_2)_2Ba + H_2O$, crystallises from water in thin plates.

β-Thioethylcrotonic acid,  $\begin{array}{l}\mathrm{SEt{\cdot}C{\cdot}Me}\\ \quad\ \|\\ \mathrm{H{\cdot}C{\cdot}COOH}\end{array}$, prepared from chlorocrotonic acid (m. p. 94·5°) in like manner, separates from water in well-defined crystals, melts at 112—113° with evolution of carbonic anhydride, and resembles the preceding compound in its behaviour and properties. The *barium* salt crystallises with 2 mols. H_2O; the other salts resemble generally those of the isomeric acid, except that the *silver* salt is not decomposed by boiling water.

β-Thioethylpropylene, $SEt{\cdot}CMe{:}CH_2$, prepared by heating either of the thioethylcrotonic acids above its melting point, is a colourless, disagreeably smelling oil boiling at 109—110°; it gives a green coloration when warmed with isatin and sulphuric acid.

β-Phenoxycrotonic acid,  $\begin{array}{l}\mathrm{Me{\cdot}C{\cdot}OPh}\\ \quad\ \|\\ \mathrm{H{\cdot}C{\cdot}COOH}\end{array}$, is obtained by heating sodium β-chlorisocrotonate with sodium phenoxide at about 130°, or by heating sodium β-chlorocrotonate with sodium phenoxide at about 180°. It separates from light petroleum in well-defined crystals, melts at 149—150° with decomposition, and is readily soluble in ether, alcohol, and chloroform, but only sparingly in boiling water. It is readily decomposed with liberation of phenol, so that it gives the characteristic reactions of phenols.

β-Phenoxypropylene, $\mathrm{OPh{\cdot}CMe{:}CH_2}$, prepared by heating the preceding compound above its melting point, is a colourless, pleasant smelling oil boiling at 160—162°. It is not decomposed when boiled with water or when distilled with concentrated potash. It gives a red coloration when boiled with Millon's reagent, and a yellow brominated derivative when treated with bromine.

α-Thiophenylcrotonic acid,  $\begin{array}{c}\mathrm{H{\cdot}C{\cdot}Me}\\ \|\\ \mathrm{SPh{\cdot}C{\cdot}COOH}\end{array}$, can be easily prepared from the sodium salt of α-chlorocrotonic acid (m. p. 97°), as described in the case of the corresponding β-compound. It separates from water in long needles, and from alcohol in well-defined crystals, melts at 86°, and decomposes at 145—150° with evolution of carbonic anhydride. It is readily soluble in ether, chloroform, and alcohol, but only sparingly in cold light petroleum, and is almost insoluble in cold water. It is much more stable than the corresponding β-acid, and when heated with concentrated hydrochloric acid or with potash, it yields only a trace of mercaptan. When warmed with concentrated sulphuric acid, it gives a cherry-red coloration. The salts of the alkalis are soluble in water and alcohol. The *potassium* salt forms colourless, deliquescent crystals. The salts of the alkaline earths are readily soluble in water and do not crystallise readily. The *mercury*, *copper*, and *silver* salts are soluble in boiling water.

α-Thiophenylisocrotonic acid,  $\begin{array}{c}\mathrm{Me{\cdot}C{\cdot}H}\\ \|\\ \mathrm{SPh{\cdot}C{\cdot}COOH}\end{array}$, prepared from α-chlorisocrotonic acid (Wislicenus, Abstr., 1887, 665), crystallises from water in nacreous plates, melts at 80°, and decomposes at 160—165° with evolution of carbonic anhydride. It is very readily soluble in alcohol, ether, and chloroform, but almost insoluble in cold water. The salts resemble those of the isomeric acid.

α-Thiophenylpropylene is formed when either of the α-thiophenylcrotonic acids is distilled; it is a colourless oil insoluble in water. The compound obtained from the iso-acid boils at 220—228°, that obtained from α-thiophenylcrotonic acid at 217—223°, but otherwise no marked difference between the two substances was observed.

The two thioethylcrotonic acids, prepared by treating the two α-chlorocrotonic acids with sodioethylmercaptide in alcoholic solution, are oily liquids which show no difference in behaviour or in properties.

F. S. K.

Linoleïc Acid. By A. Reformatsky (*J. Russ. Chem. Soc.*, **21**, 202—226).—Linoleïc acid was subjected to a most careful purification, and then to elementary analysis, in order to find its true formula; but no satisfactory results could be obtained owing to the rapid oxidation of the acid by atmospheric oxygen. The acid cannot be distilled under reduced pressure without undergoing a thorough change. Subsequent researches, especially the analysis of its derivatives, have shown, however, that its formula is not $C_{16}H_{28}O_2$, as hitherto assumed, but that it consists principally of the compound $C_{18}H_{32}O_2$; for the ethyl salt is $C_{17}H_{31}O·OEt$, and from this the pure acid can be obtained by saponification and subsequent decomposition of the alkali salt with dilute sulphuric acid.

The additive-product with iodine has the formula $C_{18}H_{32}O_2I_4$, but it could not be isolated; that with bromine is $C_{18}H_{32}O_2Br_4$; the hexabromide, $C_{18}H_{30}O_2Br_6$, therefore, is partly a product of substitution. Oxidation with alkaline permanganate yielded *tetrahydroxystearic acid*, $C_{18}H_{32}O_2(OH)_4$, the four hydroxyl-groups being added on at the two double unions. In addition to this, azelaïc and formic acids were also formed. The dihydroxystearic acid obtained at the same time is probably due to the presence of some oleïc acid. Hazura's "linolenic" and "isolinolenic" acids could not be found among the products of oxidation. It remains an open question, therefore, whether linoleïc acid is really a heterogeneous substance, as Hazura states it to be. B. B.

Monosubstituted Succinic Acids. By R. Anschütz and C. Bennert (*Annalen*, **254**, 155—168; compare Abstr., 1885, 1049).—Chlorosuccinic acid yields fumaric acid when it is boiled with water. Methyl chlorosuccinate boils at 220·8° (772·5 mm.) without decomposition; methyl bromosuccinate is decomposed into methyl fumarate and hydrogen bromide when it is distilled under the ordinary pressure.

Monochloro- and monobromo-succinic anhydrides are decomposed when distilled under the ordinary pressure, yielding maleïc anhydride and the halogen acid. Dimethyl levomalate is easily decomposed by water; when distilled under the ordinary pressure, it gives methyl fumarate and water.

Acetylmalic acid, prepared by treating acetylmalic anhydride with the theoretical quantity of water, is a colourless, crystalline compound, melts at 132°, and is decomposed by warm water. The methyl salt yields acetic acid and methyl fumarate when it is distilled under the ordinary pressure. F. S. K.

Isomerism of Maleïc and Fumaric Acid. By R. Anschütz (*Annalen*, **254**, 168—182; compare Abstr., 1887, 916, and 1888, 448).—The author does not agree with Wislicenus in the view that maleïc acid and fumaric acid are stereochemically isomeric, and he points out that Wislicenus' explanation of the conversion of maleïc into fumaric acid by hydrochloric acid is not in accordance with experiment, since the change is brought about by concentrated hydrochloric acid at a temperature (about 10°) at which chlorosuccinic acid is not changed by hydrochloric acid. The fact that chlorosuccinic anhydride does not yield fumaric acid when treated with water is also evidence against Wislicenus' assumption that chlorosuccinic acid is an intermediate product in the conversion of maleïc into fumaric acid. F. S. K.

Ethyl Methylenemalonate and its Polymeride. By N. Zelinsky (*Ber.*, 22, 3294—3302).—A polymeride of ethyl methylenemalonate, $CH_2:C(COOEt)_2$, is obtained when ethyl malonate (16 grams) is treated with methylene iodide (26·8 grams) and sodium ethoxide (= 4·6 grams of sodium) in alcoholic solution. After boiling for about 10 hours, water is added, the precipitated oil extracted with ether, and the unchanged methylene iodide and ethyl malonate removed by distilling with steam. The residual oil has the composition $C_8H_{12}O_4$; when it is submitted to fractional distillation under reduced pressure (120—130 mm.), it can be separated into a solid, amorphous substance and a thick, oily liquid of higher boiling point, both of which have, however, the same percentage composition.

The solid compound is a colourless, odourless, paraffin-like substance, which melts at 155—156°, and boils at about 225—235° (120—130 mm.). It is rather sparingly soluble in ether, benzene, and alcohol, and almost insoluble in water. A molecular weight determination by Raoult's method in glacial acetic acid solution showed that it has the molecular formula $C_{16}H_{24}O_8$. When it is heated, it gives off heavy vapours, which have a most irritating odour, and on further heating it distils at about 290—300° under the ordinary pressure, seemingly without decomposition, yielding a heavy, oily distillate with an irritating odour; this distillate gradually solidifies when kept over sulphuric acid, but it retains its sharp smell.

If the product of the action of methylene iodide on ethyl sodiomalonate is distilled under the ordinary pressure, a considerable quantity passes over between 120° and 210°. This fraction is a mobile oil with an irritating odour; it can be kept under water for a long time without undergoing polymerisation, and when treated with bromine it is converted into a compound of the composition $C_8H_{12}Br_2O_4$. This additive-product is a yellow, sharp-smelling oil, and boils at 185—190° (75—85 mm.) with slight decomposition. When kept for some time, it deposits a crystalline compound which has not yet been investigated.

When the solid polymeride (m. p. 155—156°) referred to above is hydrolysed with potash, it is converted into an acid, the calcium salt of which is much more readily soluble in cold than in hot water. This salt seems to have the composition $C_4H_4O_5Ca$. When an aqueous solution of the acid is kept over sulphuric acid, a thick, gummy mass is obtained, and finally a small quantity of a crystalline compound is deposited.
F. S. K.

Circular Polarisation of certain Tartrate Solutions. By J. H. Long. See this vol, p. 313.

Conversion of Ethyl Acetoneoxalate into Symmetrical Hydroxytoluic Acid. By L. Claisen (*Ber.*, 22, 3271—3273).—The acid (m. p. 90°) previously described (Claisen and Stylos, Abstr., 1887, 917), which is obtained from ethyl sodacetoneoxalate (ethyl sodacetylpyruvate), has the molecular formula $C_{12}H_{16}O_8$. An analogous compound of the composition $C_{11}H_{14}O_8$ can be obtained in like manner from methyl sodacetoneoxalate. Both these substances act like monobasic acids, and form normal salts with alkalis and with barium. The aqueous solutions of these salts are colourless, but become golden-yellow on adding an alkali or baryta, owing to the formation of a basic salt. When a solution of the acid in excess of baryta is warmed, barium oxalate is precipitated in considerable quantity, and the solution contains the salt of hydroxytoluic acid [Me : OH : COOH = 1 : 3 : 5].

The compound $C_{12}H_{16}O_8$ is an ethyl hydrogen salt formed from ethyl acetoneoxalate according to the equation $2COMe\cdot CH_2\cdot CO\cdot COOEt + H_2O = COMe\cdot CH_2\cdot C(OH)(COOH)\cdot CHAc\cdot CO\cdot COOEt + C_2H_5\cdot OH$. When warmed with excess of baryta, it is probably decomposed into oxalic acid and diacetoneoxalic acid, $(COMe\cdot CH_2)_2{:}C(OH)\cdot COOH$, and the latter is then converted into hydroxytoluic acid according to the equation $(COMe\cdot CH_2)_2{:}C(OH)\cdot COOH = C_8H_8O_3 + 2H_2O$.

F. S. K.

Acetyltrichlorophenomalic Acid. By R. ANSCHÜTZ (*Annalen*, **254**, 152—154; compare Abstr., 1887, 916).—*Acetyltrichlorophenomalic acid*,  $\mathrm{CH}{<}\begin{array}{l}\mathrm{CH\cdot C(OAc)\cdot CCl_3}\\ \mathrm{CO\cdot O}\end{array}$, is readily obtained by heating trichlorophenomalic acid for half an hour at 100° with excess of acetic anhydride. It crystallises from dilute alcohol in colourless prisms, melts at 86°, and is very readily soluble in glacial acetic acid, ether, benzene, and chloroform, and readily in alcohol. It is not changed by boiling water, but it is decomposed by boiling baryta-water, with formation of chloroform, acetic acid, and maleïc acid. The formation and behaviour of this compound are in accordance with the author's views that trichlorophenomalic acid has the constitution  $\mathrm{CH}{<}\begin{array}{l}\mathrm{CH\cdot C(OH)\cdot CCl_3}\\ \mathrm{CO\cdot O}\end{array}$.

F. S. K.

Formation of Hydantoïn. By R. ANSCHÜTZ (*Annalen*, **254**, 258—261).—Hydantoïn is formed when sodium dihydroxytartrate (10 grams) is rubbed to a paste with carbamide (5 grams) and 25 per cent. hydrochloric acid (12 c.c.), and the mixture warmed to 50—60°. The crude substance which separates from the filtered solution can be easily obtained in a pure condition by recrystallisation; it melts at 215—216°.

F. S. K

Chlorobenzenes obtained from Anisoïl. By L. HUGOUNENQ (*Bull. Soc. Chim.* [3], 2, 603—605).—Chlorine (1200 grams) is passed into anisoil (108 grams) containing iodine (2·5 grams), the flask being heated from 60° to 230° as chlorination progresses. The product, after cooling, washing, and crystallisation from a hot mixture of equal parts of benzene and alcohol, yields hexachlorobenzene, pentachlorobenzene, and 1 : 2 : 4 : 5-tetrachlorobenzene. From the mother liquor, an oil boiling at 247—250° separates, which appears to be a mixture of tetrachlorobenzene and trichlorobenzene. The gas evolved in the reaction is carbon oxychloride.

T. G. N.

Derivatives of Bromothymol. By G. MAZZARA (*Gazzetta*, **18**, 514.—*Benzoylbromothymol*,

$C_6H_2BrMePr\cdot OBz$ [Me : OBz : Pr : Br = 1 : 3 : 4 : 6].

To prepare this compound, thymol is mixed with an equal amount of benzoic chloride, and heated first on the water-bath, and then on the oil-bath at 160—180° in a reflux apparatus under an additional pressure of $\frac{1}{3}$ atmosphere, until hydrogen chloride ceases to côme off. The product is cooled in a stream of carbonic anhydride, dissolved in carbon bisulphide which has been freshly dehydrated with phosphoric anhydride, and bromine added in molecular proportion to the thymol originally taken. The whole is then allowed to remain for 24 hours in order that the carbon bisulphide may evaporate spontaneously.

On recrystallising the residue from alcohol, after washing it with water and pressing, the benzoylbromothymol is obtained in white, lustrous needles which melt at 65—66°. From light petroleum it separates in large, colourless crystals which melt at 66—68°.

Acetylbromothymol,

$C_6H_2BrMePr\cdot OAc$ [Me : OAc : Pr : Br = 1 : 3 : 4 : 6],

is prepared from acetic chloride and bromothymol. When freshly prepared, it is a transparent, colourless liquid, which acquires a reddish tinge on exposure to light. It becomes syrupy at low temperatures, and is decomposed by potash.

Methylbromothymol,

$C_6H_2BrMePr\cdot OMe$ [Me : OMe : Pr : Br = 1 : 3 : 4 : 6],

is obtained on heating a mixture of the proper quantities of methyl iodide and of a solution of bromothymol in methyl alcohol, heating the product with slightly alkaline water, and distilling in a current of steam. It is a dense, colourless liquid, with a faint, unpleasant odour.

Dibromocymene is prepared by heating bromothymol (100 parts) with phosphoric bromide (46 parts) on a sand-bath until no more hydrogen bromide comes off, and distilling the product in a current of steam. It is a heavy, colourless oil, boiling at 272°. When heated in a sealed tube with nitric acid of sp. gr. 1·12 for 36 hours at 180°, it is converted into dibromoterephthalic acid, which melts at 316—317° to a brown liquid. The ethyl salt of this acid melts at 123—125°. These reactions indicate that the product obtained is paradibromocymene. Consequently the constitution of bromothymol must be

[Me : OH : Pr : Br = 1 : 3 : 4 : 6].

Nitrobromothymol,

$C_6HBrMePr(NO_2)\cdot OH$ [Me : OH : Pr : Br = 1 : 3 : 4 : 6]

(compare Abstr., 1886, 1016), prepared by the action of fuming nitric acid (sp. gr. 1·46) on a solution of bromothymol in glacial acetic acid, forms thick, yellow prisms which melt at 106—107°. It separates from its solution in hot light petroleum in slender, prismatic needles which melt at 107—108°. The mother liquor from the nitrobromothymol, on further evaporation, gave a reddish-brown oil, supposed to be an isomeride, and now under investigation.

S. B. A. A.

Isomerism of Halogenthymoquinones. By F. Kehrmann (*Ber.*, **22**, 3263—3270; compare Abstr, 1889, 1184).—Mazzara (*Gazzetta*, **19**, 337) has stated that the bromothymoquinone obtained from bromonitrothymol is identical with the compound obtained from bromonitrocarvacrol, and also that dinitrothymol and dinitrocarvacrol yield one and the same hydroxythymoquinone; the author's experiments, however, seem to show that Mazzara's conclusions are erroneous.

Bromothymoquinone [O_2 : Me : Br : Pr = 1 : 4 : 2 : 3 : 5] is formed by oxidising dibromothymol [OH : Pr : Br_2 : Me = 1 : 2 : 4 : 6 : 5] with chromic acid, by oxidising bromamidothymol [OH : Pr : NH_2 : Me : Br = 1 : 2 : 4 : 5 : 6] with ferric chloride and by oxidising bromothymolparasulphonic acid [OH : Pr : SO_3H : Me : Br = 1 : 2 : 4 : 5 : 6] with chromic acid. It can be easily prepared in large quantities by dissolving thymol (1 mol.) in glacial acetic acid and gradually adding a glacial acetic acid solution of bromine (2 mols.) to the well-cooled solution. Water is added, the precipitated oil separated, dissolved in a little glacial acetic acid, and treated with a glacial acetic acid solution of chromic acid in the cold until no further development of heat occurs. The product is then precipitated with water, distilled with steam, and crystallised from cold ether. It forms long, hexagonal, orange prisms melting at 47—48°. This compound is identical with the bromoquinone obtained by Mazzara and Discalzo (Abstr., 1886, 1019) by oxidising orthobromoparamidothymol with nitrous acid and also with the β-bromothymoquinone prepared by Schniter (Abstr., 1887, 720) by treating thymoquinone with hydrobromic acid and oxidising the product with ferric chloride. The *oxime*, $C_{10}H_{12}BrNO_2$ [NOH : Me = 1 : 2], crystallises in long, lemon-yellow needles, melts at 148—152°, and is readily soluble in alcohol, glacial acetic acid, benzene, and ether, but only sparingly in hot, and insoluble in cold water. When warmed for a short time with nitric acid of sp. gr. 1 42 it is converted into dinitrothymol melting at 54—55°. The *sodium*-derivative crystallises in small, violet-brown needles, and is readily soluble in water, but only sparingly in concentrated alkalis. The *potassium*-derivative crystallises in greenish-brown needles, the ammonium-derivative in small, reddish-brown prisms. The *acetyl*-derivative, $C_{12}H_{14}BrNO_3$, separates from dilute alcohol in yellow crystals, melts at 83°, and is readily soluble in all organic solvents. When the oxime is treated with stannous chloride and alcoholic solution of hydrogen chloride, it is converted into a bromamidothymol identical with the compound prepared by Mazzara and Discalzo (*loc. cit.*) by reducing orthobromoparanitrothymol, and also with the substance obtained by Andresen (Abstr., 1881, 590) by treating thymoquinonechlorimide with hydrobromic acid.

Bromothymoquinone [O_2 : Me : Pr : Br = 1 : 4 : 2 : 5 : 6] can be obtained by oxidising bromocarvacrolparasulphonic acid

[OH : Me : SO_3H : Pr : Br = 1 : 2 : 4 : 5 : 6] or bromamidocarvacrol [OH : Me : NH_2 : Pr : Br = 1 : 2 : 4 : 5 : 6] with chromic acid. It crystallises from alcohol in large, orange plates, melts at 54—55°, sublimes readily, and is volatile with steam. It is readily soluble in alcohol, ether, benzene, and glacial acetic acid. The *oxime* [Me : NOH = 2 : 4], prepared by boiling an alcoholic solution of the quinone for four to five days with a large excess of hydroxylamine hydrochloride, crystallises from alcohol in large, lemon-yellow rhombohedra, melts at 148° with decomposition, and is readily soluble in alcohol, ether, &c. It is most probably identical with the bromonitrosocarvacrol prepared by Mazzara (*loc. cit.*) by brominating nitrosocarvacrol. F. S. K.

Action of Aniline on Citraconic Acid and on Itaconic Acid.

By R. Anschütz, F. Reuter and O. Scharfenberg (*Annalen*, **254**, 129—152; compare Abstr., 1888, 594).—Aniline citraconate separates as a jelly when citraconic acid is treated with aniline in dry ethereal solution. It separates from boiling water in crystals and melts at 90°, being converted into mesaconanilic acid (m. p. 153°).

When finely-divided citraconanil (compare Gottlieb, *Annalen*, **77**, 77) is dissolved in warm baryta, it is converted into mesaconanilic acid.

Mesaconanilic acid dissolves unchanged in cold alkaline carbonates, but when heated above its melting point, or when its aqueous solution is boiled, it is converted into citraconanil. Mesaconanilic acid is the principal product of the action of aniline (1 mol.) on citraconic acid (1 mol.) in cold aqueous solution, but small quantities of citraconanil are also formed.

Mesaconanilic acid is most conveniently prepared by treating citraconic anhydride with aniline in well-cooled ethereal or chloroform solution; it is decomposed by boiling hydrochloric acid and by boiling alkalis, yielding mesaconic acid.

The above experiments show that the anilic acid obtained from citraconanil by boiling it with baryta is identical with that prepared from citraconic anhydride and aniline, and also with that obtained from aniline citraconate.

Gottlieb's and Michael and Palmer's (Abstr., 1888, 461) citraconanilic acid (m. p. 175°) is named by the authors mesaconanilic acid because it yields mesaconic acid when treated with potash under conditions which do not change citraconic acid into mesaconic acid.

Itaconanilic acid, $C_{11}H_{11}NO_3$, can be obtained in a pure condition by treating itaconic acid with aniline in well-cooled ethereal solution. It melts at 151·5°, and is readily soluble in alcohol and hot water; it dissolves unchanged in cold sodium carbonate, but when boiled with potash, water, or hydrochloric acid, it is converted into itaconic acid.

The compound prepared by Gottlieb and also by Michael and Palmer (*loc. cit.*), and termed by them itaconanilic acid, does not behave like an anilic acid, and is, therefore, named *pseudoitaconanilic* acid by the authors. It can he obtained in the following manner:—Ethyl itabromopyrotartrate is heated at 100° with aniline (2 mols.) for four to five hours, the alcoholic solution separated from the crystals of aniline hydrobromide, and washed with water; the residual brown oil is dissolved in ether, the solution dried, and the ether evaporated at a low temperature. The crude product (ethyl itanilidopyrotartrate) is boiled with alcoholic potash and the solution acidified; on evaporating, crystals of pseudoitaconanilic acid (m. p. 190°) separate from the solution. This synthesis of pseudoitaconanilic acid seems to show that it is an anilidoparaconic acid,

$$\begin{array}{l}\text{NPh}\cdot\text{CH}_2\\ |\\ \text{CO}-\text{CH}_2\end{array}\!>\text{CH}\cdot\text{COOH},$$

as does also its behaviour with phosphoric chloride.

Pseudoitaconanilic chloride,  $\begin{array}{l}\text{NPh}\cdot\text{CH}_2\\ |\\ \text{CO}-\text{CH}_2\end{array}\!>\text{CH}\cdot\text{COCl}$, is obtained when the acid is suspended in chloroform and treated with phosphoric chloride at 50°; it is a yellow, crystalline substance, and is very readily reconverted into the acid by water.

Pseudoitaconanilic acid anilide,  $\begin{array}{l}\text{NPh}\cdot\text{CH}_2\\ |\\ \text{CO}-\text{CH}_2\end{array}\!>\text{CH}\cdot\text{CONPh}$, is easily obtained by treating the preceding compound with aniline in chloroform solution; it is identical with Gottlieb's itaconic acid anilide, and, when heated with concentrated hydrochloric acid, it is reconverted into pseudoitaconanilic acid.

Pseudoitaconanilic acid is decomposed by boiling baryta-water, yielding the barium salt of β-anilidopyrotartrate, but it is not acted on by potash at 100° or by boiling hydrochloric acid; when barium β-anilidopyrotartrate is treated with hydrochloric acid, it yields pseudoitaconanilic acid.

Pseudoitaconparatolilic acid,  $\begin{array}{l}\text{C}_6\text{H}_4\text{Me}\cdot\text{N}-\text{CH}_2\\ \qquad\quad |\\ \qquad\ \text{CO}\cdot\text{CH}_2\end{array}\!>\text{CH}\cdot\text{COOH}$, prepared by heating itaconic acid with paratoluidine in aqueous solution, crystallises from boiling water in slender, colourless needles, and melts at 184—185°. It is readily soluble in hot alcohol and chloroform, but only sparingly in cold alcohol, and insoluble in ether.

Pseudoitaconphenylhydrazilic acid,  $\begin{array}{l}\text{NHPh}\cdot\text{N}-\text{CH}_2\\ \qquad\ |\\ \qquad\text{CO}\cdot\text{CH}_2\end{array}\!>\text{CH}\cdot\text{COOH}$, prepared in like manner, crystallises from hot water or alcohol in small, yellow prisms, melts at 193—194°, and is only sparingly soluble in ether and chloroform.

Pseudoitacon-α-naphthilic acid,  $\begin{array}{l}\text{C}_{10}\text{H}_7\cdot\text{N}-\text{CH}\\ \qquad\ |\\ \qquad\text{CO}\cdot\text{CH}_2\end{array}\!>\text{CH}\cdot\text{COOH}$, separates from hot water as a colourless, crystalline powder, melts at 205—206°, and is only very sparingly soluble in ether and chloroform.

F. S. K.

Dihydroxydiphenylamine and a Brownish-red Colouring Matter. By SEYEWITZ (*Compt. rend.*, 109, 946—949).—*Dihydroxydiphenylamine*, $\text{NH(C}_6\text{H}_4\cdot\text{OH)}_2$, obtained by heating resorcinol in sealed tubes at 190—200° for 10 hours with four times its weight of ammoniacal calcium chloride, may be purified by repeated solution in alcohol and precipitation by water, and is finally crystallised from hot aqueous alcohol. It forms brownish-yellow, indistinct, microscopic crystals, only slightly soluble in cold or hot water, insoluble in benzene or ether, but very soluble in alcohol, yielding a solution with a fluorescence similar to that of fluorescein. It is somewhat soluble in hydrochloric acid, but yields no crystallisable hydrochloride, is soluble with a green colour in concentrated sulphuric acid, and is coloured violet by nitric acid. It dissolves readily in alkalis, and with barium hydroxide forms an unstable compound which crystallises from alcohol in very distinct yellow plates. With sodium nitrite in acid solution, it yields a violet-red nitroso-derivative, and it forms colouring matters with diazo-derivatives. If distilled with zinc-powder, it yields diphenylamine.

If resorcinol and ammoniacal calcium chloride in the same proportions are heated at 300° for about eight hours, a brownish-red colouring matter is formed, and is left undissolved when the product is treated with water. This colouring matter contains nitrogen, and has many of the properties of the amines. It dissolves in hydrochloric acid, and is precipitated by ammonia; it melts at 70—72°, is insoluble in water and alkalis, but dissolves readily in alcohol; it yields a diazo-derivative which forms colouring matters with phenols.

It gives fine brown colours on cotton mordanted with tannin and tartar emetic, or on linen mordanted with potassium dichromate.

C. H. B.

Benzoyl-derivatives. By O. HINSBERG and L. v. UDRÁNSZKY (*Annalen*, **254**, 252—258).—Monohydroxy- and amido-compounds can be easily converted into the corresponding benzoyl-derivative by Baumann's method (Abstr., 1887, 228); methylaniline yields a benzoyl-derivative less easily. The benzoyl-derivative of metanitraniline can be easily obtained, but not so those of ortho- and paranitraniline. Orthonitrophenol does not yield a benzoyl-derivative when it is treated by Baumann's method, but the para-compound does so fairly readily. The dihydroxybenzenes are easily converted into the dibenzoyl-derivatives.

Dibenzoylorthophenylenediamine, $C_{20}H_{16}N_2O_2$, crystallises in plates and melts above 280°. The corresponding *para*-compound crystallises in colourless plates, melts above 300°, and is only sparingly soluble in glacial acetic acid, alcohol, and ether, and almost insoluble in water; it yields a *nitro*-derivative, $NO_2{\cdot}C_6H_3(NHBz)_2$, which crystallises in small, yellow needles, melts at 251°, and is converted into nitroparaphenylenediamine (m. p. 137°) by sulphuric acid.

Dibenzoylorthotoluylenediamine melts at 263—264°, and not at 260—261° as stated by Hubner (*Annalen*, **208**, 314); when boiled for a short time with concentrated hydrochloric acid, it is converted into benzoyltoluylenediamine, but when boiled with concentrated sulphuric acid for some hours, it is converted into toluylenediamine.

Dibenzoyl-α-β-naphthylenediamine, $C_{10}H_6(NH{\cdot}COPh)_2$, crystallises in reddish plates, melts at 291°, and is only sparingly soluble in alcohol and glacial acetic acid, and almost insoluble in water.

Tribenzoyltriamidobenzene [1 : 3 : 4] crystallises from glacial acetic acid in small, colourless needles, melts at 260°, and is sparingly soluble in the ordinary solvents.

Dibenzoylorthamidophenol and the corresponding para-compound can be easily obtained by Baumann's method.

Tetrabenzoyltriamidophenol [$OBz : (NHBz)_3 = 1 : 2 : 4 : 6$] crystallises from hot glacial acetic acid in slender, colourless needles, melts at 256°, and is almost insoluble in alcohol and water. It is not acted on by strong mineral acids or by a mixture of potassium dichromate and sulphuric acid, but when heated with strong nitric acid, it yields a yellowish compound—probably a nitro-derivative.

F. S. K.

Formation of Amidines. By A. KUHLWEIN (*Chem. Centr.*, 1889, ii, 917).—When carbotriphenyltriamine is heated with carbon bisulphide at 150°, a yellow substance is formed which cannot be obtained in crystals; it is probably amidobenzothioanilide. Cyanogen forms a readily decomposable substance with carbotriphenyltriamine.

Amidotoluylenediorthotolylamidine, $C_{22}H_{23}N_3$, melting at 155°, and the isomeric para-compound, melting at 149·5—150°, are prepared from the respective toluidines by warming with carbon tetrachloride. The hydrochloride and nitrate of the former are sparingly soluble; the hydrochloride, nitrate, acetate, sulphate, and oxalate of the latter are readily soluble.

α- and β-naphthylamines also react with carbon tetrachloride; diphenylamine does not appear to do so. J. W. L.

Action of Aromatic Amines on Bromopropiolic Acid and on Substituted Acrylic Acids. By C. F. MABERY and A. H. KRAUSE (*Ber.*, **22**, 3305—3310).—Ethenyldiphenylamidine, $C_{14}H_{14}N_2$ (m.-p. 131—132°), is formed, together with a compound melting at 220°, when bromopropiolic acid is treated with aniline in alcoholic solution. The hydrochloride crystallises in needles and melts at 214—215°, the platinochloride in small, yellow prisms. When the base is heated with water at 150° for two hours, it is completely converted into a crystalline compound which melts at 111—112°, and is soluble in water (compare Hofmann. *Ber.*, 2, 649); at higher temperatures, acetic acid and a compound which is insoluble in acids and in water are formed. The compound melting at 220°, referred to above, is insoluble in hydrochloric acid and almost insoluble in water; it has the composition $C_{16}H_{14}N_4O_2$.

Ethenylditolylamidine, $C_{16}H_{19}N_2$, and a compound melting at 241—242° are obtained when paratoluidine is treated with bromopropiolic acid; the hydrochloride, $C_{16}H_{18}N_2,HCl$, melts at 198—200°. When the base is heated with water at 150°, it is completely converted into a colourless, crystalline compound melting at 145—146°; at higher temperatures it behaves like the corresponding phenyl-compound. The substance melting at 241—242° (see above) has the composition $C_{16}H_{17}N_2O_2$(?), and is insoluble in water and acids.

The compound $C_{17}H_{19}N_2O_2$, prepared by treating bromopropiolic acid with orthotoluidine, crystallises from alcohol in colourless needles, melts at 184—185°, and is insoluble in water and acids, and only sparingly soluble in alcohol.

Metatoluidine combines with bromopropiolic acid with evolution of carbonic anhydride, yielding a compound which crystallises in yellow needles.

α-Naphthylamine (2 mols.) combines with bromopropiolic acid (1 mol.) with evolution of hydrogen bromide, yielding a yellow, crystalline compound.

A compound of the composition $C_{15}H_{13}N_2Br$ separates in yellow crystals when αβ-dibromacrylic acid is treated with aniline in the cold. It crystallises from alcohol in yellow needles, melts at 145°, and is insoluble in water, and only sparingly soluble in acids.

The condensation-product obtained from paratoluidine in like manner crystallises in yellow needles, melts at 165—166°, and has the composition $C_{17}H_{18}N_2Br$; it is almost insoluble in water and acids, but soluble in soda. A compound of the composition $C_{17}H_{17}N_2BrO$, which melts at 164° and is insoluble in soda, is also formed in this reaction.

Orthotoluidine combines with αβ-dibromacrylic acid in alcoholic solution, yielding a base of the composition $C_{17}H_{18}N_2Br$; this crystallises from alcohol in pale-yellow needles melting at 115°. The *hydrobromide*, $C_{17}H_{18}N_2Br,HBr$, crystallises in yellow needles and melts at 208—209°.

ββ-Dibromacrylic acid also gives condensation-products with aromatic amines.

F. S. K.

Action of Potassium Phthalimide on Halogen-compounds containing Oxygen. By C. SCHMIDT (*Ber.*, 22, 3249—3257; compare Goedeckemeyer, Abstr., 1888, 1294).—*Metanitrophenacylphthalimide*, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}CH_2{\cdot}N{:}C_8H_4O_2$, is obtained when metanitrophenacyl bromide (1 mol.) is mixed with potassium phthalimide (1 mol.), and the mixture heated at about 100° for an hour. It separates from hot glacial acetic acid in small, pointed crystals, melts at 204°, and is only sparingly soluble in alcohol and cold, glacial acetic acid. It is not decomposed by hydrochloric acid or by boiling potash.

Phthalimidopropiophenone, $COPh{\cdot}C_2H_4{\cdot}N{:}C_8H_4O_2$, can be obtained by heating a mixture of bromopropiophenone and potassium phthalimide at 160—170° for a short time. It crystallises from alcohol in large prisms, melts at 85°, and is readily soluble in hot ether, but insoluble in water. The corresponding *acid*, $C_{17}H_{15}NO_4$, prepared by treating the imido-compound with alcoholic or aqueous potash, crystallises in slender needles melting at 140°. It dissolves in warm alcohol, being thereby partially reconverted into the imide; the same change takes place when the acid is heated at 100° for two days, but resinous products are also formed. The *silver* salt, $C_{17}H_{14}NO_4Ag$, which crystallises with 1 mol. H_2O, is soluble in water and alcohol, and is readily decomposed when heated, yielding a sublimate of phthalimide. In aqueous solutions of the ammonium salt, lead salts produce a colourless, ferric salts a brown, and copper sulphate a light-blue precipitate which is sparingly soluble in cold water.

Amidopropiophenone hydrochloride, $COPh{\cdot}C_2H_4{\cdot}NH_2,HCl$, is formed, together with resinous products, when propiophenonephthalamic acid is boiled for an hour with concentrated hydrochloric acid. The cold solution is filtered to separate the phthalic acid, evaporated to dryness, the residue taken up with alcohol, and the salt obtained in a crystalline condition by mixing the filtered solution with ether. The *platinochloride*, $(C_9H_{11}NO)_2,H_2PtCl_6$, forms orange-red crystals. The *picrate*, $C_9H_{11}NO,C_6H_3N_3O_7$, crystallises in yellow needles, turns brown at 140°, melts and turns black at 160°, and decomposes completely at 170°. When the base is set free by treating one of the salts with potash, it seems to decompose very quickly yielding resinous products; it gives the carbylamine reaction. On the addition of ammonia to a solution of the hydrochloride there is produced after some time a yellow precipitate, which dissolves in hydrochloric acid yielding a red solution. When the ammoniacal solution is extracted with ether, two compounds are obtained; the one is a colourless, crystalline substance melting at 124°, the other a volatile liquid with an aromatic odour recalling that of benzaldehyde.

When an alcoholic ammoniacal solution of bromopropiophenone, prepared from propionic chloride, benzene, and aluminium chloride by Claus and Wollner's method (Abstr., 1885, 1136), is kept for a long time and then allowed to evaporate, a colourless. crystalline substance melting at 124° separates from the solution. This compound is most probably identical with the crystalline product obtained by decomposing amidopropiophenone hydrochloride with ammonia. and is probably dimethyldiphenylaldine. It is a feeble base, and dissolves in concentrated hydrochloric acid, but is reprecipitated on adding water; in a warm solution of the hydrochloride, platinic chloride produces an orange precipitate which seems to have the composition $C_4N_2Ph_2Me_2,H_2PtCl_6$, and is decomposed by water.

Diphenylaldine platinochloride, $C_4N_2H_2Ph_2,H_2PtCl_6$, prepared by adding a solution of platinic chloride in fuming hydrochloric acid to a warm solution of isoindole (diphenylpyrazine) in fuming hydrochloric acid, crystallises in small, bronze-coloured plates, and does not melt below 300°; it is quickly and completely decomposed by water, alcohol, and dilute hydrochloric acid, with separation of the base.

Phenoxyethylphthalimide, $OPh\cdot C_2H_4\cdot N{:}C_8H_4O_2$, is formed when potassium phthalimide is heated at 190—200° for two hours with bromethyl phenyl ether (β-bromophenetoïl). It crystallises in plates, melts at 129—130°, and is soluble in boiling alcohol, benzene, and carbon bisulphide. *Phenoxyethylphthalamic acid*, $C_{16}H_{15}NO_4$, prepared by warming the imido with potash, is a crystalline compound melting at 125°; it is reconverted into the imido when heated at 140°, when boiled with alcohol, or when hydrogen chloride is passed into its alcoholic solution.

Phenoxyethylamine hydrochloride, $OPh\cdot C_2H_4\cdot NH_2,HCl$, is obtained by heating the preceding compound with concentrated hydrochloric acid, and separating the phthalic acid and the regenerated imide by filtration. It crystallises from alcohol in long, flat needles, and melts at 215°. The *platinochloride*, $(C_8H_{11}NO)_2,H_2PtCl_6$, crystallises in small, golden needles. The *picrate*, $C_8H_{11}NO,C_6H_3N_3O_7$, forms small, light-yellow, granular crystals. The free base separates as a colourless oil when the hydrochloride is decomposed with potash; it is soluble in ether, and absorbs carbonic anhydride with great readiness forming a crystalline carbonate.

Picryl chloride and potassium phthalimide react very readily when warmed together at about 70°, yielding *picrylphthalimide*, $C_6H_2(NO_2)_3N{:}C_8H_4O_2$. This compound separates from glacial acetic acid in large, yellow crystals, melts at 259°, and dissolves in boiling soda with a brownish-red coloration; it is decomposed by concentrated hydrochloric acid at 180° yielding phthalic acid and picramide (m. p. 188°). F. S. K.

Substitution of the Anilido-group for a Halogen-atom in the Benzene-nucleus. By M. Schopff (*Ber.*, **22**, 3281—3289; compare Abstr., 1889, 772).—*Metanitroparanilidobenzoic acid* (*metanitrodiphenylamineparacarboxylic acid*) [COOH : NO_2 : NHPh = 1 : 3 : 4] is formed when parabromometanitrobenzoic acid is boiled with excess of aniline; the yield is almost quantitative. It crystallises from alcohol in garnet-red needles, melts at 254°, and is readily soluble in alcohol, acetone, chloroform, and amyl alcohol, but only moderately easily in benzene, and insoluble in light petroleum. The *sodium* salt, $C_{13}H_9NO_4Na$, crystallises from alcohol in small, red, anhydrous plates and from dilute alcohol in orange needles containing 1 mol. H_2O, which is expelled at 100°. The *barium* salt, $(C_{13}H_9NO_4)_2Ba + 3H_2O$, crystallises in small, orange needles. The other metallic salts are yellow or orange, and are only sparingly soluble. The *ethyl* salt, $C_{15}H_{14}N_2O_4$, separates from alcohol in hexagonal crystals, melts at 123°, and is readily soluble in acetone, chloroform, and benzene, but only sparingly in ether, and almost insoluble in light petroleum.

Metamidoparanilidobenzoic acid [COOH : NH_2 : NHPh = 1 : 3 : 4], prepared by reducing the nitro-acid with an alcoholic solution of ammonium sulphide at 120°, crystallises from water in small, colourless needles, melts at 153°, and turns reddish on exposure to the air. It is readily soluble in alcohol, acetone, and chloroform, but only moderately easily in benzene, and is insoluble in light petroleum; it dissolves in concentrated sulphuric acid with a reddish coloration, which becomes dark red on adding a trace of nitric acid. The *hydrochloride*, $C_{13}H_{12}N_2O_2,HCl$, crystallises in needles, and is decomposed by water. The *ethyl* salt. $C_{15}H_{16}N_2O_2$, prepared by reducing the ethyl salt of the nitro-acid with alcoholic ammonium sulphide, crystallises from dilute alcohol in colourless plates, and melts at 76—77°. When the acid is distilled, it is converted into orthamidodiphenylamine (phenylorthophenylenediamine) identical with the compound obtained by reducing orthonitrodiphenylamine (*loc. cit.*) with ammonium sulphide in alcoholic solution.

Phenylazimidobenzoic acid, $N\lessgtr\begin{matrix}NPh\\N\end{matrix}\!>C_6H_3{\cdot}COOH$, is obtained when metamidoparanilidobenzoic acid is treated with sodium nitrite in dilute hydrochloric acid solution or, better, with amyl nitrite and hydrochloric acid in alcoholic solution. It crystallises from alcohol in rose-coloured needles melting at 272°.

Metanitroparatoluilidobenzoic acid [COOH : NO_2 : $NH{\cdot}C_6H_4Me$ = 1 : 3 : 4], prepared by heating bromonitrobenzoic acid with paratoluidine, is a crystalline compound melting at 257°; it resembles the corresponding anilido-derivative in its behaviour.

Metanitroparahydroxyanilidobenzoic acid [$COOH:NO_2:NH\cdot C_6H_4\cdot OH = 1:3:4$], prepared by heating amidophenol with an alcoholic solution of bromonitrobenzoic acid at 120° for seven hours, crystallises in small brown needles, melts at 260—261°, and is readily soluble in alcohol and acetone, but only sparingly in benzene, chloroform, light petroleum, and hot water. F. S. K.

Synthesis of Hydratropic Acid. By V. Oliveri (*Gazzetta*, 18, 572—575).—Pure benzyl cyanide (18 grams) is gradually added to a solution of sodium (3·5 grams) in anhydrous methyl alcohol (60 c.c.), methyl iodide (40 grams) is then added, and the mixture heated on the water-bath in a reflux apparatus until a test portion diluted with water no longer reddens blue litmus; the alcohol and excess of methyl iodide are then distilled off, and the oily residue washed, dried, and distilled. The distillate, which consists of a mixture of the nitriles of hydratropic and phenylacetic acids, is saponified, decomposed with dilute sulphuric acid, dried, and distilled. A mixture of hydratropic acid and phenylacetic acid passes over at 260—263°, and from this the former may be isolated by strongly cooling, filtering off the crystalline deposit which separates, and redistilling the liquid filtrate in a current of steam; the hydratropic acid, $CHMePh\cdot COOH$, which passes over is a colourless oil boiling between 260° and 261°.

The author considers that Trinius' synthesis of phloretic acid from paramidohydratropic acid by the diazo-reaction (Abstr., 1885, 529) is open to objection on account of the energetic reagents employed, and proposes to synthesise phloretic acid from parahydroxyphenylacetonitril. S. B. A. A.

Orthocresolglycollic Acid. By A. Oglialoro and G. Cannone (*Gazzetta*, 18, 511).—The acid was prepared by the action of monochloracetic acid on orthocresol, following the directions given by Giacosa for the preparation of phenolglycollic acid. It is somewhat soluble in hot water, less so in cold, crystallising from the hot aqueous solution in nacreous laminæ which melt at 151—152°.

The *sodium salt* (unlike the paracresolglycollate) is very soluble in water. The *barium salt*, $Ba(C_9H_9O_3)_2 + 4H_2O$, is deposited in groups of white laminæ on treating the acid with baryta-water and concentrating the solution; it melts in its water of crystallisation at 120°. The *lead salt*, $Pb(C_9H_9O_3)_2 + H_2O$, is prepared by double decomposition from the barium salt. It is only sparingly soluble in boiling water, and crystallises in small, white prisms. It is easily decomposed. S. B. A. A.

Derivatives of Benzallevulinic Acid. By H. Erdmann (*Annalen*, **254**, 182—222).—Benzallevulinic acid (γ-phenyl-β-acetylisocrotonic acid), $CHPh{:}CAc\cdot CH_2\cdot COOH$ (compare Abstr., 1886, 241), melts at 125°. The alkaline salts are very readily soluble in alcohol and water. The *calcium* salt, $(C_{12}H_{11}O_3)_2Ca + 3\frac{1}{2}H_2O$, and the *barium* salt (with $5H_2O$) crystallise in needles, and are very readily soluble in water. The *silver* salt separates unchanged from boiling water. Several other metallic salts were prepared. The *methyl* salt, $C_{13}H_{14}O_3$, prepared by warming the acid with methyl alcohol and a little concentrated sulphuric acid, is a colourless oil boiling at 200—230° (38 mm.); it combines readily with bromine in chloroform solution yielding an oily product.

Bromobenzyllevulinic acid, $CH_2Ph·CBrAc·CH_2·COOH$, was obtained, but only in an impure condition, by warming finely divided benzallevulinic acid with fuming hydrobromic acid. It melts at 125—130°, and dissolves freely in cold sodium carbonate, but the solution gradually undergoes decomposition.

When benzallevulinic acid is heated at 120° with acetic anhydride and sodium acetate, it yields a yellow, amorphous compound; with acetic chloride in the cold, it gives resinous products, and when treated with fuming nitric acid it seems to yield a mixture of an ortho- and a paranitro-compound.

Aceto-α-naphthol (Abstr., 1888, 488) crystallises from dilute acetic acid in long, yellowish-brown needles, melts at 168°, and is readily soluble in alcohol and glacial acetic acid, but only sparingly in most of the other ordinary solvents, and very sparingly in water. The sodium-derivative crystallises in yellow plates; its aqueous solution gives the α-naphthol reaction with paradiazonaphthalenesulphonic acid, an intense blue coloration with quinone chlorimides, and with silver nitrate a colourless precipitate, which rapidly darkens on warming. The *acetyl*-derivative, $C_{14}H_{12}O_3$, crystallises in colourless needles, melts at 108—109°, and is insoluble in cold alkalis. The *oxime*, $C_{13}H_{11}O_2N$, prepared by boiling the ketone with hydroxylamine in alkaline solution, crystallises in colourless, microscopic prisms, melts at 173—174°, and is soluble in alcohol and toluene.

Benzyllevulinic acid, $CH_2Ph·CHAc·CH_2·COOH$, is obtained when benzallevulinic acid is suspended in hot water and treated with excess of 8 per cent. sodium amalgam, the solution being kept acid in order to avoid the formation of benzylvalerolactone (see below). The yield is 95 per cent. of the theoretical quantity. It crystallises from dilute alcohol in long, compact needles, melts at 98—99°, and boils at 230—235° (40 mm.) with slight decomposition. It dissolves in concentrated sulphuric acid yielding a yellow solution, which turns green, and then greenish-blue if kept for two or three days. The *calcium* salt $(C_{12}H_{13}O_3)_2Ca + 3H_2O$, crystallises in needles which effloresce on exposure to the air. The *silver* salt crystallises unchanged from hot water, but it gradually darkens on exposure to light. The *oxime*, $C_{12}H_{15}O_3N$, is a mobile oil readily soluble in alkalis and in mineral acids, but only sparingly in water.

Benzylangelicalactone, $C_{12}H_{12}O_2$, prepared by heating benzyllevulinic acid at its boiling point for 10—20 minutes, is a yellowish oil sparingly soluble in boiling water. It is only very slowly decomposed by boiling water, but it is reconverted into benzyllevulinic acid by boiling baryta-water. It combines with bromine in carbon bisulphide solution, yielding an oily additive compound.

Benzylvalerolactone, $C_{12}H_{14}O_2$, is obtained when benzal- or benzyllevulinic acid is reduced with sodium amalgam in alkaline solution. It separates from carbon bisulphide in well-defined crystals, melts at 86°, and is very readily soluble in toluene, but only sparingly in hot water; it is not changed by cold alkaline carbonates, but is converted into benzylhydroxyvaleric acid when heated with alkalis.

β-Benzyl-γ-hydroxyvaleric acid, $OH\cdot CHMe\cdot CH(C_7H_7)\cdot CH_2\cdot COOH$, crystallises from water with 1 mol. H_2O in small prisms, which melt at 55—56°, and lose their water over sulphuric acid; the anhydrous compound melts at 75—76°. It is moderately easily soluble in water, and when boiled with dilute mineral acids is reconverted into the lactone. The *barium* salt crystallises in colourless plates or prisms, and is sparingly soluble in water. The *calcium* salt,

$$(C_{12}H_{15}O_3)_2Ca + 6H_2O,$$

separates from cold water in microscopic prisms.

Phenylangelicalactone, $C_{11}H_{10}O_2$, prepared by distilling α-phenyllevulinic acid (Weltner, Abstr., 1884, 747) under reduced pressure (38 mm.), crystallises from a mixture of carbon bisulphide and light petroleum in colourless plates melting at 53°. It is very readily soluble in carbon bisulphide, but only sparingly in light petroleum. It is not decomposed by boiling water, but it is readily converted into the acid by boiling lime-water. When treated with bromine in chloroform solution, it yields an oily additive-compound. F. S. K.

Action of Ethyl Sodiomalonate on Tribromodinitrobenzene. By C. L. JACKSON and W. S. ROBINSON (*Amer. Chem. J.*, 11, 541—557). —A continuation of the research described in a previous paper (Abstr., 1889, 781). The formation of ethyl bromodinitrophenylmalonate by the action of ethyl sodiomalonate on tribromodinitrobenzene is shown to take place according to the following equations:—

(1.) $C_6HBr_3(NO_2)_2 + CHNa(COOEt)_2 = NaBr + C_6HBr_2(NO_2)_2\cdot CH(COOEt)_2.$

(2.) $C_6HBr_2(NO_2)_2\cdot CH(COOEt)_2 + CHNa(COOEt)_2 = C_6HBr_2(NO_2)_2\cdot CNa(COOEt)_2 + CH_2(COOEt)_2.$

(3.) $= C_6H_2Br(NO_2)_2\cdot CNa(COOEt)_2 + CHBr(COOEt)_2.$

(4.) $CHNa(COOEt)_2 + H_2O = NaOH + CH_2(COOEt)_2.$

(5.) $CHBr(COOEt)_2 + NaOH = NaBr + CH(OH)(COOEt)_2.$

Of these reactions 1, 2, and 3 take place before, 4 and 5 after the addition of water used in working up the product.

Ethyl bromodinitrophenylmalonate, $C_6H_2Br(NO_2)_2\cdot CH(COOEt)_2$ [= 3 : 4 : 6 : 1], was prepared by making a strong solution of 20 grams of tribromodinitrobenzene, $C_6HBr_3(NO_2)_2$ [= 1 : 3 : 5 : 4 : 6], in benzene, and treating it with ethyl sodiomalonate, made by adding to 16 grams of ethyl malonate the sodium ethoxide obtained from 2·3 grams of sodium and 100 to 125 c.c. of alcohol. The mixture was allowed to remain all night at the ordinary temperature, and was then treated with water, and the aqueous solution separated by means of a separating funnel from the benzene solution, which contained unaltered tribromodinitrobenzene, together with an oily product of the reaction. The ethyl bromodinitrophenylmalonate was thrown down from the aqueous solution as a yellowish precipitate by adding dilute sulphuric acid; when recrystallised from hot alcohol, it melted at 76°. The yield was only half the theoretical, much remaining dissolved in the oily product of the reaction. It was shown that two-thirds of the bromine contained in the original tribromodinitrobenzene is removed as sodium bromide, and also that the oily product of the reaction gives tartronic acid when heated with strong hydrochloric acid in a sealed tube at 130°; hence the reaction is represented by the equations given above.

Metabromodinitrophenylacetic acid, $C_6H_2Br(NO_2)_2\cdot CH_2\cdot COOH$ [= 3 : 4 : 6 : 1], was prepared by boiling 2 grams of ethyl bromodinitrophenylmalonate with 100 c.c. of dilute sulphuric acid (of sp. gr. 1·44) in a reflux apparatus until it all dissolved. The solution, on cooling, deposited the acid in long, pale-yellow needles, which may be recrystallised from water containing a few drops of sulphuric acid, but are decomposed by pure water and by alcohol. The yield is quantitative.

Metabromodinitrophenylacetic acid melts at 177°, and dissolves in acetone, glacial acetic acid, and ether, but not to any extent in the other common solvents. When boiled with alcohol or water, it is decomposed, losing carbonic anhydride, and forming a bromodinitrotoluene which has been shown to have the constitution

$$[CH_3 : Br : (NO_2)_2 = 1 : 3 : 4 : 6].$$

From this follow the formulæ which have been assigned to the compounds mentioned above. The acid dissolves in ammonia, giving a solution which is colourless if the acid is in excess, green if the ammonia is in slight excess, brown if it is in large excess. The colourless solution gives precipitates with salts of many of the heavy metals. The precipitate with silver nitrate is at first flocculent, but becomes crystalline after a time; it has the formula

$$C_6H_2Br(NO_2)_2\cdot CH_2\cdot COOAg + H_2O.$$

With aqueous soda, the acid gives a green coloration, changing to brown as excess of soda is added. With acids, the green solution gives a colourless precipitate, which becomes purple when moistened with alcohol. The brown solution on treatment with acids yields a viscous red substance, probably of the nature of a phenol. In both these reactions bromine is removed. C. F. B.

Action of Aniline on Ethyl Oxalacetate and Ethyl Methyloxalacetate. By W. WISLICENUS and K. SPIRO (*Ber.*, 22, 3348—3352).—When aniline and ethyl oxalacetate are mixed in the cold, water separates, and *ethyl aniloxalacetate*,

$$COOEt\cdot C(NHPh):CH\cdot COOEt,$$

is formed. This is a yellowish oil, which under a pressure of 10 mm. of mercury begins to distil at 200°, but at the same time undergoes considerable decomposition. It is insoluble in water and dilute acids or alkalis, easily soluble in alcohol and ether. Alkalis and acids cause a separation of aniline. When heated, water and alcohol separate, and two substances, $C_{14}H_{15}NO_3$, melting at 107—108°, and $C_{12}H_{11}NO_3$, melting at 212—213°, are formed, but have not been further investigated. When the action of aniline on ethyl oxalacetate is carried on at a high temperature (about 130—150° is found to be the best), 2 mols. of aniline enter into the reaction, phenylamidomaleic acid phenylimide (Michael, Abstr., 1886, 698) being formed.

Aniline acts less readily on ethyl methyloxalacetate, but, on warming, *ethyl anilomethyloxalacetate* is formed. When, however, the ethyl salt is heated with aniline (2 mols.) at about 180°, *methylanilidomaleic acid phenylimide*,

$\mathrm{NPh{:}C}<\begin{matrix}\mathrm{CO-\!\!-NPh}\\ \mathrm{CHMe\cdot CO}\end{matrix}$,

is formed. It is easily soluble in boiling glacial acetic acid and alcohol, insoluble in water and ether. It crystallises in glistening, golden-yellow scales, and melts at 158—160° to a reddish-yellow liquid. L. T. T.

Sulphone-derivatives. By R. OTTO (*J. pr. Chem.* [2], **40**, 505—564).

1. Action of alkaline sulphinates on polyhalogen-derivatives of hydrocarbons, in which the halogen-atoms are linked to one carbon-atom:—

The action of sodium aromatic-sulphinates on methylene iodide has been investigated by Michael and Palmer (Abstr., 1885, 536), and by the author (Abstr., 1888, 482). There is here given the crystallography of methylphenylsulphone, methylene-iodophenylsulphone, methylparatolylsulphone and methylene-iodoparatolylsulphone.

Ethylidenechlorophenylsulphone, $\mathrm{CHMeCl{\cdot}SO_2Ph}$, is obtained when ethylidene chloride (1 mol.) and sodium benzenesulphinate (2 mols.) are heated together in alcohol in a sealed tube at 150—160°. Ethyl chloride escapes on opening the tube; water separates from the contents a dark-brown ethereal solution containing much phenyl bisulphide, little phenylbenzenethiosulphonate and ethylidenechlorophenylsulphone, together with unaltered ethylidene chloride. The aqueous solution contains unaltered sulphinate, sodium chloride, and sodium sulphonate. The sulphone is separated by evaporating the ether, and fractionally crystallising from alcohol; it melts at 52°. It differs from the isomeric phenylsulphonethyl chloride (Abstr., 1885, 263) in that it is not converted into ethylenediphenylsulphone when heated with sodium benzenesulphinate.

When sodium paratoluenesulphinate is substituted for the benzenesulphinate in the above reaction, ethylidenechloroparatolylsulphone (see below) is obtained.

When the above experiments are compared with those on methylene iodide (Abstr., 1888, 482), it is evident that the $\mathrm{SO_2R'}$ group is more easily substituted for the halogen in the methylene-derivative than in the ethylidene-derivative.

Benzylidenechlorophenylsulphone, $\mathrm{CHPh{\cdot}Cl{\cdot}SO_2Ph}$, is prepared by heating benzylidene chloride (10 grams) with sodium benzenesulphinate (20 grams) in alcohol in a reflux apparatus, the solution being kept neutral by addition of sodium carbonate. The alcohol is distilled off, the residue treated with water, and immediately shaken with ether, which does not dissolve the sulphone. It crystallises from glacial acetic acid in small, broad, vitreous, sparingly soluble needles (m. p. not given). Benzaldehyde, phenyl benzenethiosulphonate, phenyl mercaptan, and phenyl bisulphide are dissolved by the ether, the sodium chloride and sodium benzenesulphonate by the water.

Benzylidenechloroparatolylsulphone, $CHPhCl{\cdot}SO_2{\cdot}C_7H_7$, obtained in like manner from benzylidene chloride and sodium paratoluenesulphinate, crystallises from hot glacial acetic acid in small, yellowish-white, lustrous needles melting at 203°.

The above reactions confirm the author's generalisation as to the action of alkaline sulphinates on dihalogen derivatives of hydrocarbons (Abstr., 1888, 482).

The action of sodium benzenesulphinate on the trihalogen-derivatives of hydrocarbons, chloroform, and methylchloroform, has been described before (Abstr., 1888, 841); that ethylidenedisulphone should be produced in the case of methylchloroform is remarkable, and indicates that one of the chlorine-atoms first displaces a hydrogen-atom in the methyl-group, forming $CH_2Cl{\cdot}CHCl_2$ (compare the formation of symmetrical succinic acid from ethylidene chloride and potassium cyanide, Erlenmeyer and Simpson, *Zeit. Chem.* [2], 3, 593, 673).

Benzylphenylsulphone (Abstr., 1888, 841) crystallises in lustrous, slender prisms melting at 146—147°, and insoluble in water, but soluble in alcohol. Its crystallography is given.

The SO_2R group is more easily substituted for chlorine in benzotrichloride (phenylchloroform) than in methylchloroform, and more easily in this than in chloroform (compare Busz and Kekulé, Abstr., 1888, 302). In trihalogen-derivatives of hydrocarbons in which three atoms of halogen are linked to one carbon-atom, only one such atom is displaced by the SO_2R-group, the others being displaced by hydrogen.

2. Action of alkaline sulphinates on polyhalogen derivatives of fatty acids, in which the halogen-atoms are linked to one carbon-atom:—

When sodium benzenesulphinate (6·5 grams) is heated on the water-bath with dichloracetic acid (2·5 grams) neutralised with sodium hydroxide, *chloromethylphenylsulphone*, identical with methylenechlorophenylsulphone (Abstr., 1888, 483), sodium chloride, and sodium carbonate are formed. *Chloromethyltolylsulphone*, obtained from sodium toluenesulphinate and dichloracetic acid, crystallises in vitreous tables, whose crystallography is given; it melts at 84°, is insoluble in water, but soluble in hot alcohol or benzene. It can also be obtained by the action of methylene chloride on sodium toluenesulphinate.

The action of sodium benzenesulphinate on sodium α-dichloropropionate produces ethylenediphenylsulphone (Abstr., 1885, 261), and may be compared with that of the same salt on methylchloroform (see above). A small quantity of ethylidenechlorophenylsulphone is obtained at the same time. *Diphenylsulphonethylamine*, obtained by the action of ammonia on ethylenediphenylsulphone, has been described before (Abstr., 1885, 537); its crystallography is here given.

Ethylidenechloroparatolylsulphone is the chief product of the action of sodium paratoluenesulphinate on sodium α-dichloropropionate, only a little ethylidenediparatolylsulphone (Abstr., 1885, 538) being produced. It crystallises in thin, rhombic tables (crystallography given) melting at 84°; it is unchanged by heating with sodium toluenesulphinate. The corresponding bromo-derivative was not obtained when sodium α dibromopropionate was substituted for the α-dichloropropionate.

Ethyl dichloracetate (1 mol.) was heated with sodium benzenesulphinate and toluenesulphinate, respectively (2 mols.), in alcohol for eight days; chloromethylphenylsulphone and chloromethyltolylsulphone, respectively, were obtained, together with sodium chloride, sodium sulphonate, and, in the former case, sodium phenylsulphonacetate.

There is no action between sodium benzenesulphinate or toluenesulphinate and trichloracetate when heated together.

3. Action of chlorine and bromine on sulphonecarboxylic acids :—

Dichloromethylphenylsulphone, $CHCl_2 \cdot SO_2Ph$, is obtained, together with carbonic anhydride, when chlorine is passed through warm aqueous phenylsulphonacetic acid in diffused daylight, as an oil which separates from alcohol or ethyl acetate in prismatic crystals, melting at 59°.

On mixing bromine with phenylsulphonacetic acid (equal mols.), two bromo-derivatives are obtained; these may be separated by crystallising from hot alcohol, when *bromomethylphenylsulphone* remains dissolved; it forms thick, lustrous, tabular crystals melting at 46—48°, and insoluble in water. *Dibromomethylphenylsulphone* forms many-sided crystals (melting point not given), insoluble in water.

There have also been obtained in the same way, *dichloromethylparatolylsulphone*, which forms lustrous crystals melting at 114°; *bromomethylparatolylsulphone*, forming slender needles melting at 90—92°; *dibromomethylparatolylsulphone*, which forms prismatic crystals melting at 116—117°. These are all soluble in hot alcohol, but insoluble in water. The crystallography of the last five compounds is given.

It is thus seen that dihalogen-derivatives of a sulphoneacetic acid, if formed at all, immediately decompose into dihalogen derivatives of sulphones and carbonic anhydride.

α-Phenylsulphonepropionic acid, $SO_2Ph \cdot CHMe \cdot COOH$, is prepared by heating ethyl α-bromopropionate with sodium benzenesulphinate (equal mols.) for 1 to 2 days in alcohol using a reflux condenser; the alcohol is evaporated, water added, and the ethyl salt thus separated, washed and saponified with aqueous soda. The acid crystallises in aggregates of minute, white, monosymmetric or asymmetric needles, melting at 115—116°, and soluble in the usual solvents. The *sodium salt*, the *barium salt* (with 2 mols. H_2O), and the *ethyl salt* are described.

α-Phenylsulphone-α-bromopropionic acid is obtained by the action of bromine on the last-mentioned acid in ether or water at the ordinary temperature; it crystallises in small, thick, lustrous prisms and very slender needles, melting at 134°, and soluble in most solvents.

Ethylidenebromophenylsulphone, $CHMeBr \cdot SO_2Ph$, is obtained, together with carbonic anhydride, when the aqueous solution of the above is heated; it crystallises in rhombic, rectangular tables melting at 49—50°, and is soluble in alcohol and benzene.

Attempts to make α-phenylsulphonepropionic acid by heating ethyl phenylsulphonacetate with sodium and methyl iodide in alcohol failed (compare Abstr., 1889, 994).

α-Paratolylsulphonepropionic acid, prepared similarly to α-phenylsulphonepropionic acid, forms colourless crystals melting at 37°.

The ultimate product of the action of bromine on ethyl phenylsulphonacetate and on paratolylsulphonacetate at 90° is dibromomethylphenylsulphone and dibromomethyltolylsulphone respectively. Chlorine has no action on these ethyl salts.

When phosphorus pentachloride and phenylsulphonacetic acid are mixed together in molecular proportion, phosphorus oxychloride and phenylsulphonacetic chloride (m. p. 58°) are formed. When 2 mols. of the pentachloride and 1 mol. of the acid are heated together at 110°, phosphorus trichloride, phosphorus oxychloride, and a crystalline mass, probably phenylsulphonedichloracetic chloride, $SO_2Ph·CCl_2·COCl$, are obtained; but when treated with water, the crystalline mass evolves carbonic anhydride and is converted into dichloromethylphenylsulphone.

The author concludes with some remarks as to the analogy between the ketonic acids and sulphone acids (compare Abstr., 1888, 360, 577).

The crystallography of sodium benzenesulphinate and propylphenylsulphone is incidentally described in the paper. A. G. B.

"Methylsaccharin," or Methylbenzoic Sulphinide. (*Chem. Centr.*, 1889, ii, 795—796; from *German Patent* 48583 *of the Badische Anilin- und Sodafabrik*, 1889).—The following new method has been applied to the preparation of Remsen and Fahlberg's sulphinides:—

"*Methylsaccharin*," or *methylbenzoic sulphinide*, has been prepared by it, and its preparation exemplifies the method.

100 kilos. of paratoluidinemetasulphonic acid [$Me : SO_3H : NH_2 = 1 : 3 : 4$] is converted into the diazo-compound, and this is mixed with water and gradually transferred to an almost boiling solution of 48 kilos. of cuprous cyanide, 104·5 kilos. of potassium cyanide, and 500 kilos. of water. After the violent evolution of nitrogen has ceased, the solution is heated a short time to boiling, and then just sufficient sulphuric acid added to decompose the potassium cyanide, when the whole of the cuprous cyanide is precipitated. The hydrogen cyanide liberated is collected in solution of potassium hydroxide. The solution is filtered from the cuprous cyanide, and concentrated until crystallisation commences. The potassium salt of *toluenecyanosulphonic acid* crystallises out in deep-yellow, lustrous prisms, containing water of combination. The salt is readily soluble in water, but only sparingly in alcohol, which renders a dilute alcohol of advantage for purifying it.

To obtain the *sulphochloride*, $CN·C_6H_3Me·SO_2Cl$, the potassium sulphonate is completely dehydrated by heating at 100—110°; it is then mixed with an equal weight of phosphorus pentachloride and heated in a reflux apparatus at about 100°. The reaction takes place at once; the mass froths slightly at first, then becomes a limpid liquid. The contents of the retort are next heated somewhat higher, in order to distil off the phosphorus oxychloride, after which it is allowed to cool and solidify. The potassium chloride is extracted by agitating the ground-up product with water several times, after which the residue is dried and recrystallised from light petroleum. It melts at 67°.

The sulphochloride is next converted into the *sulphonamide* by the action of ammonia. Either aqueous, alcoholic, or gaseous ammonia is applicable. It is extremely insoluble in water and methylated spirit From boiling pyridine, it crystallises in white plates. It dissolves readily in cold water containing free alkali.

Methylbenzoic sulphinide,  $C_6H_3Me<\genfrac{}{}{0pt}{}{SO_2}{CO}>NH$, is prepared from the sulphonamide by hydrolysis with water. 10 kilos. of the sulphonamide is dissolved in 50 kilos. of hot water, by means of just sufficient sodium hydroxide for its complete solution. This solution is then boiled in a reflux apparatus for 4—5 hours, and allowed to cool. The addition of an acid to the solution now precipitates the sulphinide as a white, crystalline powder. It is only requisite to crystallise the crude product once from water in order to obtain colourless, lustrous crystals, melting at 246°. In cold water it is very insoluble, but is much more readily soluble in hot water. Like benzoic sulphinide ("saccharin"), it tastes extremely sweet, and may be applied to the same purposes. If too much alkali is used for the solution of the sulphonamide, the product obtained after hydrolysis will be found to be an acid, and to have lost all the properties of the sulphinide.

Synthesis of Indigo from Bromacetanilide. By W. Flimm (*Ber.*, **23**, 57—60).—The action of potash on bromacetanilide varies according to the conditions under which it takes place. Thus aqueous potash splits it up into its constituents, some phenylcarbamine being also formed, whilst alcoholic potash converts it into diphenyldiketopiperazine (Abenius, Abstr., 1889, 134). If, however, a mixture of the anilide and solid potash be fused together in small quantities. until a homogeneous, reddish-brown melt is obtained, the latter dissolved in water and a little ammonia or ammonium chloride solution added, indigo speedily separates out. The melt may also be dissolved in hydrochloric acid, and ferric chloride added, in which case the indigo separates at once. The compound gives all the characteristic reactions of indigo, and shows the same absorption spectrum. The yield is. however, small, amounting only to 4 per cent. of the anilide employed.

It would appear probable that the compound first formed from monobromacetanilide is indoxyl,  $C_6H_4<\genfrac{}{}{0pt}{}{NH\text{—}}{C(OH)}>CH$, or pseudindoxyl,  $C_6H_4<\genfrac{}{}{0pt}{}{NH}{CO}>CH_2$, and that this then undergoes oxidation with formation of indigo.

Bromacetoparatoluidide is converted on similar treatment into *dimethylindigo*. This can scarcely be distinguished externally from indigo, but yields paratoluidine on distillation with excess of potash.

The following compounds were also subjected to the same treatment, but did not yield corresponding compounds: bromaceto-α-naphthalide, bromaceto-β-naphthalide, bromacetodiphenylamine, and bromacetoorthotoluidide. H. G. C.

Symmetrical Diphenyltrimethylene Cyanide and Symmetrical Diphenylglutaric Acid. By N. ZELINSKY and M. FELDMANN (*Ber.*, **22**, 3289—3293; compare Abstr., 1889, 692).—*αα-Diphenyltrimethylene cyanide*, $CH_2(CHPh{\cdot}CN)_2$, is obtained when finely divided, anhydrous sodium hydroxide (8 grams) is added, in small portions at a time, to a mixture of benzyl cyanide (23·4 grams) and methylene iodide (26·8 grams) and the mixture heated, gently at first, and then more strongly to complete the reaction. The oily product is extracted with ether, the unchanged benzyl cyanide and methylene iodide removed by distilling with steam, and the residual diphenyltrimethylene cyanide recrystallised from alcohol. The yield of the pure product is 8 grams, and considerable quantities remain dissolved in the alcoholic mother liquors. It forms well-defined rhombic crystals, $a : b : c = ? : 1 : 0·4877$, melts at 70—71° and its molecular weight, determined by Raoult's method in glacial acetic acid and in benzene solution, was found to be in accordance with the formula given above.

Diphenylglutaric acid, $CH_2(CHPh{\cdot}COOH)_2$, prepared by hydrolysing the preceding compound with alcoholic potash, crystallises from hot water in small needles melting at 164.° F. S. K.

Fichtelite. By E. BAMBERGER and L. STRASSER (*Ber.*, **22**, 3361—3368; compare Abstr., 1889, 714, and HELL, *ibid.*, 614).—The author has carefully determined the boiling point of this compound, using a Zincke thermometer with the mercury column in the vapour. In this way the boiling point was found to be 355·2° at 719 mm., 235·6° at 43 mm. and 233·6° at 42 mm. In the previous determinations by the author and by Hell of the vapour density of fichtelite, made in air by V. Meyer's process, the numbers obtained varied between 7·37 and 7·77, but both observers noticed an apparent partial oxidation. The author has therefore repeated the vapour-density determinations in pure dry nitrogen, and obtained the numbers 8·66 and 8·72, no sign of decomposition being observed. This number agrees very closely with that (8·58) required for $C_{18}H_{32}$, the formula previously adopted by the author as the most probable one. This formula would correspond with a perhydride of retene, and its correctness is made more probable by the fact that fichtelite and retene are so often found together in peat moors. Liebermann and Spiegel have lately obtained (Abstr., 1889, 720) retene dodecahydride, $C_{18}H_{30}$, by the action of hydriodic acid and phosphorus on retene at about 250°, but were then unable to obtain the perhydride (compare next Abstr.). In his previous communication (*loc. cit.*), the author described a substance which he obtained by heating fichtelite with iodine, and which he believed to be dehydrofichtelite. He has now further investigated this reaction. When 27 grams of iodine and 25 grams of fichtelite were heated together, evolution of hydrogen iodide began at 120° and became very energetic at 150°. After keeping the mixture at 200° until evolution of gas ceased, and subsequent purification, *dehydro-*

fichtelite, $C_{18}H_{30}$, was obtained as a clear, colourless, thick oil having a beautiful pale-blue fluorescence. Under 38 mm. pressure it boils at 224—225° (corr.), and under atmospheric pressure (714 mm.) at 344—348° (corr.), but in the latter case slight decomposition takes place. Vapour density determinations carried out in air gave numbers varying between 6·15 and 8·16, but the compound showed signs of decomposition; in pure dry nitrogen, the vapour densities found were 8·59 and 8·85, theory requiring 8·51. The same substance seems to be formed, although in little more than traces by the action of sulphur and of zinc-dust on fichtelite at high temperatures. The properties of this dehydride seem to correspond with those of retene dodecahydride, except that attempts to obtain retene from it proved unsuccessful. Liebermann and Spiegel state that they obtained retene by distilling the dodecahydride with zinc-dust, but that the yield was very small, and the authors' want of success may very probably be owing to the small quantity of substance they had to treat. The lower boiling point given by Liebermann and Spiegel was uncorrected, and so corresponds very closely with that found by the authors. By further treatment of the dehydride with iodine, a *detetrahydride* boiling at 230° under 38 mm. pressure was obtained, but no lower hydrides could be isolated. When spongy platinum was suspended in the boiling dehydride, and a current of oxygen passed through the liquid, oxidation took place, and from the products a small quantity of a heavy oil boiling about 330° and soluble in glacial acetic acid was isolated; this, when oxidised with chromic acid, yielded an *orthodiketone* crystallising in small, red needles. The quantity, however, was too small to establish with certainty its identity with retenequinone.

These results, although not conclusive, leave little doubt that fichtelite is retene perhydride, $C_{18}H_{32}$. L. T. T.

Constitution of Fichtelite. By L. Spiegel (*Ber.*, **22**, 3369—3371; compare preceding abstract).—In the preparation of considerable quantities of retene dodecahydride (Liebermann and Spiegel, Abstr., 1889, 720), the author, by strongly cooling the dodecahydride, obtained small quantities of glistening crystals melting at 48°. The same substance seems to be formed when the dodecahydride is treated with phosphorus and hydrogen iodide. Although the author has not yet obtained enough of this substance for absolute proof, there seems little doubt that it is identical with fichtelite, which must, therefore, be retene perhydride. L. T. T.

Behaviour of αβ-Dinaphthylamine when Combining with Diazobenzene. By P. Mathes (*Ber.*, **22**, 3344—3348).—When an acetone solution of αβ-dinaphthylamine is added to a solution of diazobenzene, in the presence of sodium acetate, *α-benzeneazo-αβ-dinaphthylamine*, $N_2Ph{\cdot}C_{10}H_6{\cdot}NH{\cdot}C_{10}H_7$ [NH : N_2Ph = 2 : 1], is alone formed, but when the reaction is carried out in the presence of hydrochloric acid at 40—50°, besides this *ααβ*-compound, *α-benzeneazo-βα-dinaphthylamine* [NH : N_2Ph = 1 : 4], and a *disazo*-derivative, $N_2Ph{\cdot}C_{10}H_6{\cdot}NH{\cdot}C_{10}H_6{\cdot}N_2Ph$ [NH : N_2Ph = 2 : 1 and NH : N_2Ph =

1 : 4] are also formed. The disazo-compound is much less soluble in alcohol than the two azo-derivatives, and can be thus separated from them. It crystallises in long, woolly, violet needles melting at 238°. This compound is also formed by the action of diazobenzene chloride on either of the azo-derivatives, if enough solvent is used to keep these sparingly soluble substances in solution. When boiled for some time with glacial acetic acid, it is coverted into the *azine*,

$C_{10}H_6<\overset{N}{\underset{N}{|}}>C_{10}H_5{\cdot}N_2Ph$ [N : N = 1 : 2 and N : N : N_2Ph = 1 : 2 : 4].

This crystallises in brownish-yellow woolly needles sparingly soluble in the usual solvents and melting at 287°; by reducing agents it appears to be converted into a eurhodine, which, however, has not yet been isolated.

The separation of the azo-compounds is more difficult, as their solubility in most solvents is very similar. The 1 : 2-compound is, however, less soluble in benzene than the 1 : 4-derivative, and can be obtained pure when crystallised from that solvent; it forms long, woolly, intensely red needles melting at 167°. When treated with mineral acids, it is converted into an *azine*. The 1 : 4-compound cannot be obtained pure directly from the mother liquor; the best way is to dissolve the mixed azo-compounds in acetic acid and treat with hydrochloric acid. The 1 : 2-derivative is thus changed into the azine, whilst the 1 : 4-derivative is converted into its hydrochloride. The two are then precipitated with water, and separated by means of alcohol, in which the hydrochloride is easily soluble, the azine almost insoluble; the azo-base is then liberated by means of ammonia. It crystallises from alcohol in short, thick, yellowish-red prisms melting at 137°. L. T. T.

α-Naphthylamine- and α-Naphthol-ε-Disulphonic Acids. By A. BERNTHSEN (*Ber.*, **22**, 3327—3335).—When the mixture of 1 : 4′- and 1 : 3′-naphthalenedisulphonic acids, obtained by sulphonating naphthalene in the cold with chlorosulphonic acid or with fuming sulphuric acid containing 35 per cent. of sulphuric anhydride, is nitrated and the resulting nitro-acids reduced, two isomeric α-naphthylaminedisulphonic acids (δ- and ε-) are formed. These can be separated by fractional crystallisation of the normal sodium salts, inasmuch as the normal sodium salt of the so-called Schöllkopf or α-naphthylamine-δ-disulphonic acid [$NH_2 : SO_3H : SO_3H = 1' : 1 : 4'$] (German patent 40571) is relatively sparingly soluble in water, whilst that of the ε-acid remains in the mother liquors, and is best obtained by treating these with excess of hydrochloric acid, which converts it into the less soluble but well crystallised sodium hydrogen salt (Actiengesellschaft für Anilinfabrikation, German patent 45776). *α-Naphthylamine-ε-disulphonic acid*, $NH_2{\cdot}C_{10}H_5(SO_3H)_2 + 3H_2O$, which can also be obtained by nitrating pure 1 : 3′-naphthalenedisulphonic acid, and reducing the resulting nitro-acid (Ewer and Pick, G. P.-A., E. 2318; Badische Anilin- und Sodafabrik, G. P.-A., B. 9514), crystallises in colourless, lustrous scales and is extremely soluble in hot, sparingly soluble in cold water; the *sodium* salt, with 6 mols. H_2O, crystallises in long needles or thin prisms, and is extremely soluble in water; the *sodium hydrogen* salt, with 2 mols. H_2O, crystallises in long needles or thin prisms; the *barium* salt crystallises with 3 mols. H_2O in bright-yellow aggregates of needles, and with 4 mols. H_2O in colourless, lustrous, flat needles, and is readily soluble in hot, sparingly soluble in cold water; the *barium hydrogen* salt, with 5 mols. H_2O, crystallises in white, microscopic needles and is sparingly soluble in cold water. The diazo-acid is readily soluble in water, but its sodium salt is sparingly soluble and crystallises in spherical aggregates of small, white needles.

α-Naphthol-ε-disulphonic acid is formed when the diazo-compound of the naphthylamine acid is boiled with dilute sulphuric acid. Its *sodium* salt, $OH\cdot C_{10}H_5(SO_3Na)_2 + 6H_2O$, crystallises in long, colourless prisms, is soluble in 5·5 parts of water at the ordinary temperature, is precipitated from its concentrated aqueous solution by addition of salt, and gives a deep blue colour with ferric chloride. Concentrated nitric acid oxidises it readily, but does not convert it into a compound resembling naphthol-yellow. The azo-dyes derived from α-naphthol-ε-disulphonic acid are characterised by their purity of shade and by the fact that they crystallise well; the dye obtained by combination with aniline is orange-yellow; with xylidine, ponceau; with α-naphthylamine red; and with benzidine, violet.

Naphthasultonsulphonic acid ε (naphthalenesulphonelactonesulphonic acid ε; β-naphthol-αβ-disulphonic acid of G. P.-A., E. 2318; ζ-naphtholdisulphonic acid of G. P.-A., B. 9514) is obtained when diazonaphthalenedisulphonic acid ε is boiled with water and a small quantity of sulphuric acid only long enough to expel all the nitrogen, and then at once rapidly cooled. In this way, long slender needles of the *sodium* salt, $C_{10}H_5SO_3\cdot SO_3Na + 3H_2O$, are obtained, which, after drying at 110°, have the composition $C_{10}H_5SO_3\cdot SO_3Na$. This salt requires 93 parts of water for its solution in the cold, but it is more soluble in hot water, is precipitated from a 1 per cent. solution by the addition of salt, gives no colour with ferric chloride, and is not affected when boiled for a short time with concentrated nitric acid. The *barium* salt crystallises in long, colourless needles and is insoluble in cold water; the *acid* crystallises in silky needles and melts at 241°. When treated with alkalis or alkaline carbonates, naphthasultonsulphonic acid ε is rapidly converted in the cold or at once on warming into α-naphthol-ε-disulphonic acid; on treatment with ammonia, however, it forms *α-naphtholsulphonamidsulphonic acid* ε, $OH\cdot C_{10}H_5(SO_3H)\cdot SO_2NH_2$, which differs from the naphthol-ε-disulphonic acid in yielding azo-dyes having a distinctly redder or bluer shade. The sulphonamidsulphonic acid crystallises in compact needles, or long, slender prisms, and is somewhat readily soluble in cold water; the *sodium ammonium* salt, $C_{10}H_8NS_2O_6Na,NH_3 + H_2O$, forms small, compact crystals and is very soluble in water; the *barium* salt, $(C_{10}H_8NS_2O_6)_2Ba + 5H_2O$, is sparingly soluble in cold water.

The author assigns the constitution $[NH_2 : SO_3H : SO_3H = 1' : 1 : 3']$ to α-naphthylamine-ε-disulphonic acid since (1) it is obtained by the nitration of the 1 : 3′-naphthalenedisulphonic acid; (2) it contains its NH_2-group in an α-position, inasmuch as it yields α-naphthylamine on distillation with lime; and (3) it yields a sultone (sulphonelactone), a reaction hitherto obtained only in the case of the 1 : 1′ naphtholsulphonic acid (Erdmann, Abstr., 1889, 157). W. P. W.

Note by Abstractor: The constitution assigned by Bernthsen to so-called α-naphthylamine-ε-disulphonic acid has been confirmed by Armstrong and Wynne (Proc., 1890, 16). W. P. W.

α-Naphthylamine-ε-disulphonic Acid. By G. Schultz (*Ber.*, **23**, 77).—In Bernthsen's paper (preceding Abstr.), it is stated that α-naphthylamine-ε-disulphonic acid [$NH_2 : SO_3H : SO_3H = 1' : 1 : 3'$] is obtained by the reduction of the nitro-acids obtained by nitrating naphthalenedisulphonic acids produced by the sulphonation of naphthalene by three different methods. The author points out that in each of these cases 1 : 3′-naphthalenedisulphonic acid is present and undergoes nitration, and that therefore one method alone exists for the production of α-naphthylamine-ε-disulphonic acid.

In addition to α-naphthylamine-ε-disulphonic acid, other naphthylaminedisulphonic acids are produced when 1 : 3′-naphthalenedisulphonic acid is nitrated, and the nitro-acids reduced; one of these the author has examined and finds to be a β-naphthylaminedisulphonic acid. Further details are promised. W. P. W.

New Class of Diketones. By A. Béhal and V. Auger (*Compt. rend.*, **109**, 970—973).—The authors have previously shown that methylmalonic and ethylmalonic chlorides react with hydrocarbons of the benzene series, with formation of diketones of the type R·CO·CHX·CO·R. The best results were obtained by mixing 500 grams of metaxylene with 80 grams of ethylmalonic chloride, and adding about 160 grams of aluminium chloride in quantities of 20 grams at a time. When the reaction becomes less energetic, the mixture is heated at 60° for two hours. The product after purification crystallises from alcohol of 95 per cent. in confused needles which melt at 63°, and have the composition $C_{13}H_{14}O_2$. It is probably *methyldihydrometanaphthaquinone*

$$[Me : O : H,Et : O : H_2 = 1' : 1 : 2 : 3 : 4].$$

All the products formed by methylmalonic chloride or ethylmalonic chloride under similar conditions will have the same general constitution. With ammonia and the alkaline hydroxides or carbonates, they all give an intense red coloration, which is due to the hydrogen attached to the carbon between the two ketonic groups, for if this hydrogen is displaced by ethyl the coloration is not produced. The chromogenic power also disappears if the diketone is oxidised by a ferricyanide in presence of an alkali.

With hydroxylamine, the diketone yields a dioxime which crystallises in aggregations of needles, and melts at 235° with some previous decomposition. When heated with baryta-water at 195—200°, the diketone yields monobasic *methylbutylphenylacetic acid*, which melts at 74°, is only slightly soluble in water, and crystallises with difficulty. When this acid or the original diketone is oxidised, it yields propionic acid and bibasic *methylcarboxyphenylacetic acid*, $COOH\cdot C_6H_3Me\cdot CH_2\cdot COOH$, melting at 178°. When the latter is heated at its melting point, it loses carbonic anhydride, and yields a dimethylbenzoic or a methylphenylacetic acid melting at 113—114°.

C. H. B.

Compounds of the Euxanthone Series. By E. PHOMINA (*Chem. Centr.*, 1889, ii, 762; from *Arch. sci. phys. nat. Genève* [3], **21**, 429—440).—In continuation of the author's researches on the hydroxyketones, he finds that potassium hydroxide converts the ketone oxides into dihydroxyketones of the general formula $OH\cdot C_xH_m\cdot CO\cdot C_xH_y\cdot OH$. Attempts to substitute hydrogen for the "ketone" oxygen by reducing agents such as hydrogen iodide or zinc-dust proved fruitless.

β-Hydroxynaphthylhydroxyphenyl ketone, $OH\cdot C_{10}H_6\cdot CO\cdot C_6H_4\cdot OH$, melts at 168—169°, and dissolves in organic solvents, but is insoluble in water. The potassium salt crystallises in minute, sulphur-yellow needles. The *dimethyl ether* melts at 66—68°, and dissolves in organic solvents, from which it crystallises in small plates. The *diethyl ether*, which melts at 138—141°, is soluble in alcohol and benzene, crystallising from the latter in plates. The product from benzene appears to be impure. The *diacetate* melts at 107—108°, and crystallises in plates from alcohol. The *hydrazone* melts at 198°. The *oxime* melts at 187—188°, and is soluble in alcohol and benzene.

Hydroxy-α-naphthylhydroxyphenyl ketone, $OH\cdot C_{10}H_6\cdot CO\cdot C_6H_4\cdot OH$, melts at 64—66°, and is readily soluble in benzene and alcohol. The *diacetate* melts at 135—137°, and crystallises in yellow plates. The *oxime* melts at 195—196°, and dissolves readily in alcohol and benzene.

Hydroxytolylhydroxyphenyl ketone, $OH\cdot C_6H_3Me\cdot CO\cdot C_6H_4\cdot OH$, is an oil, and its derivatives appear also to be oils; they were not analysed.

J. W. L.

Tertiary Pyrrolines. By G. DE VARDA (*Gazzetta*, **18**, 546—548).—In a preceding communication (Abstr., 1889, 57), the author showed that 1-methylacetylpyrroline yields 1-methylpyrrylglyoxylic acid on oxidation with potassium permanganate. In order to determine the position of the acetyl and of the glyoxylic residue, the acid was brominated by Ciamician and Silber's method, with a view to its subsequent transformation into methyldibromomaleimide. The product described was supposed to be 1-methyldibromopyrrylglyoxylic acid; this composition is now confirmed by analysis.

On adding the brominated acid to 10 times its weight of fuming nitric acid, heating, and diluting with water, an oil separates, which may be removed by distillation in a current of steam, leaving a turbid liquid; on cooling, the latter deposits long, colourless needles which melt at 121° to a faintly yellow liquid, and exhibit all the properties of methyldibromomaleïmide. The two atoms of bromine in 1-methyldibromopyrrylglyoxylic acid therefore occupy the positions 3 : 4; 1-methylacetylpyrroline and its product of oxidation, 1-methylpyrrylglyoxylic acid, must therefore contain the acetyl or glyoxyl residue in one of the positions 2 or 5.

1-*Methyltribromopyrrylglyoxylic acid.*—By prolonged boiling of an acetic acid solution of 1-methylpyrrylglyoxylic acid with a large excess of bromine, a yellow, crystalline product is formed, which after repeated recrystallisation still contains more than 2 atoms of bromine; the author considers this product to be a mixture of 1-methyl-di- and tribromopyrrylglyoxylic acids. S. B. A. A.

Phenanthridine. By A. Pictet and H. J. Ankersmit (*Ber.*, 22, 3339—3344).—*Phenanthridine,*

$\begin{array}{l} C_6H_4\cdot CH \\ \vert \qquad\ \ \Vert \\ C_6H_4\cdot N \end{array}$

, was obtained by passing the vapour of benzylideneaniline, $CHPh{:}NPh$, through an iron tube filled with pumice and heated to bright redness or nearly to whiteness. It crystallises in long, white needles, melts at 104°, and boils above 360°. It is slightly soluble in boiling water, readily so in alcohol, ether, carbon bisulphide, chloroform, and benzene, and is somewhat volatile in steam. Its aqueous solution shows a slight blue fluorescence. When cold it is odourless, but its vapour is pungent, though less so than that of acridine. It is a tolerably strong base, and yields yellow and mostly crystalline salts, which are more soluble, less coloured, and not so fluorescent as the corresponding acridine salts. The *hydrochloride* forms broad needles, the *nitrite* yellow crystals. Phenanthridine forms no nitrosamine, and is therefore a tertiary base. The *platinochloride* crystallises in needles which are still solid at 225°; the *aurochloride* in prismatic needles almost insoluble in boiling water; the *mercurochloride* in prisms or needles melting at 190°; the *picrate* in thin needles still solid at 220°; the *dichromate* in hair-like needles easily soluble in hot water; the *methiodide* in thick prisms melting at 199—201°; and the *methochloride platinochloride*, $(C_{13}H_9N,MeCl)_2PtCl_4$, forms a nearly white precipitate.

Phenanthridine thus resembles its isomeride, acridine, very closely, the principal difference being in the behaviour of the two substances with reducing agents, acridine yielding a non-basic derivative, and phenanthridine a hydro-base which crystallises in white needles melting at 100°; it has not yet been analysed.

In preparing acridine salts for comparison, the authors found the melting point of acridine mercurochloride to be 225°. L. T. T.

Cinnamylcocaïne occurring naturally in Coca Leaves. By F. Giesel (*Chem. Centr.*, 1889, ii, 765; from *Pharm. Zeit.*, 34, 516).—The author has isolated cinnamylcocaïne from the crude bases. Its properties agree completely with those of the synthetically prepared specimens. It differs from cocaïne in its high melting point, 121°, and in its decomposition with potassium permanganate, in which case benzaldehyde is formed. Hydrolysis is effected by hydrogen chloride, when ecgonine and cinnamic acid are formed quantitatively. The author recommends the reaction with potassium permanganate as a sure means of detecting this base in commercial samples of cocaïne. The amorphous isatropylcocaïnes would not be included in this reaction, but could hardly be present in a well-crystallised specimen of cocaine (compare Abstr., 1889, 186, 283, 419: this vol., p. 310). J. W. L.

Brieger's Typhotoxine. By L. DE BLASI (*Gazzetta*, **18**, 521—527). —To determine whether the ptomaine obtained by Brieger from the broth cultures of Eberth's bacillus is due to the specific action of that organism, or only to the action of heat and acids on the albuminoids, three portions of a slightly alkaline sterilised beef extract were taken, and to two of these (A and B) a pure culture of Eberth's bacillus was added, and to the third portion (C), a pure culture of *Micrococcus candidans;* they were then allowed to remain at a temperature of 37° for 40 days and treated as follows:—

A.—This portion was directly extracted first with ether and then with chloroform; the ethereal extract was treated with water, acidified with a few drops of hydrochloric acid, the solution made alkaline with soda, again extracted with ether, washed, and distilled. On acidification, the residue gave a slight greenish coloration with phosphomolybdic acid, a reddish-yellow precipitate with potassiomercuric iodide, a yellow precipitate with a solution of iodine in potassium iodide, and a white precipitate with mercuric chloride, but no reaction was obtained either with tannin, platinic chloride, or potassiobismuth iodide.

No indication of the presence of any alkaloïdal compound was obtained either from the ethereal distillate or from the chloroform extract.

B was treated by Brieger's method, and the alcoholic extract divided into two parts. In one of these, platinic chloride produced no precipitate, but auric chloride yielded a precipitate of yellowish, hexagonal prisms containing 40·38 per cent. of gold. The other portion was freed from alcohol, and the residue taken up with water. The solution gave precipitates with phosphomolybdic acid, potassiomercuric iodide, potassiobismuth iodide, and with a solution of iodine in potassium iodide. Tannin produced no effect.

C was treated by Brieger's method. The alcoholic extract gave no precipitate with either platinic or auric chloride; the aqueous solution yielded a slight brown precipitate with a solution of iodine in potassium iodide, but did not react with any of the other reagents.

On inoculating a guinea-pig with an aqueous solution of the extract from B, pathological symptoms were developed identical with those described by Brieger; inoculation with the extract from the micrococcus culture gave rise to no morbid symptoms whatever. The author concludes that the method of direct extraction is valueless for the isolation of any definite alkaloïd, but that Brieger's method is efficient, and that the negative result obtained from the culture of the non-pathogenic organism demonstrates that typhotoxine is either the direct product of the activity of Eberth's bacillus, or is due to the secondary action of heat and acids on some unstable substance produced by that bacillus. The results of inoculation with the substances extracted from the culture of *M. candidans* prove that the action of heat and acids was ineffectual to produce any toxic substance from it. S. B. A. A.

Composition of Albumin. By E. HARNACK (*Ber.*, 23, 40—43).—The author has determined the amount of sulphur contained in the albumin free from ash, the preparation of which he has recently described (this vol., p. 272), and finds, as a mean of five closely agreeing analyses, that it contains 1·91 per cent. This number is higher than the one previously obtained by the author, but agrees with that found by Lieberkühn, and also by Loew (*Pfluger's Archiv*, 31. 393); and the empirical formula suggested by the latter, namely, $C_{210}H_{330}N_{52}O_{66}S_3$, is regarded as the most probable.

A comparison of the number of sulphur-atoms and the number of carbon-atoms in the different albuminoids, according to the present analysis, shows a very curious relation—

Thus in egg-albumin there is 1 atom of sulphur to 70 of carbon.
„ globulin „ „ „ 146 „
„ hæmoglobin „ „ „ 350 „

or the numbers of carbon-atoms present for each sulphur-atom in these three compounds are in the almost exact proportion of 1 : 2 : 5. Whether this simple relation is due to chance or not, can only be ascertained by a long series of further investigations. H. G. C.

Physiological Chemistry.

Respiration in the Horse during Rest and Work. By F. SMITH (*J. Physiol.*, 11, 65—78).—Recently Zuntz and Lehmann (*Zeit. wiss. Landwirthsch.*, 18) have published a paper on this subject. They placed the horse on what was practically a treadmill, in order to obtain work. In the present research, 35 horses were used, and 250 experiments made in all. A closely-fitting mask was fitted on the horse's face; this was connected by tubes with a meter to measure the gases; the expired air was collected, and for the analysis Hempel's apparatus with absorption pipettes was used. In one series of experiments, A, water was used as a confining medium; in another series, B, mercury was employed instead. The horse was allowed to perform natural work: walking, trotting, galloping, &c.; and immediately after coming in, the mask was adjusted, and an observation made. The mask was on for 20—30 seconds in each experiment. This method is regarded as being superior to the method of artificial work produced by Zuntz and Lehmann's moveable platform.

The capacity of a horse's lungs is about 1 cubic foot, the rate of respiration during repose is 9 to 12 per minute; this is accelerated by work in proportion to the severity of the work. The diet employed was 12 lbs. of hay and 10—12 lbs. of oats daily.

The following table gives a summary of the respiratory changes at the different paces:—

	Series.	Air expired per hour in cubic feet.	CO_2 expired per hour in cubic feet.	O absorbed per hour in cubic feet.	Respiratory quotient.	Undetermined gases per hour in cubic feet.

W. D. H.

Influence of Inorganic Salts on Development. By S. Ringer (*J. Physiol.*, **11**, 79—84).—In a number of communications (*J. Physiol.*, **4**, **5**, **6**, **7**), the author has previously shown the necessity of inorganic salts for sustaining life and vital activity, in muscular contraction, the heart beat, the action of cilia, and the life of fishes. Of these, calcium salts seem the most important, and there is antagonism between the action of these salts and those of sodium and potassium. An excellent fluid for sustaining the heart's beat is made by mixing suitable small proportions of the salts of all these metals; and of the calcium salts, the phosphate appears to be the most effective. A fish which dies in distilled water in a few minutes lives for weeks in river water, which always contains the necessary saline ingredients. In the present researches, the inquiry is extended in order to ascertain whether the same is true for the development of frog's spawn, and the growth of tadpoles, and it was found that it is so. Placed in distilled water, they die in a few hours; the addition of sodium hydrogen carbonate, or of lime-water, or calcium chloride, is insufficient to maintain life. Calcium hydrogen carbonate and tribasic calcium phosphate, on the other hand, sustain life for a considerable time, and development progresses. It would appear that those salts of lime where the base is least saturated by the acid are those most capable of sustaining function. W. D. H.

Method of Raising the Specific Gravity of the Blood. By W. Hunter (*J. Physiol.*, **11**, 116—120).—After injecting blood into the peritoneal cavity of an animal, the blood corpuscles of the animal become, within an hour or two, apparently much increased in number. This is not a real increase, but is due to the fact that the density of the animal's blood (as determined by Roy's method, Abstr., 1887, 608) is increased. The increase of specific gravity is due to the fact that the injection into the peritoneum sets up irritation, and leads to the transudation of blood plasma from the circulation. Later this subsides, and then there is a real increase in the animal's blood corpuscles, due to absorption of those from the foreign blood which is injected. The injection of a solution of sodium phosphate, or other neutral salt, similarly raises the specific gravity of the blood; but the effect is not so marked and is more transient.

W. D. H.

Human Chyle. By D. Noël Paton (*J. Physiol.*, **11**, 109—114).—Very few analyses of human chyle have been recorded. Rees obtained a specimen from a criminal after execution (*Phil. Trans.*, 1842). Specimens have also been obtained in cases where the thoracic duct or the lacteals have ruptured into a serous cavity; here, however, one has to deal with a mixture of chyle and the lymph of the serous membrane. In one of these cases, the analysis was made by Hasebrock (Abstr., 1888, 736).

In the present case, chyle was obtained from a patient in whom the thoracic duct had been cut in an operation for the removal of a tumour of the neck. Systematic observations could only be made at the time when the patient was in an emaciated and dying condition; but from these it was roughly estimated that in health, the flow must have been between 3,000 and 4,700 c.c. in 24 hours, or between 5·2 and 7·9 kilos. per 100 kilos. of body weight. Four specimens were obtained for analysis; the following table gives the results in parts per 1,000:—

Water	943 —958
Solids	56 — 41
Inorganic	6·2 — 6·7
Organic	35 — 50
Proteïds	11·8 — 13·7
Fats	24
Cholesterin	0·6
Lecithin	0·36

The percentage of solids gradually decreased as the patient became weaker; this was due to a decrease in the organic constituents. The proteïds were present in smaller amount than in previously recorded analyses. The diet given was rich in fats, which accounts for the high percentage of fat in the chyle.

W. D. H.

Nutritive Value of Different Albuminoïds. By S. Gabriel (*Bied. Centr.*, **18**, 807—815; from *J. f. Landw.*, **37**, 175—190).—A wether was fed daily with barley-straw (500 grams containing 3·25 grams of nitrogen) and an amount of albumin containing 9 grams of nitrogen; this latter was mixed with starch in such quantity that the amount of non-nitrogenous extract always remained the same. The experiment was divided into eight periods, in the first seven of which a different albuminoïd was used; in the last, no albuminoïd was given. The substances given daily during the eight periods were as follows:—I, rye (559·00 grams); II, peas (272·73 grams), and starch (302·28 grams); III, conglutin (63·02 grams), and starch (512·32 grams); IV, meat meal (free from fat, 63·65 grams), and starch (512·32 grams); V, albumin (74·87 grams), and starch (512·32 grams); VI, caseïn (71·31 grams), and starch (512·32 grams); VII, glutin (63·38 grams), and starch (512·32 grams); VIII, starch (580·32 grams). In each case the animal had, in addition, salt (8 grams) and water (3 litres); the water which was left was weighed. The urine and fæces were daily collected, weighed, and the nitrogen determined. The amount of nitrogen digested was found by subtracting the amount in the fæces from the amount in the food (12·25 grams); whilst the amount of nitrogen of the albuminoïd food which remained undigested was found by subtracting 4·4 grams (the amount of nitrogen in the fæces during the period (VIII) when no albumin was given) from the nitrogen of the fæces from the other experiments. The results indicate that of the pure albuminoïds (III, V, VI), 12·2 to 15·5 per cent. remains undigested. Stutzer found in artificial digestion experiments for conglutin 0·98 per cent., and for caseïn 8·24 per cent. of the total nitrogen remained undigested. When the amount of nitrogen fixed by the animal (the nitrogen digested less that of the urine) is calculated to a percentage of the total digested nitrogen, great differences are found. The number for meat meal is 41·88, for rye 6·31, and for conglutin, albumin, caseïn, and free albumin 27·70, 32·56, 29·77, and 21·82 respectively. The fact that when glutin, which is not capable of assimilation, was given, the animal not only did not lose, but gained nitrogen, points to the conclusion that the glutin saved the whole of the digestible albumin of the straw from being destroyed and caused it to be deposited.

With regard to the last period where no albumin was given, it was found that the fæces always contained starch; this observation agrees with that of Haubner and others that large amounts of starch are only completely digested when a certain amount of albumin is present.

Neither the nitrogen nor the carbon in different albuminoïds forms a criterion of their nutritive value. Conglutin, which differs most in its composition from other proteïds, approaches albumin and caseïn very nearly. On the whole, the three animal albuminoïds seem to act more favourably than those of vegetable origin; but more experimental evidence is required before generalising this fact.

N. H. M.

Value of Commercial Foods. By W. Kniebim (*Bied. Centr.*, **18**, 815—820).—The object of the experiments first described was to determine the relative values of several kinds of cake with regard to the production of milk. The cow received 15 kilos. of clover-hay and 1·5 kilo. of cake. Rape-cake produced an increased amount of milk on the first day; the same was observed with cocoanut-cake. The increase was, in both cases, considerable, and the effect of the cocoanut-cake was more lasting than that of the rape-cake. In other experiments, in which 10 kilos. of green fodder was given, linseed-cake (1·5 kilo.) gave an increase of 12 per cent., and cocoanut-cake raised the yield of milk by 11 per cent.; hemp-cake had no effect at all. Sunflower-cake, poppyseed-cake, and cocoanut-cake (1·5 kilo. in each case) were given, together with meadow hay of bad quality (14 kilos.); in each case the yield of milk was considerably increased —the greatest increase being produced by the cocoanut-, and the least by the sunflower-cake.

Further experiments are described, in which oat-meal, sunflower-cake, cocoanut-cake, and pea-meal (1·5 kilo.) were given, along with a still poorer food, consisting of hay (9 kilos.) and oat-straw (3 5 kilos.). Cocoanut-cake and sunflower-cake gave equally good results; pea-meal was less effective.

In order to determine whether the failure of hemp-cake was due to its being less digestible, experiments were made with bullocks, horses, sheep, and rabbits. The effect on bullocks was comparatively slight. The horses were found to be capable of doing much less work when much hemp-cake was given to them, whilst with sheep the cake was found to be distinctly injurious, causing the animals to become thinner. Rabbits could not be kept alive on hemp-cake alone. It is possible that the cake might give better results when used with less nitrogenous fodder.

Sesame-cake was also found to be a very good milk producer.

Experiments with rabbits showed that cotton-seed-cake and earth-nut-cake are very digestible. N. H. M.

Nutritive Value of Wheat-meal. By A. W. Blyth (*Proc. Roy. Soc.*, **45**, 549—553).—In these experiments, two persons were fed on whole-meal and distilled water for a period of 28 days in one case, and a week in the other, the food and excreta being analysed in each case. The experiment on the first patient consisted of three parts: (1) a period of 8 days, during which the insufficient quantity of 16 ozs. per day of whole-meal was taken; (2) a period of 14 days, during which 20 ozs. per day was taken; and (3) a period of 7 days, during which 28 ozs. per day was taken. In the second case the proportion of whole-meal per day was 16—22 ozs. In the first case there was loss of weight during the first two periods, but a slight increase during the third. In the first period, nitrogen was excreted in excess of that ingested, phosphoric acid was in equilibrium, but more salts were excreted than taken in. In the second period nitrogen and phosphoric acid were in equilibrium, and there was retention of salts. During the third period there was retention of nitrogen, phosphates being in equilibrium. In both cases there was an excretion of sulphates in the urine, and of unoxidised sulphur from the intestinal canal, although the flour only contained traces of sulphur. In the first case, chlorine was excreted in excess of that taken in. The above renders it evident that the sulphur in albumin is of importance as a food, and that the sulphur excreted must have been obtained from sulphur stores in the body. If the excretion of the bowel is considered as waste, then 15·6 per cent. of the nitrogen in food is not assimilable, 37 per cent. of the fat is not digested, and 51·8 per cent. of the ash also passes away. H. K. T.

Occurrence of Mercury in Tapeworms. By L. Oelkers (*Ber.*, **22**, 3316—3317).—Two tapeworms from a syphilitic patient, who had used mercury ointment, were found to show a peculiar grey colour, due to the presence of some mercury compound, probably the oxide or sulphide. F. S. K.

Influence of Nicotine and Atropine on Salivary Secretion. By J. N. LANGLEY (*J. Physiol.*, 11, 123—158).—This paper, which is the sixth in a series of communications on the salivary secretion, relates chiefly to the connections of the nerves which pass to the submaxillary and sublingual glands to various groups of nerve-cells or ganglia in different animals. An important method of determining this point depends on the fact that, whereas atropine paralyses the secretion by affecting the nerve-endings, and has no poisonous effect on nerve-cells or gland-cells, nicotine, on the other hand, produces a somewhat similar effect, by its poisonous effect on nerve-cells; it leaves nerve-fibres and gland-cells intact; this is true, whether the drug be injected into the circulation, or applied locally to the ganglion. W. D. H.

Influence of Sodium Phosphate on the Excretion of Uric Acid. By A. HAIG (*Medico-Chir. Trans.*, 72, 399—406).—Disodium hydrogen phosphate is a well-known solvent of uric acid, and increases the excretion of that substance. When, however, commercial preparations of the phosphate were employed in cases of gout, it was found that attacks were precipitated, and both in these cases and in healthy persons the amount of uric acid excreted was diminished. Analysis revealed the fact that these preparations contained from 1·2 to 6·8 per cent. of sodium sulphate; it is this impurity which causes the retention of uric acid. The pure phosphate prepared from sodium hydroxide and phosphoric acid acts as stated at the commencement of this abstract.

The addition of a little sodium hydrogen carbonate increases the efficiency of the phosphate in this direction; the addition of acid (such as dilute phosphoric acid, which causes the formation of dihydrogen sodium phosphate) diminishes it. The acid phosphate is another frequent impurity of commercial preparations, and this is an additional reason why the pure salt should be employed. The phosphate and the salicylate (Abstr., 1888, 1322) act differently in relation to acidity of the urine, the excretion of uric acid being hindered by acidity in the former case, accelerated in the latter. In many cases where the powerful effect of salicylate is unnecessary, or its toxic effects are to be feared, the use of the phosphate as a substitute is recommended. W. D. H.

Clay-coloured Stools without Jaundice. By T. S. WALKER (*Medico-Chir. Trans.*, 72, 257—273).—The object of this paper is to establish the following propositions:—That the presence of the pancreatic juice in the intestines is as essential as that of the bile to produce the brown colour (stercobilin) of the dejections; that clay-coloured stools may, consequently, be caused by disease of the pancreas when the liver is perfectly healthy; that they may be caused either by cutting off the supply of bile as in ordinary obstructive jaundice, or the supply of pancreatic juice; that the bile pigment which appears in the fæces is that only which has been acted on by the pancreatic juice, and that consequently the latter organ has a hitherto unsuspected physiological and pathological importance as a factor in the elimination of bile.

These propositions are supported by the records of two cases: *Case* 1 was that of a man who died in his ninety-first year, and who, for 24 years previously, had passed colourless stools; during all this time, except for a few days, jaundice was absent. *Post mortem*, the liver was healthy, the bile-ducts patent, and fresh bile was present in the duodenum. The pancreas, on the other hand, was enlarged, and its duct absolutely impervious, owing to the presence in it of a large stone, about 8 inches long. *Case* 2 was similar; clay-coloured stools occurred for seven years; jaundice was absent. *Post mortem*, liver and bile-ducts healthy; pancreatic duct obliterated, owing to cicatrisation of an old ulcer. In these cases the question arises what becomes of the bile-pigment, and it is suggested that as it is not acted on by pancreatic juice, it is completely reabsorbed.

In conclusion, it is pointed out that Bernard noticed the occurrence of a brown tint when bile was mixed with pancreatic juice; that previous clinical observers have, in a few scattered cases, noted the simultaneous occurrence of clay-coloured stools with pancreatic disease, and that in the fœtus, meconium is coloured by unchanged bile-pigments, not by stercobilin; the pancreas not beginning to secrete until after birth, and the process of absorption being probably also in abeyance until then. W. D. H.

Physiological Action of the Active Principle of Jequirity. By S. Martin and R. N. Wolfenden (*Proc. Roy. Soc.*, 46, 94—100).—Klein has shown that the poisonous properties of the seeds of *Abrus precatorius* (jequirity) cannot be due to a bacillus, and Warden and Waddell (Non-bacillar nature of Abrus poison, Calcutta, 1884) showed it to be due to the action of a poisonous proteïd. The proteïds in the seeds are two in number, a globulin and an albumose, and the present paper relates to the physiological action of the first of these. The proteïds were obtained by extracting the crushed seeds with 15 per cent. solution of sodium chloride; they were precipitated from this extract by saturation with ammonium sulphate; the precipitate was redissolved by adding water; and from this solution the globulin was precipitated by dialysis, collected, washed, and dried.

The actions ascribable to this globulin are the production of local œdema and inflammation when subcutaneously injected or applied to the eye, the presence *post mortem* of petechiæ beneath the serous membranes, and the occurrence of hæmorrhagic gastro-enteritis. It also produces a remarkable fall of body temperature after subcutaneous injection, and in lethal doses, it causes rapidity of breathing shortly before death. It has little or no effect on blood pressure. The activity of this globulin is destroyed by heating the solution to 75° or 80°, the temperature at which it enters into the condition of a heat coagulum. W. D. H.

Toxic Action of the Albumose from Jequirity Seeds. By S. Martin (*Proc. Roy. Soc.*, 46, 100—108).—This is a continuation of the research of which the preceding abstract is a *résumé*. The albumose was obtained by precipitating the two proteïds of the seeds by means of alcohol. The precipitate was allowed to remain under absolute alcohol for several months: the globulin was thus rendered insoluble; the albumose, however, was freely soluble in water after this treatment. It gave the following reactions: The aqueous solution was neutral to litmus-paper, and gave no precipitate on boiling. Acetic acid and also nitric acid gave precipitates which dissolved on heating, and reappeared on cooling. Copper sulphate gave a precipitate soluble in excess of the reagent. Copper sulphate and potash gave a "biuret" reaction. Mercuric chloride gave a precipitate insoluble in excess of the reagent. The symptoms produced by the albumose closely resemble those noticed when the globulin is hypodermically injected. There is gradually increasing weakness, with rapid breathing and lowering of body temperature, but no convulsions or paralysis. It also causes severe conjunctivitis when applied to the eye. Its poisonous properties are lessened by heating at 70—75°, and completely destroyed at 85°.

The albumose is not, however, so powerful a toxic agent as the globulin, the dose necessary to produce the same effects being larger.

A comparison is drawn between the action of these proteïds and those of other poisonous substances of the same class, especially those in snake-venom.

The following table contrasts the activity of the venom of various snakes and of Abrus:—

Common adder.—Fatal dose in man, 0·0021 gram per kilo. of body weight (Fontana).

Australian tiger-snake.—Fatal dose in dog, 0·00485 gram per kilo. of body weight.

Cobra.—Fatal dose in dog, 0·000079 gram per kilo. of body weight (Vincent Richards).

Abrus poison—

Globulin.—Fatal dose, 0·01 gram per kilo. of body weight.

Albumose.—Fatal dose, 0·06 gram per kilo. of body weight.

Peptic albumoses.—Fatal dose in dog, any dose over 0·3 gram per kilo. of body weight (Pollitzer).

W. D. H.

Acetonuria and Diabetic Coma. By S. West (*Medico-Chir. Trans.*, 72, 91—110).—A systematic examination of the urine for acetone was made in a number of cases of healthy people, of those suffering from various complaints, and of those suffering from diabetes. The tests employed were le Nobel's or Legal's nitro-prusside test, and Lieben's iodoform reaction. The first was applied to the urine direct, the latter to the distillate from the urine. In addition to these, the red reaction which is given by ferric chloride was sought; whether this is produced by ethyl acetoacetate or some allied compound is at present uncertain. The main results of the investigation were as follows:—Acetone is absent, or almost so in healthy urine. Acetonuria is common in diabetes without coma, and is not constantly present in cases of diabetic coma. It varies greatly in the same case from time to time, without any evident cause. It stands in no relation to the amount of sugar in the urine, but varies independently of variations in the sugar and specific gravity. It is, moreover, often found in other diseases than diabetes; for instance, in four cases of pneumonia, in one case of cirrhosis of the liver, in one of spinal affection, in one of cerebral hæmorrhage, and in one of delirium tremens.

The iron reaction (? diaceturia), on the other hand, is rare except in cases of diabetes. It may be present when acetone is absent, or absent when acetone is present. They may, however, be both present or both absent at the same time, and neither appears to stand in any definite relation to coma. The presence of acetone in the urine, or the occurrence of the iron reaction is, however, by no means without clinical significance. They indicate defective metabolism, and that the patient is in a worse condition than when the tests applied gave negative results. Acetone and the substance which gives the iron reaction may be bye-products in the formation of the at present unknown poison, and their presence often indicates the presence of this poison and the onset of coma. The occurrence of the iron reaction should be regarded as more serious than that of acetone.

These conclusions confirm in the main those of v. Jaksch (*Acetonuria u. Diaceturie, Berlin*, 1885); the terms acetonæmia and acetonuria are misleading if used as synonymous with diabetic coma.

W. D. H.

Pernicious Anæmia. By F. W. Mott and S. A. Vasey (*Lancet*, 1890, 1, 287—289).—In a case of pernicious anæmia previously recorded (*Lancet*, 1889, 1, 520), it was noted that the urine had a high colour, although its specific gravity was low, and that the liver *post mortem*, on staining sections with potassium ferrocyanide and hydrochloric acid, became intensely blue and thus gave evidence of excess of iron. It was therefrom inferred that in the liver the hæmoglobin of the corpuscles is split up into an iron-free pigment of the nature of hydrobilirubin, which passes into the urine as urobilin, and an iron-containing constituent which remains behind in the liver cells.

A case of a precisely similar kind is now related, and the view above stated is fully borne out by the results of analysis:—

	Weight in grams.	Ferric oxide per cent. in organ.	Total ferric oxide in whole organ.	Total ash in organ.	Percentage of ferric oxide in ash.
Anæmic liver..	1240	0·29	3·60	1·05	27·2
,, kidney	282	traces	—	1·25	—
,, spleen.	141	trace	—	0·9	—
Normal liver...		traces, along with distinct traces of copper.	—	1·16	—

An interesting point in addition to the high percentage of ferric oxide obtained from the liver is the low percentage in the spleen. This is especially noteworthy, as the view is very generally held that the spleen is an important site for the destruction of blood corpuscles.

The above analysis, as well as certain experiments of Schäfer, showing the absence of free hæmoglobin in the blood of the splenic vein, lend no support to this doctrine.

Hunter (*Practitioner*, Sept., 1889) has published a similar case to the above. The pigment in the urine in this case was not, as in Mott's case, normal urobilin, but pathological urobilin.

Copeman (*Lancet*, 1890, 1, 375) records a fourth case of the same nature, and in this, as in Mott's case, the urinary pigment was normal urobilin. W. D. H.

Pfeiffer's Test for Latent Gout. By W. ROBERTS (*Lancet*, 1890, 1, 9—10).—At the seventh congress of German physicians (Wiesbaden, 1888) Pfeiffer introduced the following urinary test for discovering the condition known as latent gout, and the allied condition urolithiasis; the acid urine of the 24 hours is divided into two parts, one part is passed through a filter on which pure uric acid has been placed, the other part is not so treated. An equal volume of each portion is then acidified with strong hydrochloric acid, and set aside until the precipitated uric acid has fully separated. The two precipitates are collected and weighed. In normal urine, the weight is approximately the same in both cases. But in the case of gout, or uro-lithiasis, the portion passed through the uric acid filter is found to have the greater portion of its uric acid removed from it, and little or no formation of uric acid crystals occurs on subsequently treating the filtrate with hydrochloric acid. On repeating these experiments in the present research, the test was found to be most untrustworthy and misleading. Nearly all acid urines desposit a portion of their uric acid upon the pure acid on the filter; but the amount so deposited in normal acid, as well as in gouty urine, depends on the interaction of a number of factors, namely:—the degree of acidity of the urine, its comparative richness in uric acid, the rate of filtration, and the amount of uric acid placed on the filter. A simpler and more trustworthy test consists in placing several portions of the urine in corked phials in a warm place (to prevent precipitation of urates), a few drops of chloroform being added to prevent putrefaction. Sooner or later crystals of uric acid are deposited if the urine is acid; the time at which crystals first make their appearance giving an indication of the degree of precipitability of the urine, that is of its proneness to deposition of uric acid. If crystals generally appear in 2 or 3 hours, this would indicate a morbid imminence of gravel; if only after 12 or 24 hours, the occurrence does not come within the range of pathological significance. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Behaviour of the Vegetable Cell with very Dilute Alkaline Silver Solution. By O. LOEW and T. BOKORNY (*Chem. Centr.*, 1889, ii, 849—850, from *Bot. Centr.*, 1889, 39). The authors have made several further experiments with the object of determining the cause of this reaction (Abstr., 1888, 983), more especially since Pfeffer (Abstr., 1889, 1028) has concluded that the reducing power is due to albumin tannate or to tannin.

Having observed that if spirogyra be cultivated in solutions of nitrates, a part of the tannin disappears, the authors cultivated *Spirogyra nitida* in a solution containing 1 part of sodium and potassium nitrates, and of sodium and magnesium sulphates in 10,000 parts of distilled water. When sown, the spirogyra contained a fair quantity of starch, fat, and tannin. After allowing the vessel to remain for 12 days in a somewhat shaded part of the room, the algæ were quite healthy, and were, moreover, free from fat and tannin, and contained but little starch. Dilute ammonia caused a considerable precipitate, which was free from fat and tannin, but still reduced silver solution with energy. Thirty per cent. acetic acid, or protracted heating at 70—80° destroyed this reducing power. Since these tannin-free cells contain nothing besides albumin, the authors conclude that the reducing power must be attributed to it, and that the treatment with acetic acid or the process of heating causes such a change in the albumin as to destroy its reducing power. J. W. L.

Occurrence of Iodine in Fucus vesiculosus and Chondrus crispus. By L. VAN ITALLIE (*Arch. Pharm.* [3], 27, 1132—1134).—By Flückiger's method (Abstr., 1887, 996), a faint iodine reaction was obtained with 3 grams of *Fucus vesiculosus*, and with 10 grams of *Chondrus crispus*. 50 grams of the former plant was extracted with 40 vol. per cent. alcohol, the solution neutralised with sodium carbonate, evaporated to a syrup, this extracted with water, and treated with chloroform; the chloroform remained colourless. The addition of nitrous acid dissolved in dilute sulphuric acid set free its iodine, which amounted to 5·1435 milligrams, or 0·0113 per cent. of the absolutely dry substance, and 0·01029 per cent. of the plant dried over lime. The whole of the iodine was found to be extracted by the above process. The material separated by absolute alcohol gave no reaction for iodine. From these reactions, the author concludes that the iodine is present in *F. vesiculosus* as iodide. The amount of iodine in *C. crispus* was too minute to estimate. Neither plant gave evidence of the presence of bromine. J. T.

Chemical Constituents of Scopola carniolica. By W. R. DUNSTAN and A. E. CHASTON (*Pharm. J. Trans.* [3], 20, 461—464).—*Scopola carniolica* is a solanaceous plant indigenous to Austro-Hungary. It has lately been exported to this country with a view to its employment in medicine as a substitute for belladonna. The total alkaloid was extracted from the carefully dried (30—40°) rhizome, no temperature above 40° being employed in the process, and no alkali being used, except very weak ammonia, so that the possibility of the occurrence of any change in the alkaloïds during their extraction was avoided; on crystallising the alkaloid from ether, pure hyoscyamine (m. p. 108—109°) was obtained. To ascertain whether any other mydriatic alkaloïd was present, the residue obtained from the ethereal liquid was dissolved in diluted hydrochloric acid, and fractionally precipitated with gold chloride; each fraction was then recrystallised until its melting point was not changed by a repetition of the process. From the eight fractions of precipitate, 27 specimens of recrystallised aurochloride were obtained. With the exception of what was possibly a trace of hyoscine aurochloride, nothing but hyoscyamine aurochloride was found (m. p. 159—162°, corr.). A similar process of fractional precipitation of the aurochloride was conducted with a small quantity of alkaloïd, which had not been extracted by ether from the alkaline aqueous liquid. This yielded only hyoscyamine aurochloride. The salt was identified by its melting point, as well as by the results afforded by its analysis; the alkaloïd was also regenerated from it, and shown to correspond with pure hyoscyamine. The plant is abundant, and would therefore seem to constitute an important source of this alkaloïd. The rhizome is also shown to contain rather more than 0·1 per cent. of cholesterol, melting at 132—133°, and affording analytical results which agree with the formula $C_{26}H_{44}O + H_2O$. When dried at 100°, the crystals lost water, leaving the anhydrous substance, which melts at 137·5°. The benzoate was prepared by dissolving the substance in benzoic chloride, and heating the liquid for 15 minutes near its boiling point. On pouring it into aqueous soda, the benzoate remains insoluble; after purification and crystallisation from ether, it melted at 145·5°. The cholesterol from *S. carniolica* most nearly resembles the phytosterin of Hesse. The substance has not before been obtained from an atropaceous plant, but the authors have since isolated it from *Atropa belladonna.* There were also obtained from *S. carniolica* a fat which is under examination, a crystalline sugar yielding an osazone identical with that of dextrose, and a crystalline substance whose aqueous solution when alkaline is highly fluorescent, and appears to be methylæsculetin. The paper is followed by others in which different observers record the results of therapeutical, botanical, and pharmaceutical examinations of the plant. Therapeutically it appears to have some marked advantages as compared with belladonna. W. R. D.

Analyses of the Seed of Calycanthus glaucus. By H. W. Wiley (*Amer. Chem. J.*, 11, 557—567).—The analyses cannot be given in full. The seeds were found to contain only a very small quantity of starch, but large amounts of sugars, albuminoïds, and oil: there being as much as 47 per cent. of the latter.

This oil has a faint yellow colour, and a peculiar odour. Its sp. gr. when obtained by extracting the seeds with petroleum = 0·9058; the sp. gr. of the expressed oil = 0·9110 (water at 100° = 1). It is free from volatile acids, gives a fatty acid crystallising at 12·5°, and has a refractive index of 1·47351 at 28° (water at 28° = 1·33338). The crude expressed oil absorbs 129·53 per cent. of iodine, the purified extracted oil 128·66 per cent.

The oil contains an alkaloïd discovered by Eccles, and named by him *calycanthine.* This was obtained from the seeds by powdering them, extracting the fat with petroleum, and digesting the residue with various liquids, best with dilute sulphuric acid (1 : 50). The sulphuric acid extract is made strongly alkaline with ammonia, and extracted repeatedly with ether; on evaporating the ether extract, calycanthine crystallises in feathery masses on the sides of the dish. The kernels of the seeds contain about 3 per cent. of the alkaloïd, the hulls about 1 per cent. The alkaloïd is insoluble in alcohol and water. With sulphuric acid, it gives a pale-yellow colour, with nitric acid a persistent bright-green, with sulphuric acid and potassium dichromate a fine, blood-brick-red, and with sulphuric acid and cane-sugar a fine purple, persisting for some time, and finally changing to blue. Owing to the presence of sugar in the seed, this last reaction may be obtained by the simple application of sulphuric acid to the raw seed. C. F. B.

Bark of Quina morada (Pogonopus febrifugus, Benth.-Hook.). By P. N. Arata and F. Canzoneri (*Gazzetta*, 18, 409—421).—The authors have examined a specimen of bark found in Bolivia and in the north of the Argentine Republic, commonly known as "Cascarilla," or "Quina morada," and credited with many of the therapeutic characteristics of the true cinchona bark. For a variety of reasons the authors consider it to belong to the *Pogonopus febrifugus, Benth.-Hook.*, syn. *Howardia Wedd*, *rubiacea*, described by Griselbach. In appearance the bark is irregular on the outside and scaly within; the colour varies from yellowish-white to reddish, and is a dirty-white on freshly-exposed surfaces; it is soft and spongy to the touch, a little lighter than water, has a slightly bitter taste, scarcely any odour, and burns very readily, leaving a white ash. It imparts a bluish fluorescence to water with which it has been boiled, and a yellowish-blue fluorescence to alcohol.

Two substances were extracted from this bark, namely, a blue fluorescent substance, moradin, and an alkaloïd, moradëine.

To isolate these, the powdered bark is extracted with alcohol, the extract treated with an alcoholic solution of lead acetate, filtered, freed from lead, and concentrated, when a crystalline deposit of moradin is obtained. The mother liquor is then treated with potash and ether, the ethereal extract treated with hydrogen chloride, and the precipitate of moradeïne hydrochloride purified by again treating it with soda, ether, &c.

Moradin contains no nitrogen, and its formula is either $C_{21}H_{18}O_8$ or $C_{16}H_{14}O_6$. The former agrees better with the composition of the acetyl-derivative, triacetylmoradin.

Moradin crystallises in slender, colourless needles, or in large, anhydrous prisms, and melts at 201—202°. It has the characters of an acid, but none of its salts could be isolated. Alkalis increase, and acids (except acetic) diminish the fluorescence of its solutions. Ferric chloride gives a green coloration and, after a time, a green precipitate; gold chloride gives a blue coloration and green precipitate. It is dissolved by concentrated sulphuric acid, forming a yellow solution, from which it is re-precipitated unchanged on adding water. Although not a glucoside, it reduces Fehling's solution when heated with it; it also reduces silver nitrate and basic lead nitrate. Potassium permanganate in alkaline solution and ferric chloride in alcoholic solution oxidise it to quinone. The action of nitric acid is characteristic; the concentrated acid has no action in the cold, but forms oxalic acid on heating; on boiling with very dilute (4 per cent.) acid, quinhydrone and quinone are successively formed. Its reactions place it in the class of oxyhydroquinones, since it gives as products of decomposition a di- or tri-hydroxybenzoic acid which colours ferric salts green, a polyvalent phenol, probably hydroxyquinol, and quinone. It is probable that two of the oxygen-atoms are contained in the same way as in hydroxycoumarin (umbelliferon).

Triacetylmoradin crystallises from its alcoholic solution in white, shining prisms which melt at 177—178°. It is not fluorescent, and has no acid properties. It is insoluble in alkalis in the cold, and decomposes when warmed with them.

Moradeïne crystallises in opaque, colourless prisms, very soluble in alcohol, ether, chloroform, &c., but only slightly in water. It melts at 199—200°, and exhibits the general reactions of an alkaloïd, forming a well-crystallised platinochloride and aurochloride, &c.

S. B. A. A.

True Winter Bark. (Drymis Winter-Forster.) By P. N. ARATA and F. CANZONERI (*Gazzetta*, 18, 527—539).—After an historical summary of the introduction of the bark into Europe, the author describes the genuine bark from the Straits of Magellan; this occurs in the form of deeply-furrowed, curled-up fragments with an earthy fracture, exhibiting, when in small pieces, an internal reddish-brown coloration. When fresh, it has a bitter and pungent taste and an agreeable odour, recalling both turpentine and cloves. The sun-dried bark yielded: water (at 110°), 13·713 per cent.; ash, 3·338 per cent.; soluble in ether, 3·841 per cent.; in alcohol, 6·465 per cent.; in water, 13·981 per cent.; ligneous matter, 49·200 per cent. An analysis of the ash is also given. The ethereal solution contains a peculiar essence, fatty compounds, resins, and waxy matter; the alcoholic extract contains reddish, uncrystallisable resins. Citric acid was carefully looked for, but not found. The essence was isolated by distilling the bark with water, exhausting the distillate with petroleum, and distilling off the solvent. The crude oil, amounting to 0·6428 per cent. of the weight of the bark employed, is a mixture of several substances.

Winterene, $C_{15}H_{24}$, is the essential oil separated from this by fractional distillation. It passes over between 260° and 265°; sp. gr. at 13° = 0·93437. Index of refraction = 1·4931; sp. rotatory power at 16° $[\alpha]_j = +11·2$. It is readily oxidised on exposure to the air, becoming yellow. The formula $C_{25}H_{40}$ was calculated from the ultimate analysis and vapour-density, but the authors consider that the ready oxidisability of winterene and its analogy to similar essences points rather to the formula $C_{15}H_{24}$, which would place it in the group of sesquiterpenes, such as cedrene, cubebene, &c., the boiling points of which are between 250° and 268°.

Iodine dissolves in winterene producing a greenish-yellow coloration which changes to green after a time.

On adding picric acid containing a few drops of sulphuric acid to winterene, a yellowish-red, crystalline compound is formed.

Pure winterene is coloured green by a solution of bromine in chloroform, orange-red by a solution of chloral hydrate in sulphuric acid, rose to yellow by concentrated sulphuric acid or by sulphuric acid and chloroform, dirty-yellow by Fröhde's reagent and by ferric chloride and sulphuric acid, rose to violet by nitric acid.

The reactions of the essence after oxidation are also given.

S. B. A. A.

Nitrous Acid in the Atmosphere. By L. ILOSVAY (*Bull. Soc. Chim.* [3], 2, 666—667).—The liquid obtained by washing with water, bedewed grass and foliage-leaves, collected in the morning, contains nitrous acid, which is absent from noonday and evening gatherings. Nitrites are condensed on leaves during the day in damp, dull, rainless weather, and in dry, clear, sunny weather are replaced by nitric acid and ammonia.

Washed soils moistened and exposed to air determine similar surface condensations, the nitrogen-compounds being derived from the atmosphere and varying in amount with the duration of exposure.

T. G. N.

Causes of the Exhaustion of Arable Soil by Cropping without Manures. By P. P. DEHÉRAIN (*Ann. Agronom.*, 15, 481—505).—The author has made a comparative study of certain plots at the experimental station of Grignon, some of which have been cropped without manuring for a number of years, while others have received regular dressings of farmyard manure.

Unmanured Plots.—Plots 21, 37, and 53 received no manure since 1874.

Manured Plots.—Plots 32, 33, 36, and 49 had received regular dressings of farmyard manure.

Comparative Crops. Sugar-beet.—In 1887 plot 37 yielded 13,900 kilos., and plot 53 10,000 kilos. per hectare, against 35,000—40,000 kilos. yielded by the regularly manured plots. *Red clover:* in 1888 plot 37 yielded 3,200 kilos. hay per hectare, and plot 53 2,600 kilos. against 8,800 kilos. yielded by a plot manured during the preceding years. *Trifolium incarnatum:* the continuously unmanured plot yielded 3,600 kilos. green in 1888 against 15,000 kilos. by the regularly manured plot. *Cereals:* for these crops the exhaustion is much less noticeable than for the preceding. In 1888, plot 37 yielded 31 metric quintals of oats (*avoine des salines*) against 33 by the manured plots; and plot 53 yielded 22 quintals of oats (*avoine à grappes*) against 32 yielded by the manured plots.

Although the difference is, in the case of the phosphoric acid, considerable, yet it cannot be said that the unmanured plots fail to yield crops on account of exhaustion of mineral food.

Phosphoric Acid and Potash in the Soil.

Percentage in the soil (depth not stated) of	Continuously unmanured.		Regularly manured.
	Plot 37.	Plot 53.	Plot 36.
Total P_2O_5	0·102	0·104	0·155
P_2O_5 soluble in acetic acid	0·012	0 015	0 034
Total K_2O soluble in aqua regia	0·090	0·091	0·117

Organic Matter in the Soil.—The carbon and nitrogen in the soils of plots 37 and 21 (unmanured) and of plots 32 and 49 (manured) were determined in 1878 and again in 1888 after 10 years' interval.

The results so far seem to connect the exhaustion, so conspicuous when beet-root or clover is grown, with the great loss of organic, and especially carbonaceous matter, the diminution in the important plant foods, nitrogen, phosphoric acid, and potash being relatively inconsiderable.

	Plots.		Plots.	
	37.	21.	49.	32.
Percentage of nitrogen in 1878	0·167	0·174	0·200	0·200
,, ,, ,, 1888	0·148	0·150	0·190	0·186
Loss	0·019	0·024	0·010	0·014
Percentage of carbon in 1878	1·519	1·630	1·52	1·66
,, ,, ,, 1888	0·730	0·730	1·61	1·60
Loss or gain	−0·789	−0·900	+0·09	−0·06
Proportion $\frac{C}{N}$ in 1878	9·0	9·3	7 6	8·3
,, ,, ,, 1888	4·9	4·8	8·4	8·5

The author next examines the various reasons that suggest themselves to account for this connection.

Retention of Moisture by Humus.—Parallel plots in the same strip of ground were selected from those continuously unmanured, and therefore poor in organic matter, and from those regularly or frequently manured and rich in organic matter, and samples taken carefully to the same depth and under exactly similar circumstances during every month from November, 1888, to November, 1889, for the determination of moisture. The results of each pair of plots are plotted in curves showing the percentage of moisture at the consecutive dates; but the general results may be summed up thus:—The soil of the unmanured plots 21, 37, and 53, poor in organic matter, gave an average of 17·6 per cent. of water over the time named; that of the manured plots, 17, 33, and 49, rich in organic matter, 18·5 per cent. If this difference is reckoned on the hectare of soil, it amounts to 32·4 tons of water; but as the total water contained in the soil is 623 6—666 tons, no weight can be attached to the absence of so small a fraction. Other experiments showed that the difference in the loss by drainage was not greater than in the case of two samples of the same soil.

Quantity of Nitrates Formed.—Equal weights of the different soils were placed in glazed pots, and the initial nitrogen as nitrate determined in each. These pots were placed in the open, the drainage-water from each collected from May 14 to November 12, and the nitrogen as nitrate determined in each lot of water. The mean results for the plots in question were—

	Rain-fall.	Drainage.	Initial N as nitrate in soil.	N as nitrate in drainage.
	litres.	litres.	grams.	grams.
Plots 17 and 33 regularly manured ..	31·64	8 360	0·368	0·877
,, 21, 37, and 53 unmanured	31·64	9·116	0·322	0·624

From these figures it appears that the quantity of nitrate formed, even in the exhausted soils during the growing season, was amply sufficient for the requirements of good crops; 0·322 gram of nitrogen nitrified per 30 kilos. soil being equivalent to 113 kilos. per hectare.

Production of Carbonic Anhydride.—Determinations made by Boussingault and Lewy's method of the carbonic anhydride contained in 100 litres of the interstitial air of two soils on the same dates gave—

	June 7.	June 18.
	grams.	grams.
Plot 53 unmanured	1·13	0·98
,, 49 manured	1·38	1·16

These differences are again slight, and tend to confirm recent results of Wolny and of Schloesing, showing that there is no direct relation between the richness of a soil in organic matter and that of its interstitial air in carbonic anhydride. The foregoing experiments fail to yield any explanation of the facts, but the following one shows conclusively the actual importance of the organic matter of soil to the growth of sugar-beet. 30 kilos. of the rich soil of plot 49 and 30 kilos. of the exhausted soil of plot 53 were placed in similar pots, the latter being enriched by the addition of 3 grams of sodium nitrate, 3 grams of superphosphate, and 3 grams of potassium chloride, equivalent to 360 kilos. of each per hectare. Sugar-beet seeds were sown in each pot; on July 17 all the young plants but one were removed from each pot, and on October 25 the weight of the single root grown in each pot was taken.

	Soil rich in organic matter (49).	Soil artificially enriched (53).
	grams.	grams.
Weight of young plants removed July 17	6·78	2·51
„ entire plant on Oct. 25	730	165
„ root on Oct. 25	410	92
Percentage of sugar in juice	15·04	11·11
Sugar in entire plant	61·60	10·12

From all the facts given in this paper the author concludes that a portion of the organic matter of soil frequently manured with farm-yard manure probably serves as direct nutriment for the sugar-beet and some other plants, and that for this purely mineral food cannot be successfully substituted. J. M. H. M.

Experiments at Rothamsted on the Growth of Potatoes. By J. H. Gilbert (*Agr. Students' Gazette*, 4, Pt. ii).—The experiments were conducted for 12 years on the same land. The following table shows the various manuring as well as the average yearly produce per acre for the 12 years, except in the farm-yard manure series, where the average of six years is given:—

	Good.		Small.		Diseased.		Total.	
	tons.	cwts.	tons.	cwts.	tons.	cwts.	tons.	cwts.
Unmanured	1	13·5	0	5 0	0	1·25	1	19·75
Superphosphate of lime	3	5·0	0	5·6	0	2·75	3	13·4
Mixed mineral manures	3	7·75	0	4·9	0	2·6	3	15 25
Ammonium salts	1	17·75	0	6·1	0	1·9	2	5 75
Sodium nitrate	2	4·6	0	5·25	0	2·6	2	12·5
Ammonium salts and mixed minerals	5	18·9	0	7·25	0	8·4	6	14·5
Sodium nitrate and mixed minerals	5	17·4	0	6·4	0	9 25	6	13·0
Farm-yard manure	4	11·9	0	7·0	0	5·75	5	4·6
Farm-yard manure and superphosphate	4	16·9	0	7·25	0	7·5	5	11·6
Farm-yard manure and superphosphate and sodium nitrate	5	17·75	0	6·6	0	17·9	7	2·25

The mixed minerals include superphosphate and potassium, sodium, and magnesium salts. The ammonium salts contained 86 lbs. of nitrogen whilst farm-yard manure supplied about 200 lbs. of nitrogen per acre per annum. It is remarkable that there is much less increase of produce of potatoes by nitrogenous manures alone than by mineral manures alone.

With regard to the various constituents of the tubers, the average amount of nitrogen per acre in those grown without manure was only 14·9 lbs., which is less than would be yielded by wheat or barley grown under the same conditions. Mineral manures alone raised the amount of nitrogen to about 20 lbs., whilst nitrogenous manures alone only raised the amount taken up to 19·7 lbs. (with ammonium salts) and 23·0 lbs. (with nitrate). With the same application of nitrogen, but in conjunction with mixed minerals, the amount of nitrogen stored up in the tubers is raised to about 50 lbs. per acre. Of the other constituents, the most prominent is potash; under the influence of superphosphate alone, 30 lbs. per acre more potash is taken up than without manure, with superphosphate and mixed minerals (including potash) the increase is 33 lbs., whilst with minerals and nitrogenous manure together, nearly 70 lbs. more potash is recovered per acre than where no manure is applied. The presence of potash seems to be essential for the formation of starch and sugar. The accumulation of phosphoric acid, which is more directly connected with the nitrogenous constituents, is much less than that of potash.

As to the composition of the whole tubers and of the juice. there is an indication that the juice is richer in nitrogen, the more nitrogen there is applied in the manure and the less matured the crop; it includes, in fact, material for further maturation. The amount of juice is generally about 80 per cent. of the fresh tubers. The percentage of ash-constituents is higher in the juice than in the tubers; its amount varies considerably according to the manuring, but the composition of the ash of the tubers and the juice is always very similar. The greater part of the nitrogen is in the juice.

Of the total nitrogen of the tubers, Schulze found an average of 18·3 per cent. to exist as albuminoïds in the marc. In the Rothamsted experiments, the average was found to be only 15 per cent. The average percentage of total albuminoïd nitrogen was 56·2 (Schulze) and 63·6 (Rothamsted). The two sets of experiments show that, as a rule, less than 20 per cent. of the total nitrogen is in the form of insoluble albuminoïd. On the other hand, Schulze's results show an average of 43·8, and those obtained at Rothamsted 36·2 per cent. of total nitrogen, of the tubers to be non-albuminoid: most of it existing as amides and much less as ammonia and nitric acid than is usual in the case of root crops. The nutritive value of this large proportion of nitrogenous matter is, to say the least, doubtful, and inasmuch as most of the albuminoïd matter itself is in the juice of the potato, it is probable that a good deal is lost as food.

Provided that the necessary minerals are present, the use of nitrogenous manure gives rise to a great increase of starch in the potato, just as in the case of root crops there is an increase of sugar under these conditions, and in the case of the cereals an increase of starch and cellulose. It is chiefly for the increased production of non-nitrogenous substances (starch, sugar, and cellulose) that direct nitrogenous manures are used.

Diseased potatoes contain considerably less dry matter than good ones, which is shown by the higher percentage of mineral matter in the dry substance of the bad ones to be due, not to acquisition of water, but to the loss of solid substance, and it is further shown that it is chiefly the non-nitrogenous organic substance which is lost. The cause of the disease is a fungus which converts the starch into sugar; the loss of substance is perhaps mainly due to the evolution of carbonic anhydride, as a coincident of the growth of the fungus deriving its nutriment from ready-formed organic substance; a characteristic action in the growth of these non-chlorophyllous plants. The fungus accumulates a large proportion of both the mineral and nitrogenous substance of the juice of the tubers, which perhaps partly explains the fact that the disease develops much more in tubers grown by highly nitrogenous manures, and which have a highly nitrogenous juice, than in those grown under ordinary conditions. N. H. M.

Experiments with Farm-yard Manure. By E. HEIDEN (*Bied. Centr.*, 18, 794—796; compare Abstr., 1888, 872).—The object of the experiments was to determine what changes take place when the liquid manure is kept alone, when treated with sulphuric acid containing phosphoric acid, and when kept covered with a layer of oil. The manure was well mixed, and three lots of 100 kilos. put into barrels and treated as described. Nitrogen as ammonia and organic nitrogen was determined in the manure at the beginning and at the end of the experiment, which lasted about six months. The manure kept without any preservative lost 11·9 per cent. of the nitrogen as ammonia and 18·5 per cent. of its organic nitrogen, corresponding with 12·9 per cent. of the total nitrogen. The sample treated with acid lost 13·8 per cent. of the ammoniacal nitrogen, but the amount of organic nitrogen was almost doubled, so that the loss of total nitrogen was only 1·5 per cent. The manure kept under oil lost 6·8 per cent. of the total nitrogen, or 5 per cent. of the ammoniacal nitrogen and 18 per cent. of the organic nitrogen. N. H. M.

Analytical Chemistry.

Modified "Orsat" Apparatus. By J. RUFFLE (*J. Soc. Chem. Ind.*, 8, 3—4).—The author describes with the aid of a diagram, a new form of bulb, which is said to be less subject to fracture and more easily prepared and cleaned than the bulb used in Orsat's apparatus for the rapid determination of oxygen. D. B.

Gas Sampling and Testing Apparatus. By J. E. STEAD (*J. Soc. Chem. Ind.*, 8, 176—178).—The author describes, with the aid of a number of diagrams, various forms of apparatus for sampling and testing gases, designed by him for the purpose of examining blast and other furnace gases. The sampler is a modification of the apparatus described by Gruner, by which a large vessel filled with mercury is used to collect the gas. The author's apparatus is so arranged as not only to take the sample, but also to take the place of the old form of gas pipette. Three forms of gas-testing apparatus are described, their mode of working being explained with the help of diagrams. D. B.

The Concentration of Reagents. By R. BLOCHMANN (*Ber.*, 23, 31—35).—When the usual instructions for the preparation of reagents are carried out, the concentration of the solution obtained shows no relation whatever to that of an "equivalent" solution. It is, therefore, very difficult to estimate the amount of the reagent necessary in processes of precipitation, neutralisation, &c., and the author proposes, in order to overcome this difficulty, to make all the solutions approximately double-normal, normal, or semi-normal, according to the solubility of the substance; using the last-named strength for all expensive reagents. Very sparingly soluble salts, such as calcium sulphate, may be employed in saturated solutions, and the strength of oxidising and reducing solutions should be such that 1 litre will give off or absorb (O 2 =) 8 grams of oxygen. Under "concentrated acids" are understood anhydrous sulphuric acid, a saturated solution of hydrochloric acid, and a mixture of equal weights of anhydrous nitric acid and water. Tables giving the specific gravity and percentage composition of these solutions may be found in the original.

H. G. C.

Note by Abstractor.—A similar proposition to the above was made many years ago in Harcourt and Madan's "Exercises in Practical Chemistry," and the necessary directions for the preparation of the solutions may be found on p. 439 (3rd edition). H. G. C.

Estimation of Chlorine and Hydrogen Chloride in a Mixture of the two Gases. By W. YOUNGER (*J. Soc. Chem. Ind.*, 8, 88—90).—This method, which the author finds to give very accurate results, is based on the absorption of the gases in a standard solution of arsenious acid, to which a small quantity of sulphindigotic acid has been added. The absorption is accomplished in one vessel, described with the aid of a diagram, which, along with a graduated box as an aspirator, renders it possible to read off the grains of chlorine per cubic foot, the aspiration being stopped when the sulphindigotic acid is bleached. The hydrogen chloride may be estimated in the same solution by titration with silver nitrate. D. B.

Analysis of the Atmosphere. By O. PETTERSSON and A. HÖGLAND (*Ber.*, 22, 3324—3325).—The authors find that the oxygen of the air may be accurately determined in the portable apparatus previously described (Abstr., 1887, 999), by means of absorption with a solution of sodium hyposulphite. The mean of very numerous determinations made in Stockholm during October, November, and the first half of December, 1889, gave the oxygen in the air as 20·940 per cent. L. T. T.

Estimation of Free Oxygen in Water. By M. MÜLLER (*Chem. Zeit.*, 13, 1188—1190).—The author comments on the uncertainty of the present methods for ascertaining the wholesomeness of water; he considers it desirable to inquire into the quality as well as the quantity of organic matter present, for which purpose oxidation with permanganate is not efficient, but the free oxygen in the water appears to be an important factor. He has noticed in numerous experiments when waters have been retained in perfectly full, well-stoppered bottles, that in good waters the oxygen suffers only slight reduction or none at all, whereas in bad waters the oxygen is consumed with comparative rapidity in a few days, presumably on account of decomposing the readily oxidisable organic matter. It is pointed out that the free oxygen is not eliminated from water by boiling even for two hours. The author has devised the following method:—Some crystalline manganous sulphate is dissolved in the water, which completely fills a two- to three-litre bottle, fitted with a doubly bored india-rubber stopper, and connected by means of one bore with an upright wide tube filled with the same water; by lowering this, potassium hydroxide is admitted from the tap funnel in the other bore, causing the precipitation of manganous hydroxide, which absorbs all the free oxygen, forming manganic hydroxide. Hydrochloric acid and potassium iodide are now added through the funnel, the manganic oxide gives rise to the liberation of chlorine, which in its turn sets free iodine, the latter is titrated in a dish with sodium thiosulphate, and the amount of oxygen corresponding therewith is calculated. If nitrous acid is present, it is determined by adding hydrochloric acid and potassium iodide to a quantity of water equal to that taken for the oxygen estimation, titrating the liberated iodine, and deducting this quantity from the oxygen titration.

R. Hefelmann and K. Barth (*ibid.*, 1337) point out that this method is only applicable to waters free, or almost free, from organic matter, because organic matter not only absorbs iodine, but even chlorine, and also renders the direct estimation of nitrous acid impossible.

D. A. L.

Estimation of Sulphur in Pyrites. By G. LUNGE (*Zeit. ang. Chem.*, 1889, 473—477).—Objections have, on various grounds, been raised to the oxidation of the sulphur in pyrites by aqua regia, as advocated by the author. When barium sulphate is precipitated from a solution containing iron, low results are always obtained, in spite of the fact that the precipitate invariably contains iron. Jannasch and Richards have shown that this is due to the precipitation of a barium iron sulphate, which slowly loses sulphuric anhydride on ignition. When oxidising the pyrites in the dry way, Fresenius obtained about 1 per cent. more sulphur than by wet oxidation. In 1881 the author recommended as an improvement on his process that the iron should be removed by ammonia before precipitating with barium chloride. To this Jannasch and Richards objected that part of the sulphur would be contained in the precipitate as basic ferric sulphate. The author now shows that if the precipitation is performed according to the rules which he laid down in 1881, and which are embodied in the *Taschenbuch für Sodafabrikation*—"The warm solution to be mixed with a moderate excess of ammonia, filtered after 10 minutes, and the precipitate most thoroughly washed with boiling water"—the precipitate will not retain a trace of sulphate, and the results agree exactly with those obtained by dry oxidation. Results only about 0·2 per cent. lower can be obtained by the author's "old method" if the precipitate is only moderately ignited, the errors compensating one another (compare Abstr., 1888, 85). Jannasch and Richards ignited their precipitate very intensely, and state that even after half an hour the expulsion of the sulphuric anhydride was not complete. The fusion method is less rapid than the aqua regia process, and is liable to the error of including in the estimation the sulphur in impurities (barytes, &c.), which is not available in practical use. M. J. S.

Estimation and Occurrence of Sulphur in Coal. By G. H. BAILEY (*J. Soc. Chem. Ind.*, 8, 360—365).—The author has examined the different methods in use for determining sulphur in coal. He finds that the magnesia method (Eschka's process) gives constant results, whilst the methods based on oxidation with potassium chlorate or potassium nitrate, and the methods due to Grace Calvert, show large variations between one determination and another. Experiments were also made with a view of learning what portion of the sulphur appeared in the flue gases, and what part remained in the ash, and whether these numbers were actually such as are arrived at by an examination of the coal according to the method suggested by Calvert. The results show that the sulphur existing in coal in the form of sulphates remains in the ash, and does not take part in the production of sulphurous anhydride in the flues. A large quantity of sulphur is also retained by the flue dust, and in samples examined by the author as much as 15 to 20 per cent. of sulphur has been found. D. B.

Estimation of Sulphuric Anhydride in Fuming Sulphuric Acid. By B. SETLIK (*Chem. Zeit.*, 13, 1670).—The following method is based on the fact that sulphuric acid only fumes so long as sulphuric anhydride is present. Water is run drop by drop from a graduated burette into 100 grams of the fuming sulphuric acid contained in a flask and well cooled. The operation is complete when a drop falling in the middle of the acid dissolves quietly without fumes; 1 c.c. of water corresponds with 4·444 per cent. of sulphuric anhydride. Acids containing above 35 per cent. of sulphuric anhydride should be diluted to 30—35 per cent. with monohydrated sulphuric acid of undoubted strength before titrating with water.

D. A. L.

Volumetric Estimation of Combined Sulphuric Acid. By L. W. ANDREWS (*Amer. Chem. J.*, 11, 567—571).—The solution of the sulphate is diluted until it contains not more than 2 per cent. of sulphuric anhydride, and is then heated to boiling. Excess of a solution of pure barium chromate in hydrochloric acid is gradually added, and the boiling continued for a few minutes. Pure calcium carbonate now added to the hot liquid until no more carbonic anhydride is evolved, and the boiling again continued for a few minutes. The precipitate is filtered and washed until the wash-water is colourless, potassium iodide and hydrochloric acid are added to the filtrate, and the iodine liberated is titrated with a decinormal solution of sodium thiosulphate, 1 c.c. of which is equivalent to 0·002662 gram SO_3.

In the presence of ferric, nickel, or zinc salts, ammonia must be used instead of calcium carbonate to neutralise the acid liquid. The precipitate is, however, much more difficult to wash in this case, and a very thick filter must be used. The method is not available in the presence of phosphoric acid or of reducing agents. Test experiments are given, in which the error varies from 0·1 to 0·4 per cent. It is proposed to use this method for the indirect determination of sodium and potassium by weighing them as sulphates and estimating the sulphuric anhydride as described above. C. F. B.

Kjeldahl's Method of Estimating Nitrogen. By R. NIEBLING (*Chem. Zeit.*, **13**, 1670—1671).—The author takes exception to the introduction of unnecessary complications in the distilling apparatus required for the Kjeldahl method. He points out that with a bulb in the distillation tube, into which perhaps the continuation of the tube may protrude, no soda passes over when the operation is conducted properly; moreover, with a tube sufficiently long (½ to 1 metre), even cooling may be dispensed with, the ammonia being completely absorbed if the tube only dips into the acid; such apparatus is readily rinsed and cleaned. To prevent bumping, zinc-dust is added to the alkaline liquid before distilling. The boiling should proceed slowly at the commencement. When measuring the acid with a pipette, the last drops are most uniformly removed, not by blowing, but by touching the side of the flask neck. D. A. L.

Estimation of Nitric Acid by Diphenylamine. By J. A. MULLER (*Bull. Soc. Chim.* [3], **2**, 670—672).—5 c.c. of a solution of diphenylamine (0·2 gram) in concentrated sulphuric acid (1 litre) is shaken with 1 c.c. of the clear liquid to be estimated, and the amount of nitric acid present is determined by a comparison of the blue tint produced with that yielded by solutions of potassium nitrate, corresponding to 0·5—5 milligrams of nitric anhydride per litre. The solutions to be estimated must not contain more than 0·01 gram of nitric anhydride per litre, or the colour produced is too deep for comparison.

The tint is not affected by dilute hydrochloric acid, but is altered by hydrobromic and hydriodic acids. T. G. N.

Detection of Traces of Nitrous Acid. By G. LUNGE (*Zeit. ang. Chem.*, 1889, 666—667).—Ilosvay has improved Griess' test by using acetic acid instead of a mineral acid. The colour is more intense and more rapidly developed. He dissolves (1) 0·5 gram of sulphanilic acid in 150 c.c. of dilute acetic acid, (2) boils 0·1 gram of α-naphthylamine with 20 c.c. of water, pours off the colourless solution, and mixes it with 150 grams of dilute acetic acid. The author prefers to mix these two solutions, thus gaining the advantage of having only a single reagent instead of two, and one which indicates by its colour whether it has become contaminated by nitrous acid derived from the air. The mixture is not affected by light, but should be protected from the air. Should it, however, become coloured by absorption of nitrous acid, it may be shaken with zinc-dust and filtered: the colourless filtrate is as serviceable as the original reagent. It will detect 1 part of nitrous acid in 1,000,000,000 parts of water. M. J. S.

Götz's Method of Estimating Phosphorus in Iron. By K. Bormann (*Zeit. ang. Chem.*, 1889, 638—639; see Abstr., 1887, 865).—The author has improved the method, so that it is applicable to samples rich in carbon. 1·2 grams of steel is dissolved in 25 c.c. of nitric acid; the solution is concentrated as much as possible and treated with 8 to 16 drops of potassium permanganate solution containing 12 grams in a litre. The precipitated manganic peroxide is dissolved by a little hydrochloric acid, and the solution is again concentrated as much as possible. While hot it is mixed with 10 c.c. of a 25 per cent. solution of ammonium nitrate, and then 25 c.c. of Finkener's ammonium molybdate solution, and the whole is rinsed with ammonium nitrate solution into a pear-shaped vessel of 60—70 c.c. capacity, having at its smaller end a tubular prolongation of 40 mm. length, 0·2 c.c. capacity, and marked with 40 graduations. A number of these vessels are then rotated, at the same time, in a Braun's centrifugal machine for two minutes, whereupon the precipitate collects in the narrow tube, and its volume can be read off. Up to 0·25 per cent., silicon has no disturbing influence, but above that percentage gelatinous silica separates. A single estimation occupies half-an-hour, but 60 to 80 can be completed in four or five hours, and the results agree with gravimetric methods within ± 0·005 per cent. M. J. S.

The "Citrate Method" of Phosphoric Acid Estimation. By O. Reitmair (*Zeit. ang. Chem.*, 1889, 702—709).—The author gives a copious review of the investigations and proposals that have been made in connection with this process, and then submits the following view of the nature of the reactions which take place:—The solution in ammonium citrate of the insoluble orthophosphates of the formula $M''HPO_4$ or $M''_3PO_4(M''_3 = M'''_2)$ results from the formation of soluble double salts of the constitution $M''NH_4PO_4,(NH_4)_3C_6H_5O_7$. When, however, M'' is magnesium, this double salt readily, but never quite completely, decomposes, with separation of $MgNH_4PO_4$, especially in presence of an excess of a magnesium salt. Now, on adding magnesia mixture to an ammoniacal solution containing phosphate and citrate, a small amount of this double salt is produced, together with magnesium ammonium phosphate and magnesium ammonium citrate, and, since the latter is incapable of decomposing the double salt, a portion of the phosphoric acid escapes precipitation. If, now, the original solution contains the double citrate of an earthy or alkaline earthy metal, the principal reaction consists in the conversion of this by magnesium ammonium citrate into the magnesium double salt, which is then, by a further quantity of magnesium chloride, decomposed as before, but when the excess of magnesium chloride is large, a small part of the original salt, $M''NH_4PO_4$, is precipitated, whilst if the excess of magnesium chloride is small, part of the magnesium double salt escapes decomposition. Moreover, if the amount of ammonium citrate is insufficient, the double earthy phospho-citrate may be incompletely converted into $MgNH_4PO_4,(NH_4)_3C_6H_5O_7$, with the result that the precipitation will be slow and incomplete. Since the error caused by the imperfect decomposition of the magnesium ammonium phospho-citrate is fairly constant, its percentage amount may be reduced by taking a large quantity of substance; the quantity of ammonium citrate used must not be too small, but as the citrate is increased the quantity of magnesia mixture must be augmented also. The error caused by precipitation of $M''NH_4PO_4$ will be examined in a later communication. M. J. S.

Estimation of Water and Carbonic Acid in Salts. By T. M. CHATARD (*Amer. J. Sci.* [3], **37**, 468—471).—The author gives a drawing of an apparatus that has been used for the analysis of natural and artificial alkaline carbonates with very satisfactory results. About 1 gram of the salt is placed in a platinum boat, and inserted in a combustion-tube with a hot asbestos plug pushed in close behind the boat. The tube is connected with a U-tube containing glass beads moistened with sulphuric acid, and is gradually heated. A water-bath is now placed so that one limb of the U-tube, attached to the combustion-tube, fits into a curved recess in the side of the bath. A small spirit-lamp keeps the bath hot, so that the water driven out of the salt may not condense in the upper part of the limb. After highly heating the tube for half-an-hour, the water-bath is removed, and the apparatus allowed to cool. Throughout the process a current of perfectly dried air is passed through. As soon as the tube is cool, the U-tube is disconnected, and the boat, with its contents, removed, and placed in a weighed, well-stoppered glass tube. The increase of weight of the U-tube gives the amount of water in the sample, whilst the weight of the small tube subtracted from the sum of the weights of the tube, the boat, and the salt, shows a loss, which is water plus the carbonic anhydride originally existing as hydrogen alkali carbonate in the salt. It is found impracticable to collect and weigh the carbonic anhydride without sacrificing the water determination. The method is more rapid and quite as accurate as the distillation process. B. H. B.

Volumetric Estimation of Carbonates. By J. A. MULLER (*Bull. Soc. Chim.* [3], **2**, 483—485).—The coefficient of absorption per c.c. for carbonic anhydride in hydrochloric acid (containing 32 per cent. of hydrogen chloride) is 0·0018 gram per c.c., and in presence of quantities of calcium chloride, varying from 0·03—0·07 gram per c.c. is 0·0014 gram per c.c. T. G. N.

Estimation of Calcium in presence of Phosphoric Acid, Iron, Aluminium, and Manganese. By O. REITMAIR (*Zeit. ang. Chem.*, 1889, 357—362).—For the rapid estimation of calcium in such substances as basic slag, Immendorf precipitates it with ammonium oxalate in a solution feebly acidified with hydrochloric acid. The precipitate is free from phosphoric acid. It, however, contains small quantities of the other metals (as oxalates) and of silica, so that, whether the estimation is completed gravimetrically or by titration with permanganate, the results are too high. The impurities can, for the most part, be removed by igniting the precipitate, dissolving in hydrochloric acid, oxidising with bromine, and precipitating with ammonia and ammonium sulphide. An abridged method consists in dissolving the impure calcium oxalate in hydrochloric acid without previous ignition, and reprecipitating by addition of ammonium oxalate and acetic acid, but the result is less exact. Still better is it to make both precipitations by Classen's method (Abstr., 1879, 969) with an intermediate ignition of the precipitate. The method is rapid, since filtration can be commenced a few minutes after precipitation, and the precipitates obtained are purer than by the other processes. The first is apt to contain somewhat considerable proportions of manganese, besides traces of other metals; the second is pure calcium oxalate. M. J. S.

Estimation of Zinc in Calamine. By W. MINOR (*Chem. Zeit.*, **13**, 1670).—Ordinary calamine contains, besides zinc carbonate, varying amounts of zinc silicate and sulphide (blende). The total zinc is readily estimated in the usual manner; whilst the proportion of blende may be determined by boiling the calamine carefully with dilute sodium hydroxide, which dissolves the zinc carbonate and silicate, leaving the sulphide. The quantity of blende and zinc silicate together may be determined by boiling with 50 per cent. acetic acid, which removes the zinc carbonate. In this way the proportion of all three is ascertained.

Boiling with ammonia is of no use, as some, but never the whole of the zinc silicate, dissolves as well as the zinc carbonate. D. A. L.

Separation of Zinc from Nickel. By H. ALT and J. SCHULZE (*Ber.*, **22**, 3259—3262).—When hydrogen sulphide is passed into an aqueous solution of zinc sulphate and nickel nitrate, strongly acidified with succinic acid, the zinc is precipitated completely, whilst the whole of the nickel remains in solution; the solution may be hot or cold and an excess of hydrogen sulphide has no effect on the results, but the precipitation must take place in absence of salts, otherwise nickel sulphide is precipitated. Quantitative experiments gave very accurate results.

The quantitative analysis of an alloy such as German silver, is best carried out as follows: The alloy (1·5 to 2 grams) is dissolved in nitric oxide, the solution freed from acid by evaporating, the stannic oxide separated by filtration, and the copper precipitated with hydrogen sulphide. The filtrate is evaporated to a small bulk to free it from hydrogen sulphide, almost neutralised with potash, heated to boiling, and treated with a 10 per cent. solution of sodium acetate (10 to 20 drops); the employment of a larger quantity of sodium acetate is unnecessary and disadvantageous. The basic ferric acetate is separated by filtration, the acetic acid expelled by boiling with a mineral acid, and the boiling solution treated with sodium carbonate. The precipitated zinc and nickel carbonates are washed, dissolved in succinic acid, the solution filtered to free it from threads of paper, and diluted to a known volume (500 c.c.). A portion

(100 c.c.) of this solution is mixed with succinic acid (5 grams), diluted with a little water, heated almost to boiling, and hydrogen sulphide passed in excess. The solution is kept for 24 hours to allow the precipitate to settle, then filtered, and the zinc sulphide washed in the usual way and weighed (as sulphide). The filtrate from the zinc sulphide is acidified with hydrochloric acid, evaporated to expel the hydrogen sulphide, heated to boiling, and the nickel precipitated with potash. Even in presence of a large quantity of succinic acid, the precipitation of the nickel is complete.

An analysis of German silver, carried out as described above, gave the following results (in percentages):—Sn = 0·08, Fe = 1·08, Cu = 63·25, Zn = 20·20, and Ni = 15·34, total 99·95 per cent.

F. S. K.

Application of Hydrogen Peroxide in Analysis. By C. Hiepe (*Chem. Zeit.*, **13**, 1303).—The author suggests the following expedient to avoid the inconvenience experienced by the separation of sulphur from the aqueous solution obtained by extracting the cold mass, after the fusion with sulphur and anhydrous sodium carbonate, in the analysis of alloys containing tin, antimony, copper, lead, bismuth, &c. The solution containing the tin and antimony is mixed with sodium hydroxide, heated to boiling, treated with hydrogen peroxide until colourless, avoiding excess, and a little hydrogen sulphide is then passed through the solution, or some sodium sulphide added to convert any heavy sulphates into sulphides. On acidifying this solution, tin and antimony sulphides are precipitated in a good condition to be readily washed or otherwise treated.

The hydrogen peroxide must be pure; the author has found magnesium chloride in many commercial samples. D. A. L.

Precipitation of Manganese as Peroxide. By H. Alt (*Chem. Zeit.*, **13**, 1339).—When estimating manganese by precipitation with bromine, it is recommended to expel the air from the moderately acid solution, by boiling; to add ammonium chloride and ammonia, and then aspirate through it air previously passed through bromine-water; by this means the manganic hydroxide is precipitated without attaching itself to the sides of the containing vessel, and can be easily and perfectly transferred to a filter. D. A. L.

Estimation of Iron in Water. By J. C. Bell (*J. Soc. Chem. Ind.*, **8**, 175).—70 c.c. of the water is evaporated to dryness in a platinum dish and the residue ignited gently. 1 c.c. of pure nitric acid is added, and the mass heated on a water-bath. The residue is again moistened with 1 c.c. of a 10 per cent. solution of hydrochloric acid, after which 5 or 10 c.c. of water is added, and the whole warmed on a water bath. The solution is then filtered, and made up to 50 c.c. in a 50 c.c. Nessler tube. The contents are transferred to another tube containing 1 c.c. of freshly prepared ferrocyanide solution, and treated with 1 c.c. of dilute nitric acid. This is then compared with a tube containing a known quantity of iron (see Abstr., 1875, 285).

D. B.

Estimation of Ferric Oxide and Alumina in Phosphatic Manures. By E. GLASER (*Zeit. ang. Chem.*, 1889, 636—638).—In the so-called "conventional method," in which the iron and alumina are separated from the calcium as phosphates by acetic acid, the results vary much according to the quantity of acetic acid used. The author has therefore sought to separate the calcium first, in order that the iron and aluminium phosphates may be thrown down by ammonia. The phosphate is dissolved in the usual way; 100 c.c. of the solution corresponding with 1 gram of the substance is placed in a ¼-litre flask, and mixed with 25 c.c. of concentrated sulphuric acid. After five minutes, alcohol is added and the mixture cooled, then made up to the mark and mixed. After half an hour it is filtered; 100 c.c. is evaporated in a platinum basin, and when free from alcohol is precipitated hot with ammonia, the excess of which is boiled off. After cooling, the precipitate is filtered off, washed with warm water, and ignited. Its weight, divided by 2, gives the joint amount of the bases. Numerous test analyses show the accuracy of the method, as well as the low results yielded by the "conventional method."

M. J. S.

Precipitation of Alumina and Ferric Oxide by Ammonia. By G. LUNGE (*Zeit. ang. Chem.*, 1889, 634—635).—If the older practice is followed of boiling off all the excess of ammonia, the precipitate will contain much basic sulphate, which will require prolonged ignition with the blowpipe to reduce it to oxide. In the author's improved method for estimating the sulphur in pyrites (p. 413) the precipitation of basic sulphates is avoided, but it remained to be seen whether the determination of the alumina was in any way affected by the free ammonia, and more especially whether accurate results would be obtained without the intense ignition. Four quantities of aluminium sulphate were acidified with hydrochloric acid, and then mixed with a moderate excess of ammonia. Three of them were filtered without boiling; of these, two were ignited with the blowpipe, and the third with a Muencke burner only. The fourth was boiled until almost all the ammonia was expelled, and the precipitate was ignited first with the Muencke burner and then with the blowpipe. The ultimate results of all four agreed closely, but the fourth only after intense ignition. This shows that (in presence of ammonium chloride) the excess of ammonia need not be boiled out, and that the precipitate then requires only moderate ignition (compare Meineke, Abstr., 1889, 441).

M. J. S.

Estimating Tungsten in Metallic Tungsten. By A. ZIEGLER (*Chem. Zeit.*, 13, 1060).—In order to expedite the roasting for Preusser's method, the pulverised metal is mixed with dry ammonium nitrate; the roasting may then be conducted in a platinum crucible without fear of forming a platinum-tunsten alloy, inasmuch as the particles of tungsten become coated with oxide during the volatilisation of the ammonium nitrate.

D. A. L.

Analysis of Wolframite and Scheelite. By B. SETLIK (*Chem. Zeit.*, 13, 1474). The wolframite or scheelite is finely pulverised and dried at 110°; 3 to 5 grams are fused in a platinum crucible for about 2 hours with three or four times as much sodium carbonate. The mass is boiled with water, filtered, and washed. The iron and manganese may be estimated in the residue. For the estimation of the silica, tin, and tungsten, the solution is poured into excess of hydrochloric acid, boiled for half an hour, and the precipitate washed, dried, ignited, and weighed. The silica is then driven off by means of hydrofluoric acid, and the residue after weighing is fused with potassium cyanide until reaction ceases, extracted with water, and the metallic tin dissolved in iron sulphate and titrated with permanganate. The quantity of tungsten is then readily calculated. The amount of tungstic acid in wolframite varies from 60—80 per cent., and of manganese from 10 to 20 per cent. D. A. L.

Electrolytic Estimation of Antimony. By A. LECRENIER (*Chem. Zeit.*, **13**, 1219).—Classen's method is efficient in the absence of polysulphides, but the removal of excess of sulphur entails much loss of time. The following modification is recommended:—The antimonous or antimonic solution is treated with excess of sodium sulphide, then with a 20 per cent. solution of sodium sulphite, and is carefully heated until colourless. When this solution is submitted to electrolysis, the antimony is precipitated in a few hours, and is free from sulphur. A current liberating 2·5 c.c. of water-gas per minute is the best, although a stronger current may be used. Some sulphur is deposited on the positive pole. D. A. L.

Separation of Bismuth from Lead. By G. LEMME (*Chem. Centr.*, 1889, ii, 939—940).—The author recommends Hertzog's method (*Chem. Centr.*, 1887, 1241); sufficient water must, however, be added to completely decompose the bismuth chloride, as also a sufficiency for the complete solution of the plumbic chloride; whilst, on the other hand, a sufficient amount of acid must be employed in order to prevent the precipitation of the oxychloride.

For the quantitative determination of lead in solution, the author has successfully employed the alkalimetric method, phenolphthalein being used as indicator. To the neutral solution of lead nitrate sufficient cold saturated solution of Rochelle salt is added to redissolve the precipitate at first formed; the solution is then coloured with phenolphthalein, and titrated with decinormal alkali until a deep-red coloration is produced. Finally decinormal nitric acid is added until decolorisation is produced. J. W. L.

Clarke's Soap Test. By F. L. TEED (*J. Soc. Chem. Ind.*, **8**, 256).—The author finds that an equivalent of lime requires 1⅓ equivalents of soap, or $CaSO_4$ requires $2\frac{2}{3}NaC_{18}H_{33}O_2$; whilst an equivalent of magnesia requires 1½ equivalents of soap, or $MgSO_4$ requires $3NaC_{18}H_{33}O_2$. D. B.

Detection of Ceresin, Ozokerit, and Paraffin in Beeswax. By H. HAGER (*Chem. Centr.*, 1889, ii, 815—816; from *Pharm.*

Centralb., **30**, 565—566).—The specific gravity is determined by dropping the dried melted wax on to well sized paper, and submitting this to the swimming test described by the author (*Analyst*, **4**, 206). The density of pure wax he finds to vary between 0·956 and 0·964.

The test he recommends for paraffins is as follows: 1—2 grams of wax, finely cut up and dried by exposure to the air, is heated by a small flame until vapours commence to be evolved. A wide-mouthed vessel of one-half to two-thirds litre capacity is inverted over it, and the vapours allowed to condense. The first vapours collected are principally paraffin. The condensed substance is dissolved off with about 3 c.c of chloroform, one-half of which is distilled off, and the residue saponified with a little sodium hydroxide. On cooling, the paraffin that may be present will swim on the surface. If a drop of the chloroform solution of the vaporised substance is allowed to evaporate on a glass slide, paraffin appears in the microscopical field in single fragments, which appear, when viewed with a low power, as stars. Vapour of pure beeswax is not so white as that of paraffin, and the chloroform solution of the deposit is dark coloured; whilst the residue of a drop deposited on the glass slide appears as a dull layer without stars. J. W. L.

Adulteration of French Essence of Turpentine. By A. Aignan (*Compt. rend.*, **109**, 944—946).—Essence of turpentine is frequently adulterated with about 5 per cent. of resin oil which cannot be satisfactorily detected by chemical methods. The resin oils are generally met with under three types: *selected rectified white oil*, $[\alpha]_D = -72°$, *best rectified white oil*, $[\alpha]_D = -32°$, and *rectified white oil*, $[\alpha]_D = -21°$. The first is generally used for the adulteration of the turpentine, and although it has a higher rotatory power of the same sign, the rotatory power of the mixture is lower than the normal rotatory power of the turpentine, $[\alpha]_D = -61° 30'$, which is practically constant for the pure essence from different sources. The rotatory power of the adulterated turpentine is measured, and the formula $[\alpha]_D = -61° 30' \frac{7° 30'}{5} h$ enables the percentage amount of the white oil h to be calculated. For adulteration with best rectified white oil, the expression is $[\alpha]_D = -61° 30' + \frac{8° 30'}{5} h$, and for rectified white oil $[\alpha]_D = -61° 30' + \frac{9° 30'}{5} h$. Sometimes essence of turpentine is mixed with *essence of resin*, the first product of the destructive distillation of resin, but this is detected by its strong disagreeable odour. The percentage proportion e can be calculated from the rotatory power by means of the formula $[\alpha]_D = -61° 30' + \frac{6}{5} e$ for ordinary essence of resin, and $[\alpha]_D = -61° 30' + \frac{3}{5} e$ for refined essence of resin. C. H. B.

Analysis of Essential Oils. By R. Benedikt and A. Grüssner (*Chem. Zeit.*, **13**, 1087—1088).—The authors have applied their method of boiling with hydriodic acid in the apparatus they devised, and have ascertained the "methyl number" (the quantity of methyl in 1 gram of the oil calculated from the weight of silver iodide obtained) in 57 samples of essential oils, in which the "acid," "ether," "saponification," and "iodine" numbers had previously been determined by Kremel. The "methyl number" for absolute alcohol is 326. A good many of the oils containing no methyl nucleus gave no "methyl number," such as oleum absinthii, amygdalar. amar., terebinthinæ, &c. For the others, the "methyl numbers" given are as follows; their origin is also given in the original paper:—

Ol. anisi	82·8
„ *stellati*	79·8
aurantii florum	0·0
„ *corticum*	6·9
bergamottæ	6·6 and 0
betulini	22·4
calami	24·2
carvi	6·6, 8·3, 0
caryophyllorum	88·8, 86 9, 73·8
cassiæ florum	6·7
„ *foliorum*	73·2
cinnamoni	25·7
citri cuticum	23 6 and 0
elemi	12·1
fœniculi	65·7
gaultheriæ (artficial)	89·4
laurocerasi	13·8 and 0
lavandulæ	2·4 and 0
olibani	9·1
petroselini	92·2

The authors consider that these numbers will be useful in the examination of essential oils, and that the method should take its place among the quantitative reactions. The quantity of eugenol, anethoil, &c., can be calculated from the "methyl number." Oils containing sulphur cannot be examined in this way; and those containing the higher alkyls, butyl, amyl, &c., may be known by not giving clear distillates over the silver iodide. D. A. L.

Examination of Oil of Cassia. By H. Gilbert (*Chem. Zeit.*, **13**, 1406—1407).—It is pointed out that oils of cassia and cinnamon may be highly adulterated with resin oils and still pass the tests of the German Pharmacopœia. With nitric acid, sp. gr. 1·45 at 15°, or with 1·50 acid at 6°, both the pure and impure oils give crystals without development of heat; however, with the 1·50 acid at 15° both react violently, with development of heat and without the formation of crystals; therefore, the G. P. test, as neither the sp. gr. nor the temperature of the acid is stated, may lead to the condemnation of a pure oil and *vice versâ*. By determining the "acid number," the adulteration can be detected, as the following numbers show :—

	Acid numbers.
Genuine oil of cassia (with 6 per cent. non-volatile residue)	13
Genuine oil of cassia after 40 hours' aëration......	13
Genuine Ceylon oil of cinnamon (2 per cent. residue)	9
,, ,, ,, ,, (2½ ,, ,,)	10
Adulterated oil of cassia (28 per cent. residue)....	47
,, ,, ,, (prepared from pure oil of cassia by intermixing 20 per cent. of colophony).	40
Colophony, sp. gr. 1·08.........................	150

D. A. L.

Gravimetric Estimation of Thiocyanates. By H. Alt (*Ber.*, **22**, 3258—3259).—The following method can be employed for the estimation of thiocyanates; it is based on the conversion of hydrogen thiocyanate into hydrogen cyanide and hydrogen sulphate by oxidising agents such as nitric acid.

The thiocyanate is dissolved in water, a little more than the calculated quantity of crystalline barium chloride added, and the solution strongly acidified with nitric acid. Barium sulphate gradually separates from the solution, and the precipitation can be hastened considerably by warming gently. The hydrogen cyanide is then expelled by boiling, the solution is diluted with hot water, filtered, and the residual barium sulphate dried and weighed.

Quantitative experiments gave results agreeing very well with those obtained by Volhard's method. F. S. K.

New Reaction of Thiocyanic Acid. By G. Colasanti (*Gazzetta*, **18**, 397—399).—Solutions of thiocyanic acid or of potassium or sodium thiocyanate acquire a permanent, bright emerald-green coloration on the addition of one or two drops of a solution of copper sulphate. The intensity of the coloration varies with the amount of thiocyanic acid present, which may be colorimetrically determined, therefore, by comparison with a standard solution. Although copper sulphate is a less sensitive reagent than ferric chloride, it is capable of imparting a green coloration to an aqueous solution containing $\frac{1}{4000}$ part of potassium or sodium thiocyanate.

The presence of thiocyanates in human urine may be well shown by preparing it in the manner indicated by Gscheidlen (Abstr., 1877, 205), and adding one or two drops of a dilute copper sulphate solution to the neutral aqueous extract. The intensity of the coloration obtained corresponds with a higher percentage of thiocyanic acid than that found by Gscheidlen.

Saliva must be freed from mucus by precipitation with alcohol, the filtrate evaporated to dryness on the water-bath, and the residue taken up with water and acidified with a trace of acetic acid before the addition of the copper sulphate. The green coloration is not so brilliant as that obtained with urine. S. B. A. A.

Examination of Crude Phenol and Cresol. By W. W. Staveley (*Chem. Zeit.*, 13, 1126—1127).—It is pointed out that the method of testing crude phenols and cresols, by shaking with a double volume of 9 per cent. soda, and measuring the volume of undissolved liquid either with or without the addition of light petroleum, is untrustworthy, because, firstly, the quantity of soda is insufficient for material containing more than 60 per cent. of phenol; secondly, cresol, although insoluble in petroleum in the presence of water, is soluble when the petroleum contains 10—20 per cent. of coal-tar oils, moreover the higher homologues of cresol are soluble in any case; thirdly, the water in the crude phenol is taken up by the alkali, and is reckoned as phenol; and, fourthly, material containing even 2 to 3 per cent. of naphthalene gives a perfectly clear solution. The method is more workable if four volumes of 10 per cent. soda are used, the alkaline layer separated, neutralised with dilute acid, agitated with a measured volume of benzene, and the volume read off. In Williams' method for examining carbolic powders (this vol., p. 300), the quantity of alkali is also insufficient for treating rich material, whilst in Tidy's method not only is this the case, but also the solubility of the coal-tar acids in sodium sulphate is overlooked, and there is loss by volatilisation of the phenol. In Tóth's method the strong alkali, of sp. gr. 1·250—1·300, gives rise to a strong solution of the cresoxides, which dissolve large quantities of hydrocarbons; moreover any light hydrocarbons present could hold the free phenols in suspension, and so prevent their solution in the alkali. For estimating water in crude phenols, agitation of 50 c.c. with 30 to 50 c.c. of benzene and 30 c.c. of 50 per cent. sulphuric acid is recommended; the sulphuric acid is better than calcium chloride, which in its turn is better than sodium chloride. D. A. L.

Estimation of Glycerol in Soap Lyes and Crude Glycerol. By O. Hehner (*J. Soc. Chem. Ind.*, 8, 4—9).—The author has investigated the chief methods in use for the estimation of glycerol in order to test their accuracy. He finds that the method based on the extraction of glycerol from the concentrated liquors by means of alcohol and ether is useless, unless the final evaporation is conducted in a vacuum, owing to the loss of glycerol by volatilisation. The lead oxide process gives good results with glycerols of fair purity, but in samples containing notable quantities of free alkali, sulphates, or resinous substances, the method gives untrustworthy results. The dichromate method is rapid, accurate, and presents no difficulty. With pure glycerol the oxidation is absolutely quantitative. Crude glycerols are treated as follows:—For the removal of chlorine and of aldehydic compounds, some silver oxide is added to a weighed quantity of the sample (about 1·5 grams), which is placed in a 100 c.c. flask. After slight dilution, the sample is allowed to remain with the silver oxide for about 10 minutes. Basic lead acetate is then added in slight excess, the bulk of the mixture made up to 100 c.c., and a portion filtered through a dry filter. 25 c.c. is placed in a beaker, and treated with 40—50 c.c. of standard dichromate solution, and about 15 c.c. of strong sulphuric acid; the beaker is then covered with a watch-glass, and heated for two hours in boiling water. After this, the excess of dichromate is titrated back with ferrous ammonium sulphate.

The acetin method (Abstr., 1888, 1345) is rapid and simple, and gives concordant results when the following precautions are observed:— The heating at the various stages should be carried on in a reflux apparatus, and the sodium acetate should be cautiously heated before use. After acetylation is complete, the operations should be conducted as rapidly as possible, owing to the fact that triacetin is gradually decomposed when in contact with water. The free acetic acid must be neutralised as cautiously as possible, and with rapid agitation of the diluted solution, so that the alkali may not be locally in excess more than is unavoidable, on account of its action on the triacetin. To ensure the greatest amount of accuracy, the author advises taking the mean of the results obtained by the dichromate and triacetin methods. D. B.

Estimation of Glycerol in Wine and Beer. By H. v. Toerring (*Zeit. ang. Chem.*, 1889, 362—365).—The chief improvement introduced into the process is the purification of the glycerol by distillation under reduced pressure. The beer (50 c.c.) or wine (15 c.c.) is concentrated on the water-bath to 10 c.c., and then mixed with 15 grams of plaster of Paris. The resulting dry mass is powdered and extracted in a syphon extraction apparatus with absolute alcohol for six hours. The alcoholic extract, or the original wine, if it contained less than 5 per cent. of extractive matter, is mixed with a little water, and then evaporated until every trace of alcohol is expelled. The residue is introduced into a small retort (100 c.c.), enclosed in a sheet-iron air-bath, and connected with a Liebig's condenser, a flask to receive the distillate, and a pump. The water is first distilled over by heating the bath to 150—170° without working the pump. The apparatus is then exhausted to the tension of aqueous vapour, and the bath raised to 190—210°, when the glycerol distils over completely within an hour. After cooling, a little water is introduced into the retort and distilled over, to rinse out the last traces of glycerol. The distillate is best treated by the method of Diez. The aqueous solution, which should contain 0·5 to 1 per cent. of glycerol, is mixed with 5 c.c. of benzoic chloride and 35 c.c. of 10 per cent. soda solution, and is vigorously shaken for some time, with frequent cooling. When the precipitated glyceryl benzoate has hardened, it is crushed beneath the liquid, and collected on a tared filter, washed with water, dried at 100°, and weighed; 1 part of glycerol gives 3·85 parts of benzoate. M. J. S.

Polariscopic Estimation of Sugar in Sweet Wines. By A. Bornträger (*Zeit. ang. Chem.*, 1889, 477—486, 505—508, 538—545).—The sugar in wine is a variable mixture of dextrose and lævulose, with sometimes saccharose. The usual mode of examination consists in estimating the total quantity of sugar by titration with copper solution, and then ascertaining by the optical method the proportions of the two glucoses, and inverting with hydrochloric acid for the detection of saccharose. The author considers that in our present ignorance of the true rotatory power and reducing action of lævulose, the exact calculation of the proportions of the sugars has only a relative value. His mode of preparing the wine for examination is as follows:—The wine is accurately neutralised in the cold with soda or potash, evaporated on the water-bath until the alcohol is expelled, mixed after cooling with a moderate quantity of lead acetate, made up to the original volume, and filtered. After the lapse of 24 hours this filtrate is fit for both polariscopic examination and for titration. If, however, the wine is so dark coloured that the above method only gives a sufficiently colourless filtrate when the amount of acetate is large enough to produce an alkaline reaction, it is necessary to neutralise the filtrate with acetic acid and dilute to double the volume. Special experiments have been made on each feature of the above process. Although the specific rotatory power of both dextrose and lævulose varies with the strength of the solution, yet within the limits occurring in wines the variations need not be taken into account. The specific rotatory power of lævulose increases, however, so much more rapidly than that of dextrose, that in wines containing a great excess of the former little more can be done than to state the fact of an excess. The removal of the alcohol is considered to be essential, since the specific lævorotatory power of inverted sugar diminishes with progressive increase in the amount of alcohol present; moreover, after removing the alcohol, less lead acetate is required for decolorisation. The evaporation temporarily reduces the rotatory power, but the original rotation is always restored by 24 hours' repose after dilution. The presence of alkaline chlorides (derived from the hydrochloric acid used for inversion and the alkali for subsequent neutralisation) increases the rotation, but with the proportions recommended (one-tenth vol. of acid of 1·1 sp. gr.), this is almost exactly compensated by the evaporation, for in the presence of chlorides the recovery of the rotatory power, diminished by evaporation, is not complete in 24 hours. It is very important to avoid an alkaline reaction at any stage, as even in the cold this soon diminishes the rotation. M. J. S.

Detection of Sugar in Urine. By WERNER (*Chem. Centr.*, 1889, ii, 812—813; from *Pharm. Centralh.*, 30, 515).—The author has found that Maschke's modification of Böttger's test for sugar in urine always gives trustworthy results (this Journal, 1877, ii, 930).

J. W. L.

Unfermentable Dextrorotatory Constituent of Honey. By E. v RAUMER (*Zeit. ang. Chem.*, 1889, 607—609).—See this vol., p. 356.

Estimation of Potassium Hydrogen Tartrate and of Tartaric and Malic Acids in Wine. By R. GANS (*Zeit. ang. Chem.*, 1889, 669—671).—The investigation was undertaken to ascertain how far the estimation of these three acid substances by Borgmann's method would be affected by the presence or absence of other constituents of grape must and wine. The method consists in evaporating to a syrup, precipitating the potassium hydrogen tartrate by alcohol and filtering, the precipitate being then dissolved in hot water and titrated by soda. The alcoholic filtrate is divided into two equal parts, one of which is neutralised with potash and then added to the other. The potassium hydrogen tartrate so produced is then separated as before, and the potassium hydrogen malate should be found in the filtrate. In presence of much sugar, a portion of the potassium hydrogen tartrate escapes precipitation, whilst on the other hand, part of the tartaric acid is retained by the filter in spite of repeated washings with alcohol. This affects also the tartaric acid estimation, which is further vitiated by a portion of the malic acid not passing into the alcoholic filtrate. In the absence of sugar, however, nearly the whole of the malate is precipitated and is thereby estimated as tartaric acid, and at the same time the amounts of the other errors are altered. The method is therefore perfectly useless for comparing the acid constituents of must with those of the wine made from it. M. J. S.

Estimation of Tartaric Acid in Vinegar. By A. JOLLES (*Chem. Centr.*, 1889, ii, 944; from *Zeit. Nahr. Hygiene*, 3, 185—186). —The author takes advantage of the fact that tartaric acid gives a yellow coloration with dilute ferric chloride solution. 5 c.c. of the vinegar is diluted to 1000 c.c., and of this solution from 5 to 20 c.c is filled into narrow tubes so that the depth of liquid may be about 20 cm. 2 c.c. of the ferric chloride solution (1 per cent) is added, and the depth of colour produced compared with that from known quantities of tartaric acid contained in similar tubes. For this purpose, a 0·1 per cent. tartaric acid solution is recommended. Coloured vinegars must be decolorised. J. W. L.

Adulteration of Milk. By PERRON (*J. Pharm.* [5], 21, 63—66).—Samples of milk were suspected to be adulterated by the addition of fatty oil converted into an emulsion by means of borax or yolk of egg. In these cases the lactometer may give false indications. The borax is easily detected on examining the ash of the milk spectroscopically. The addition of oil to take the place of cream surreptitiously removed is readily ascertained by determining the solidifying point of the fatty acids obtained from the milk by evaporation, extraction with ether, saponification, and treatment with dilute sulphuric acid. Butter gives acids which solidify between 37·5° and 38·5°, whilst the oils give acids solidifying below 10°. J. T.

Testing Lard for Cotton-seed Oil and Beef Stearin. By J. PATTINSON (*J. Soc. Chem. Ind.*, 8, 30—32).—The silver nitrate test is based on the reducing action of cotton-seed oil, the reduced silver imparting a colour to the lard. The author recommends adding an alcoholic solution of silver nitrate to an ethereal solution of the lard. For beef stearin, the best test is the microscopical appearance of the crystals formed from an ethereal solution of the lard, the crystals of beef stearin forming curved tufts, the terminations being pointed and hair-like, whilst lard crystals are usually found in oblong plates, occasionally radiated, and have oblique terminations. The author finds that pure lard has an iodine absorption of from 57 to 63, cotton-seed oil, 105 to 116, beet stearin, 23 to 28, and beef fat about 41 per cent. When the amount of cotton-seed oil is ascertained by the silver test, a near approach to the amount of beef stearin present can be calculated from the iodine absorption after making allowance for the influence of the known quantity of cotton-seed oil. The sp. gr. test is also useful. At 210° F., pure lard has a sp. gr. varying from 0·860 to 0·861, cotton-seed oil is 0·868, and beef stearin, 0·857. Some adulterated samples of lard which have come under the author's notice have had a sp. gr. of 0 8635. D. B.

Examination of Castor Oil. By H. Gilbert (*Chem Zeit.*, **13**, 1428).—The test in the German pharmacopœia for castor oil cannot detect an admixture of resin oil, because the two kinds of oil have many properties in common; but saponification distinguishes between them: for example, an impure sample gave all the G. P. tests, and was right as to consistency and colour, but was suspicious in odour and taste; when saponified with soda, the number was 126 instead of 180—181·5, and the ether extract had the characters of resin oil. Moreover, when castor oil is shaken with an equal volume of nitric acid of sp. gr. 1·31, the former becomes slightly brown, the latter remains colourless, whereas the resin oil under similar circumstances becomes black and the acid yellowish-brown; whilst mixtures of castor and resin oils react like the latter, but with less vigour.

D. A. L.

Examination of Wax. By H. Röttger (*Chem. Zeit.*, **13**, 1375—1376).—By Hübl's method, the wax is warmed with 95 per cent. alcohol and titrated with deminormal alcoholic potash, more alcoholic potash is then run in, the mass saponified by heating on a water-bath, and titrated back with deminormal hydrochloric acid; the first titration gives the "acid" number, the second the "ether" number, and the two together the "saponification" number.

Numerous investigations have shown that these numbers for pure yellow beeswax range respectively between 19 and 21 (mostly 20) for "acid" numbers, 73 and 76 (mostly 75) for the "ether" numbers, whilst the "saponification" numbers vary between 92 and 97, being in most cases 95, and the "ratio" of the "acid" to the "ether" numbers 1 : 3·6—3·8 (3·7).

Buchner examined some so-called pure, white wax, and from his results inferred that chemically bleached wax had higher "acid" and "saponification" numbers, 23·01 and 98·36, and a lower "ratio," 1 : 3·2. This has not been confirmed by subsequent investigators. Firstly, Helfenberg has shown that unpurified wax, or that purified either with charcoal or with permanganate, does not give abnormal numbers, and now the author has obtained the following numbers from wax bleached with sulphuric acid:—

Sp. gr.	"Acid" number.	"Ether" number.	"Saponification" number.	Ratio.	.e
0·966	20·2	76·7	96·9	3·79	1.

Therefore it does not appear necessary to adopt any different normal numbers for bleached than for yellow wax. The author points out that often the so-called genuine wax of commerce is no such thing; for example, two samples marked genuine and pure gave the following numbers:—

	I.	II.
"Acid" number..........	29·7	31·46
"Ether" "	87·5	67·66
"Saponification" number..	117·2	99·1
"Ratio"	2·9	2·14

Analysis of Methylanilines. By F. Reverdin and C. de la Harpe (*Bull. Soc. Chim.* [3], 2, 482—483; compare Abstr, 1889, 1038; this vol., p. 309).—Replying to the criticism of Giraud on their process, the authors deny the necessity for employing absolutely pure acetic anhydride, and state that if the operation is conducted in a large cooled flask there is no need to dilute the reagent.

T. G. N.

Estimation of Nicotine in Tobacco. By R. Kissling (*Chem. Zeit.*, 13, 1030).—Popovici (Abstr., 1889, 802) obtained low results by the author's method when estimating nicotine by means of the polariscope, and he attributed it to loss by volatilisation while evaporating the ether. The author now states that when the operation is carefully conducted the loss from this source is negligible; moreover, as Popovici compared his tobacco extracts with standard numbers obtained with pure nicotine solutions, the author suggests that the results may be influenced by substances other than nicotine present in the tobacco extracts. D. A. L.

Estimation of Tannin by Permanganate. By F. Gantter (*Zeit. ang. Chem.*, 1889, 577—580).—The method known as the "cubic centimetre method" gives results which vary much with comparatively small alterations in the manner of conducting it. Seemingly, the oxidation of both the tannin and the indigo used as indicator is very imperfect in the cold. At the boiling temperature the oxidation is complete, but the end of the reaction is masked by the formation of a brown precipitate. This can be dissolved by boiling with a known quantity of oxalic acid, and the titration can then be completed with the same ease as one of oxalic acid alone. From experiments with pure tannin, as well as from others with extract of oak bark, in which a gravimetric method was used for comparison, it is found that 1 milligram of tannin requires 3·988 milligrams of potassium permanganate (or is equivalent to 7·951 milligrams of oxalic acid), and that within wide limits the concentration of the solution has no influence. The solutions required are—(1) potassium permanganate, containing 3·988 grams per litre; (2) oxalic acid, 7·951 grams per litre. The extract from 10 grams of bark is made up to 1 litre; 10 c.c. is mixed with 10 c.c. of dilute sulphuric acid and heated to boiling. Permanganate is then added in quantities of c.c. until the disappearance of the red colour becomes slow; the mixture is again boiled up, and the permanganate is added drop by drop, waiting each time until the liquid has become colourless. When the brown precipitate no longer disappears on vigorous boiling, 1 c.c. more is added, and the boiling is continued for some time. Oxalic acid is then added until the liquid is colourless, and the titration is finished as usual. For accurate work, a second portion of the extract should be titrated in the same manner after removal of the tannin by hide, but for technical purposes this is scarcely necessary.

M. J. S.

Volumetric Estimation of Tannin in Wines. By L. Roos, Cusson, and Giraud (*J. Pharm.* [5], 21, 59—63).—A 10 per cent. solution of tartaric acid is made very slightly alkaline by the addition of ammonia, and to this is added a neutral lead acetate solution until the precipitate which first forms just ceases to be redissolved; after being filtered, the solution is ready for use. This solution completely precipitates tannin from its solutions; it is standardised by means of a solution of pure tannin as follows:—25 c.c. of a tannin solution of 5 grams per litre is placed in a flask with 4 or 5 drops of ammonia. The lead aceto-tartrate solution is run in, a couple of c.c. at a time, from a burette. After each addition, a drop of the solution is placed on a double filter-paper, the upper one of which retains any precipitate that may have been conveyed by the drop, while a drop of sodium sulphide is brought into contact with the liquid in the lower paper. A brown stain, due to excess of lead, only appears after the tannin is completely precipitated. After a preliminary estimation, the titration is more accurately made by adding a few drops at a time of the lead solution when near the end of the process. The estimation of tannin in wine is made in precisely the same manner. The method is very rapid, and gives very satisfactory results.

J. T.

Determination of Lupulin in Hops. By F. Reinitzer (*Bied. Centr.*, 18, 859).—A portion of the hops (not weighed) is sifted by Haberlandt's process, and any grains which pass through the sieve removed with forceps. The lupulin is then weighed, shaken, and washed with chloroform into a dry filter, in which it is then wrapped and extracted with chloroform for about an hour. When dry, it is removed from the filter-paper to the weighing glass previously used, and weighed. The amount of lupulin husks is thus determined, and that of the lupulin found by subtracting this amount from the original weight.

A second weighed portion of the hops is then extracted with chloroform in a Soxhlet's apparatus, shaken on a sieve, the pieces of leaf removed with forceps, and the lupulin brushed through. The sifted portion is again sifted to obtain it free from grains. The pure lupulin husks are now weighed, and from the numbers, with the help of those previously obtained, the original weight of lupulin is calculated. The method gives much more concordant results than that originally employed by Haberlandt, and gives a better insight into the composition of hops than was previously possible. Examples of analyses are given which support this statement.

Diastasic Power of Extract of Malt. By R. A. Cripps (*Pharm. J. Trans.* [3], 20, 481).—The author refers to the very discordant results of published determinations of the digestive power of malt extracts; he describes his slightly modified method of estimation, and declares that extract of malt should completely digest its own weight of potato starch in from 10 to 15 minutes at 37°. R. R.

Detection of Carbonic Oxide Hæmoglobin. By A. Welzel (*Chem. Centr.*, 1889, ii, 942; from *Centr. med. Wiss.*, 27, 732—734). —Zinc chloride or very dilute platinic chloride solutions produce a bright-red coloration with carbonic oxide hæmoglobin, whilst normal blood is coloured brown or very dark brown. If the blood is diluted with water, the precipitated hæmatin and albumin are coloured. Carbonic oxide blood after standing in cold water for two minutes becomes raspberry-coloured, oxyhæmoglobin greyish-brown. 25 per cent. of carbonic oxide blood was detected by this means. Phosphomolybdic acid or 5 per cent. phenol produces a carmine-coloured precipitate with carbonic oxide blood, a reddish-brown one with oxyhæmoglobin; 16 per cent. of the former can be detected by this reaction. If 15 c.c. of 20 per cent. potassium ferrocyanide solution in 2 c.c. of dilute acetic acid is added to 10 c.c. of carbonic oxide blood, an intense, bright-red coloration is produced; normal blood becomes dark-brown-coloured with this treatment. If 4 parts of normal blood is diluted with 4 parts of water and shaken with 3 volumes of a 1 per cent. tannin solution, it becomes coloured primarily bright-red with a yellowish tinge; at the end of 1 to 2 hours it has become brownish, and finally has turned grey at the end of 24 hours; carbonic oxide blood treated in the same manner is also coloured bright-red at first with a bluish tinge, which colour, however, remains unchanged. Both of these reactions were observable with 1 per cent. carbonic oxide blood in 1·0 per cent. hæmoglobin, and carbonic oxide was detected in air by its means when present to the extent of 0·0023 per cent. Phenylhydrazine produces a bright-red coloration with blood containing carbonic oxide, and a dark-red coloration changing to black with normal blood; the blood is diluted to 1 in 40 for this reaction. If more than 5 drops of the phenylhydrazine solution is added, a greyish-violet coloration is obtained with oxyhæmoglobin, and a rose-red colour with carbonic oxide blood. A rabbit died when its blood was three-fourths saturated with carbonic oxide

General and Physical Chemistry.

Refractive Power of Solutions of Simple Salts. By E. Doumer (*Compt. rend.*, 110, 40—42).—If μ is the refractive power of the salt with respect to water, and P*m* its molecular weight, then the product μP*m* is the *molecular refractive power*. All salts of the same acid and of the same type have the same molecular refractive power. For the chlorides $M'Cl$, $\mu Pm = 21·5$; for the chlorides $M''Cl_2$, 42·8; for the sulphates M'_2SO_4, 42·5; for the sulphates $M''SO_4$, 43·1; for the nitrates MNO_3, 21·7.

The molecular refractive powers of salts of different types are multiples of the same number—

KCl.	K_2SO_4.	Na_3PO_4.	$PtCl_4$.	$Al_2(SO_4)_3$.
20·7	43·1	64·3	89·8	130·5

The molecular refractive power is a function of the valency of the metallic constituent of the salt.

The observed deviations from the mean value of μP*m* may be traced to chemical as much as to physical causes. Seven out of the sixty-two salts examined seem to depart from the third law. Twenty examples of double salts indicate that their refractive power is the sum of the refractive power of their constituents.

These results lead to the conception of *optical equivalents*.

C. H. B.

Refractive Power of Solutions of Double Salts. By E. Doumer (*Compt. rend.*, 110, 139—141; see preceding abstract).—The molecular refractive power of double salts is the sum of the molecular refractive powers of their constituent salts, a result similar to that obtained by Berthelot and by Landolt with certain organic liquids.

The refractive power of different double salts is proportional to the valency of their respective metallic constituents. It follows that the refractive powers of any salts, double or simple, are proportional to the valencies of their metallic radicles. These facts make it possible to determine the refractive power of a simple salt which is difficult to prepare and purify alone, but which forms readily crystallisable double salts.

Observations of the refractive power also throw light on the constitution of double salts. For example, if potassium ferrocyanide is a compound of K_4 with the radicle FeC_6N_6, the sum of the valencies of the metal is 4, but if it is a double cyanide $4KCN,Fe(CN)_2$, the sum of the valencies of the metals is 6. As a matter of fact, the refractive power of the ferrocyanide is 21·5 × 6, and hence it would follow that it is really a double salt.

C. H. B.

Absorption of Ultra-Violet Rays by Derivatives of the Paraffins. By J. L. SORET and A. A. RILLIET (*Compt. rend.*, **110**, 137—139).—It is very difficult to obtain compounds sufficiently pure for observations of this kind. The alcohols show great transparency to the ultra-violet rays, and apparent exceptions are probably due to impurities. The rectification and prolonged desiccation of the alcohols often leads to slight oxidation, which greatly impairs their transparency. Hartley and Huntington concluded that in the series of alcohols the absorption of the ultra-violet increases as the complexity of the molecule increases. The authors found, however, that if the process of drying had been rapidly carried out, ethyl alcohol is not appreciably less transparent than methyl alcohol.

Ketones are very opaque to the ultra-violet rays, but the differences between different individuals were not greater than might be attributed to small quantities of impurities.

Haloïd-derivatives containing the same electro-negative radicle do not differ appreciably in their absorptive power, or, in other words, the substitution of one alkyl radicle for another has little effect on their transparency. This is especially well marked in the case of the iodo-derivatives. The haloïd salts of sodium and potassium are decidedly less opaque than corresponding alkyl-compounds, and, hence, the substitution of an alkyl radicle for an alkali metal reduces the transparency. There are other differences between the spectra of the two classes of compounds which indicate that their molecular grouping is not similar. Haloïd-derivatives containing different electro-negative radicles have very different degrees of transparency, iodo-derivatives absorbing most, and bromo-derivatives less, whilst chloro-derivatives are very transparent.

Pure ether is almost as transparent to ultra-violet rays as pure water.

No new conclusions were drawn from an examination of many acids of the acetic series and their sodium and alkyl salts. The difficulties in the way of obtaining these compounds sufficiently pure are extremely great. Vapours of liquids which are volatile and have sufficient absorptive power, also exert an absorptive action on the ultra-violet rays.

The action on the ultra-violet rays constitutes a very delicate test of the purity of an organic compound. C. H. B.

Spectroscopic Evidence of Traces of a New Element, belonging to the Eleventh Series in Mendeléeff's Table, and occurring in Tellurium and Antimony, and also in Copper. By A. GRÜNWALD (*Monatsh.*, **10**, 829—861).—The author finds a coincidence between certain of the lines in the ultra-violet spectra of tellurium, antimony, and copper, and argues that this points to the occurrence of a common impurity in the three elements. He is of opinion that this impurity was originally present in the tellurium, and that from this a portion of it is transferred to the antimony and copper in the reduction of these metals from their ores. Many of the above coincident lines are transformed on multiplication by $\frac{11}{10}$ into lines of the primary element "*b*" in the water spectrum, and this, in accordance with the principle formerly laid down by the author (Abstr., 1889, 455), indicates that the above impurity largely consists of an element occurring in the eleventh horizontal line in Mendeléeff's table. The character of the spectrum shows that it cannot be one of the known elements in this series, and the author believes that it is an unknown element in the tellurium group, with an approximate atomic weight of 212, and probably identical with Brauner's austriacum. It is, therefore, an element which in general properties closely resembles tellurium and also antimony, and is, hence, difficult to separate from these. In copper, it probably behaves as an electronegative element, on the assumption that pure copper is an alkali metal of low melting point, and is ordinarily found combined with this difficultly fusible non-metallic constituent.

The author states that Brauner, according to a verbal communication, has quite independently arrived at conclusions similar to the above. H. C.

New Fluorescences. By L. DE BOISBAUDRAN (*Compt. rend.*, **110**, 24—28 and 67—71).—The author has examined the fluorescences obtained with the oxides of samarium, *Zα*, and *Zβ* as active substances, and silica, zirconia, stannic oxide, and tantalic oxide as solid solvents.

Samarium oxide in silica gives a moderately intense rose-red fluorescence with a spectrum of one very broad red band. If the passage of the discharge is continued, the rose-red fluorescence becomes feeble, and is partially replaced by the blue fluorescence of pure silica. The same mixture, previously more strongly heated, gives a fine orange fluorescence, showing three broad nebulous bands, each containing a very distinct although slightly nebulous line.

Samarium oxide in zirconia gives at first a beautiful orange fluorescence with several well-defined lines, but their brilliancy and distinctness rapidly diminish as the passage of the discharge continues.

Zα in silica gives a brilliant yellow fluorescence characterised by a strong dissymmetrical band. The fluorescence of *Zβ* was faintly visible, and as the discharge continues, the bands of *Zα* fade considerably but those of *Zβ* remain unaltered.

Zα (1 per cent.) in zirconia gives a yellow fluorescence which at first is somewhat brilliant, but rapidly becomes feeble as the discharge continues. The spectrum contains a yellow and a blue band, each with a nebulous line, and is very different from that of *Zα* in silica.

Zβ (0·42 per cent.) in silica gives a fluorescence which at first is brilliant and almost white, but quickly becomes green, because the yellow band of *Zα*, present as impurity, fades rapidly, whilst the green band of *Zβ* retains its intensity. It follows that the fluorescence is a more sensitive test for *Zα* than for *Zβ*, a result which is also obtained in other media.

Zβ (2 per cent.) in zirconia gives only a yellow fluorescence showing nothing but a feeble spectrum due to the presence of traces of *Zα*.

Samarium oxide in stannic oxide, previously heated at the melting point of silver, shows only a feeble orange fluorescence, but if more strongly calcined, it gives at first an orange-yellow to pale-yellow fluorescence, according to the perfection of the vacuum. This, however, very rapidly becomes faint as the passage of the discharge continues; and the same stannic oxide alone gives a yellow fluorescence which is very similar to that obtained in presence of samaria and is probably due to some impurity.

Samaria in tantalic oxide gives a dull orange fluorescence which becomes feebler as the discharge continues, although less rapidly than when zirconia or stannic oxide is the solvent. Its spectrum consists of two somewhat feeble, broad and nebulous bands, similar in position to those given by samaria in alumina, but different in character.

$Z\alpha$ (1 per cent.) in stannic oxide gives no noteworthy fluorescence.

$Z\alpha$ (1 per cent.) in tantalic oxide, after strong calcination, gives a very feeble greenish-yellow fluorescence which rapidly becomes fainter as the discharge continues. It shows faintly the bands due to $Z\beta$.

$Z\beta$ (3 per cent.) in stannic oxide also gives practically no fluorescence.

$Z\beta$ (3 per cent.) in tantalic oxide gives a beautiful but not very brilliant, slightly yellowish-green fluorescence which is less affected by the continuation of the discharge than the corresponding fluorescence of $Z\alpha$. The bands of $Z\alpha$ were also faintly visible.

These results afford further evidence of the fact that the fluorescence of one and the same active substance may vary considerably in different solvents. The alterations in the bands, &c., may be due to combination taking place between the solids. There is a general similarity between the spectra of the same substance in various media, but when it is a question of identity or otherwise between two substances, it is essential that the conditions should be identical. The rapid extinction of the fluorescence observed in some cases when the discharge is continued depends on both the nature of the active substance and the nature of the solvent. In silica or tantalic oxide, the fluorescence of $Z\alpha$ fades rapidly, but that of $Z\beta$ does not alter. The fluorescences of samarium oxide and $Z\alpha$ in zirconia fade more rapidly and completely than in silica. As a rule, the fading depends more on the solvent than on the active substance, but each constituent of the mixture tends to confer on it its own special properties.

Samaria in alumina and silica respectively affords a good example of the influence of calcination on the fluorescence. Samaria in alumina moderately calcined gives a spectrum of three diffuse bands, the central orange one having a relatively distinct line; but the same mixture, after being more strongly heated, gives a second spectrum of a totally different type, consisting of three groups of much more brilliant and distinct lines, their mean wave-lengths being higher than those of the bands of the first type. Samaria in silica, however, when treated similarly, gives only a spectrum of the first type, the three bands being much more luminous than in the case of alumina, and each having a strong line. Of course the position of the bands is not the same with the two oxides. C. H. B.

Conditions of Equilibrium between Electrolytes. By S. Arrhenius (*Zeit. physikal. Chem.*, 5, 1—22).—The author first considers the equilibrium between an acid and one of its salts. If x represents the fractional amount of dissociated acid, and d that of the salt, and V the volume in litres containing a gram-molecule of the acid, and n molecules of the salt, then $(nd + x)x = KV(1 - x)$, K being the dissociation constant which is determined from the conductivity of the acid. This formula is found to hold in the case of acetic and formic acids and their sodium salts. For feeble acids x is small, and in comparison with nd or 1 becomes negligible, so that since d is practically independent of the dilution, the degree of dissociation, that is, the strength of a feeble acid when a salt is present in the same solvent, becomes proportional to the amount of the salt.

Equilibrium between a feeble acid, such as acetic acid, and a salt such as sodium chloride is a case of equilibrium between four substances, the above two and the sodium acetate and hydrochloric acid that are formed. If the fractional dissociation of these substances in the order named be expressed by $d_1d_4d_2d_3$, and 1 mol. of acetic acid on being brought into contact with n mols. of NaCl gives rise to x mols. of HCl and sodium acetate, then—

$$d_2xd_3x = d_1(1 - x)d_4(n - x).$$

This expression is also found to agree with the experimental results.

From this last expression it is possible to deduce a value for the so-called "avidity" measured by Thomsen and Ostwald, and the author finds that for monobasic acids the avidities for any given dilution are approximately proportional to the degrees of dissociation of the acids at this dilution. Ostwald's results are shown to be in agreement with this conclusion.

It is found from the above that the Guldberg-Waage theory is only applicable to equilibrium between four electrolytes when two out of the four are strongly dissociated. The conclusion drawn from this theory, that the avidities of acids are proportional to the square roots of their affinity coefficients, is incorrect.

The decomposition of certain salts by water, which was observed by Walker to follow the ordinary laws of mass action, is shown by the author to take place in accordance with the equation last stated. In this case it is necessary to assume that the water is an electrolyte and partially dissociated. H. C.

Electrolytic Crystallisation and Dimorphism of Lead. By O. Lehmann (*Zeit. Kryst. Min.*, 17, 274—279).—The author has formerly shown that the electrolytic formation of crystals may be compared with ordinary crystallisation on the assumption that the metal which separates out at first remains dissolved in the electrolyte, and that, when the latter becomes saturated, it crystallises out in the ordinary manner. Ostwald has shown that the free metal may be capable of existing in the electrolyte (Abstr., 1888, 1142), and the above view is also supported by the observation of the author (this vol., p. 317) that during electrolysis, the metal which separates out is deposited more readily on an electrode of the like metal than on that of another. He now finds that when the strength of the current is increased until the metal no longer forms a uniform deposit on the surface of the electrode, the crystals that are deposited arrange themselves into a skeleton-like structure, and that further increase in the current strength will only alter the mass of the structure, but not its form. Lead forms an apparent exception to this rule, for with a weak current it separates out in leafy crystals which appear to belong to the monosymmetric system, and are similar to those forming the ordinary lead tree; whilst with a strong current the crystals obtained are those of the regular system and under favourable circumstances, well formed octohedra.

To explain this dimorphism, the author assumes that the rate at which the lead-atoms separate out being far less in the first than in the second case, different molecules are formed in the solution, and that since, as above stated, the metal separates out from the solution in crystalline form, the one set of molecules will form crystals which are distinct from those of the other. H. C.

Sodium Phosphite and Pyrophosphite. By L. AMAT (*Compt. rend.*, **110**, 191—194).—*Disodium phosphite*, $HPO_3Na_2 + 5H_2O$, is neutral to phenolphthaleïn, and melts at 53°; heat of dissolution at 13·5 = − 4·6 Cals. The anhydrous salt is obtained by drying the preceding salt in a vacuum, and finally at 150°; heat of dissolution at 13·5° = + 9·15 Cals.

Monosodium phosphite, $2HPO_3HNa + 5H_2O$; heat of dissolution at 15° = − 5·3 × 2. Heat of dissolution of the anhydrous salt = + 0·75 Cal. at 13°, but increases distinctly with the temperature. Combining these numbers with the heat of solution and neutralisation of phosphorous acid, and the heat of dissolution of sodium hydroxide, we have—

PO_3H_3 solid + NaOH solid = HPO_3HNa solid + H_2O solid.................... develops +25·2 Cals.
PO_3H_3 solid + 2NaOH solid = HPO_3Na_2 solid + $2H_2O$ solid.................... „ +41·6 „

Sodium pyrophosphite; heat of dissolution at 13° = + 0·3. If the pyrophosphite were at once transformed into phosphite in contact with water, it would be very considerably higher, and hence a solution of the pyrophosphite is not identical with a solution of the acid phosphite, a fact which is also proved by its behaviour with phenolphthaleïn, methyl orange, and silver nitrate.

The pyrophosphite is converted into phosphite or phosphorous acid by treatment with sodium hydroxide or sulphuric acid respectively. The change $H_3P_2O_5Na_2$ solid + H_2O liquid = $2HPO_3HNa$ solid develops + 2·54 × 2 Cals., according to the result with soda; whilst the results with sulphuric acid give $H_2P_2O_5Na_2$ solid + H_2O solid = $2HPO_3HNa$ solid develops + 6·23 Cals.

From the heat of dissolution of the monosodium phosphites, $2HPO_3HNa$ solid + $5H_2O$ solid = $2HPO_3HNa,5H_2O$ develops + 19·30 Cals., or 3·86 Cals. per molecule of water. It follows, therefore, that the combination of a molecule of water with sodium pyrophosphite liberates more heat than the combination of a molecule of water of crystallisation with the phosphite. C. H. B.

Heat of Formation of Platinic Chloride. By L. PIGEON (*Compt. rend.*, **110**, 77—80).—In order to avoid the presence of nitrogen oxides and the difficulties of removing them, platinic chloride was prepared by passing chlorine into ammonium platinochloride suspended in water heated at 110°. The solution was evaporated by a gentle heat and finally in a vacuum, when orange-red, deliquescent prisms of hydrogen platinochloride, $H_2PtCl_6 + 6H_2O$, were obtained. If this salt is heated at 360°, it loses water and hydrogen chloride, but first melts and then intumesces. If, however, it is allowed to remain over potash at the ordinary temperature, it loses 4 mols. H_2O, and the dehydrated salt when heated in chlorine at 360° does not melt, but gives off water and hydrogen chloride and yields the tetrachloride as a brown powder. When the latter is heated only to dull redness, it decomposes, and the upper part of the crucible, &c., is studded with small, distinct crystals of platinum, a result similar to that obtained by Moissan with platinum fluoride.

Anhydrous platinum chloride dissolves in dilute hydrochloric acid with development of heat—

$PtCl_4$ solid + 2HCl diss. = H_2PtCl_6 diss. develops + 24·8 Cals.

A further quantity of hydrochloric acid produces no thermal disturbance. Combining this result with Thomsen's value for the heat of formation of dissolved hydrogen platinochloride from solid platinum, gaseous chlorine, and dissolved hydrochloric acid (84·6 Cals.), the following results are obtained:—

Pt solid + Cl_4 gas = $PtCl_4$ solid .... develops +59·8 Cals.
$PtCl_4$ solid + 2KCl solid = K_2PtCl_6 ..... „ +29·7 „
$PtCl_4$ solid + 2NaCl solid = Na_2PtCl_6.... „ +13·9 „

The heat of dissolution of hydrogen platinochloride, $H_2PtCl_6 + 6H_2O$, is +4·34 Cals. C. H. B.

Influence of Certain Groups on the Thermochemical Value of the Hydroxyl- and Carboxyl-groups in the Aromatic Series. By P. ALEXÉEFF and E. WERNER (*Bull. Soc. Chim.* [3], **2**, 717—728).—The introduction of the NO_2 group into a phenol augments the heat of neutralisation by alkaline hydroxides, the increase being greatest for the orthonitro- and least for the metanitro-derivative, whilst the introduction of nitrogen into a phenol, as in the case of the azophenols, determines a diminution which is greatest for the para-derivative.

The substitution of NO_2 for H in the benzoic acid molecule causes an increase in the heat of neutralisation for the ortho- and the para-derivative, whilst the heat evolved by the meta-compound is diminished, and in the azobenzoic acids the nitrogen appears to exercise a diminishing effect, which is greatest for the para-derivative.

With the amidobenzoic acids, the influence of the NH_2 group is to diminish the heat of neutralisation in the descending order, ortho, para, meta.

The substitution of an alkyl radicle for hydrogen also diminishes the heat of neutralisation, but a subsequent introduction into the molecule of NO_2 causes an increment, and in the cases of azocumic and hydrazocumic acids the introduction of nitrogen and of the NH-group again raises the heat of neutralisation.

Numerous experimental data are given which bear out the above conclusions. T. G. N.

New Form of Mixing Calorimeter. By S. U. Pickering (*Phil. Mag.* [5], 29, 247).—The apparatus consists of an oblong platinum vessel, divided into two compartments of 400 c.c. capacity by means of folding doors, which are pressed against a framework by two pairs of bow-shaped iridio-platinum springs; a strip of india-rubber round the edges of the doors prevents leakage. A stirrer worked by an electromotor and a delicate thermometer are placed in each compartment, and as soon as the temperature in each is identical, two ebonite knobs are pressed together, whereby the lower springs are lowered below the doors, and the upper ones are raised above them, the doors then fly open, and allow the liquids to mix. The advantages consist in starting with the liquids at the same temperature, thus eliminating errors due to a comparison of two thermometers, and obviating the necessity of knowing the heat capacity of the two liquids. The two thermometers are used simply to double the value of the observation; the mean difference between the rise registered by them in a number of determinations was found to be only 0·0008°, representing 0·6 cal. S. U. P.

Gradual Alteration in Glass produced by Altering its Temperature a Few Degrees. By S. U. Pickering (*Phil. Mag.* [5], 29, 289).—Observations are quoted to show that a specific gravity bottle, the capacity of which had remained unaltered for six months while kept at 18°, experienced a sub-permanent contraction on being cooled to 8°. The contraction continued during several days, and, although it was not affected by a temporary heating even to 38°, it appeared that prolonged heating at this and lower temperatures restored the bottle to its original capacity. The maximum contraction observed amounted to 0·0001 of its total volume, a quantity which would be equivalent to $\frac{1}{15}$° in a mercurial thermometer. S. U. P.

Determination of Vapour-densities of Substances below their Boiling Points. By R. Demuth and V. Meyer (*Ber.*, 23, 311—316).—The vapour-density of a substance can be determined at a temperature considerably below its boiling point by the ordinary displacement method of V. Meyer, provided that the vaporising bulb is filled with hydrogen, and that some means are adopted for ensuring the rapid distribution of the substance over the bottom of the vaporising bulb.

The determinations are most easily carried out when the substance is solid at the ordinary temperature; in such cases it is not weighed out in any vessel, but is simply cast into a small rod and, after weighing, dropped into the apparatus, where it melts and is quickly distributed over the surface of the bulb. In the case of liquids the authors recommend the use of small vessels made of Wood's fusible metal, which melts quickly when introduced into the vaporising bulb, and thus ensures rapid distribution. These bulbs can be made so thin that there is no danger of breaking the apparatus. Mercury or small platinum spirals can be employed to break the fall when necessary, but sand, asbestos, &c., must not be used. If the liquid acts on Wood's metal, or if the temperature at which the experiment is to be carried out is below the melting point of the alloy, short, wide, cylindrical stoppered glass tubes can be used; as soon as the tube has been introduced into the apparatus, the liquid is made to flow out by tapping the stem of the vaporising bulb.

The capacity of the vaporising bulb should be about 100 c.c., and its diameter 30 mm.: it should be rather flat at the bottom, and the upright tube should not be more than 4 to 5 mm. wide. The quantity of substance taken should be such that its vapour occupies about 9—11 c.c.

Experiments with xylene (b. p. 140°) at 100°, nitrobenzene (b. p. 206°) at 176°, naphthalene (b p. 218°) at 183°, paranitrotoluene (b. p. 238°) at 205°, and ether (b. p. 35°) at 17° showed that the results are as accurate as those obtained in the ordinary way with the apparatus filled with air. F. S. K.

Viscosity of Liquids. By J. WAGNER (*Zeit. physikal. Chem.*, **5**, 31—52).—The viscosity of dilute solutions of a number of salts was examined by the method employed by Arrhenius (Abstr., 1888, 336), and the results obtained by the latter, more especially the correctness of the exponential formula used by him to express the relative viscosities of solutions, were fully verified. The formula gives in all cases approximate expression to the observed values, but generally is not quite within the limit of experimental error.

The author also finds that the viscosity of dilute solutions is an additive function of the metallic and non-metallic radicles of the dissolved salt. This property, which depends on the existence of dissociated molecules in the solutions, is not as marked in the case of the viscosity as with some other of the properties of dilute solutions, but this is explained by the fact that those molecules which remain undissociated exercise their full influence on the viscosity, whereas the influence which they have in many other cases is only small. The dissociated ions have seemingly in some cases greater, and in other cases less viscosity than the original salt.

The viscosities of the different metals are compared one with another. Those of allied metals are found to be of the same order, but in these cases the viscosity decreases as the atomic weight increases. H. C.

Nature of Osmotic Pressure. By L. MEYER (*Zeit. physikal. Chem.*, **5**, 23—27).—The author objects to the term "osmotic pressure" as used by Van't Hoff (Abstr., 1888, 778). To regard this pressure as caused by the substance which does not pass through the membrane is incorrect, as it is simply due to a larger passage of liquid in one direction than in the other. It also cannot be said to be due to dissolved substance or the solvent alone, since by altering the nature of the membrane the solvent and dissolved substance may be made to change places, one membrane being only permeable by the first, and another only permeable by the second.

H. C.

Exceptions to the Gaseous Laws in Solutions. By A. A. NOYES (*Zeit. physikal. Chem.*, 5, 53—67).—The gaseous laws applied to dilute solutions by Van't Hoff are found to be subject to numerous exceptions, which it may be assumed are caused by a diminution of the free path of the moving molecules, owing to the space being partly occupied by the molecules of the solvent and of the dissolved substance, and also perhaps due to an attraction existing between the dissolved substance and the solvent. On these assumptions, the author finds that Boyle's law in solution must be altered to $p(v - d) = K$, p being the osmotic pressure, v the volume in litres of the solution containing a gram-molecule of the dissolved substance, and d and K being constants. This expression is found to be in very close agreement with the results obtained by Beckmann for the reduction of the freezing point in various solutions (Abstr., 1889, 11), this latter being proportional to the osmotic pressure, and therefore giving the value of p.

The reasoning by means of which the above formula is deduced gives $d = (1 - a_1)\dfrac{b - Bc}{1 - c}$, in which a_1 is a constant, B the volume of the gram-molecule, and b the volume of the molecules in a gram-molecule of the dissolved substance, and c the volume of the molecules in a litre of the solvent. The author shows that the values of d in various cases are in general agreement with the above expression, which theoretically should obtain for this constant.

Although in these deductions account is taken of a specific attraction between the dissolved substance and the solvent, the same result is obtained if this be neglected, so that seemingly it does not exist.

H. C.

Solubility of Saline Mixtures. By A. ÉTARD (*Bull. Soc. Chim.* [3], 2, 729—734).—When a small quantity of water acts on excess of sodium and potassium chlorides, the curve expressing the amount of mixed salts contained by the resulting solutions is rectilinear, and from its angular coefficient, the author finds that the temperature at which water would disappear from the solution is 738°, which is the melting point of potassium chloride (Carnelley); and the respective weights of potassium chloride and of sodium chloride which would be present at this temperature are calculated to be 16·7 per cent. of sodium chloride and 83·3 of potassium chloride. These weights contain sensibly equal amounts of metalloïd and of metals, thus:—

NaCl	16·7	= Na	6·58	+	Cl	10·1
KCl	83·3	= K.....	43·6	+	Cl	39·6
	100·0		50·18			49·7

Moreover, these numbers are such as correspond with the association of the same number of chlorine and of potassium + sodium atoms—

$$\left(\frac{39{\cdot}6 + 10{\cdot}1}{35{\cdot}5}\right)\text{Cl} = 1{\cdot}408 \,.\, \frac{43{\cdot}6}{39}\text{K} + \frac{5{\cdot}6}{23}\text{Na} = 1{\cdot}408.$$

The curves representing the chlorine and potassium + sodium present in the mixed salts dissolved, are also right lines which meet at 738°. These results may have some relation to the hypothesis of Arrhenius. T. G. N.

Substitution of Salts in Mixed Solutions. By A. Étard (*Compt. rend.*, **110**, 186—188).—The solubility of potassium iodide between −22° and 0° is represented by a line sharply inclined to the axis of temperature; from 0° to 108°, by another right line ($0{\cdot}1257t$); and from 108° to 220°, by another right line ($0{\cdot}0603t$). Calculation of the *limiting temperature* by extrapolation gives 637°, practically identical with the melting point of the iodide, 639°.

As a general rule with all salts, the higher the temperature the less is the inclination of the right line representing the solubility to the axis of temperature, and the irregularities in solubility are observed below 130°, a temperature above which hydrates rarely exist.

If a small quantity of water is brought into contact with a mixture of potassium iodide and bromide, the total quantity of salt dissolved is the same as if the iodide alone were present, and the limiting temperature is the melting point of the iodide. The bromide obeys the law of solubility of the iodide, and at the limit of solubility the ratio of bromide to iodide in the solution would be 33·6 : 66 4.

Potassium chloride mixed with the iodide behaves in a precisely similar manner, and at the limit of solubility the ratio of chloride to iodide would be 20 : 80.

Potassium bromide and chloride behave similarly, the ratio at the limit of solubility being KCl : KBr. : : 25 : 75.

The phenomena might be explained by supposing that mutual substitution took place, but the ratios of the constituents of the dissolved mixtures have no direct relation to their molecular weights.

C. H. B.

Molecular Constitution of Compounds at their Critical Point. By P. A. Guye (*Compt. rend.*, **110**, 141—144).—From the definitions, the value of b in the equation of Van der Waals should be proportional to the molecular refractive power of the substance, which the author calculates from the expression $R = \frac{N^2 - 1}{(N^2 + 2)d}$. Now, the critical coefficient χ, or the ratio of the absolute critical temperature to the critical pressure, is also proportional to the value of b, and therefore to the molecular refractive power. Hence, if f be a constant for all substances, we have—

$$(1.)\ \frac{MR}{\chi} = f.$$

The author has calculated the molecular refractive power of all substances for which the other data required were known. The value of f varies between 1·6 and 2·0, the mean being 1·8. The variations from the mean amount to about 10 per cent., which is also the possible error in the magnitude of χ. This holds good through a wide range of critical temperatures, and for very different substances. It is important to note that if the refractive power is calculated to the molecular weight, the value of f is 1·8, but if it is calculated to the equivalent, the value of f is sometimes 1·8 and sometimes 0·9.

The relation may also be written in the form—

$$(2.)\ M = f\frac{\chi}{R},$$

and, hence, the molecular weight of a substance at its critical point can be calculated if the critical coefficient and the refractive power are known. The results obtained show that the molecular weights of liquids at their critical points agree with those calculated according to Avogadro's law.

It is evident that the relation (1.) can only hold good if the molecular refractive power and the critical coefficient of a substance are characterised by the same variations, and it follows that the knowledge of the critical coefficient of a substance only is sufficient for the determination of its molecular weight at the critical point. The molecular refractive power can be calculated from the coefficients of refraction of the constituent atoms, and if these coefficients are divided by 1·8, a new series of numbers is obtained, which the author terms *critical atomic coefficients*, and from these the critical coefficient of a substance can be calculated. The values obtained in this way agree with the experimental numbers, within the limits of experimental errors.

It is always possible, therefore, to calculate a value for the critical coefficient with such an approximation to accuracy that on comparison with the experimental number a choice can be made from several possible formulæ of that one which most accurately represents the molecular weight of the substance at its critical point. C. H. B.

Equilibrium in Homogeneous Solutions when unequally heated. By P. VAN BERCHEM (*Compt. rend.*, **110**, 82—84).—Hydrochloric acid and ammonia solutions respectively were enclosed in sealed tubes, the upper parts of which were heated. The contents of the hot and cold parts of the tube were analysed, and it was found that there is a decided concentration of the gases in the cold part of the solution. This result is not due to distillation, for if the hot and cold portions of the liquid are separated by air, the difference in composition becomes very much greater. C. H. B.

Residual Affinity of Inorganic Salts. By B. LACHOWICZ (*Monatsh.*, **10**, 884—905; compare Abstr., 1888, 1281, 1889, 569).—Most organic bases give precipitates of definite composition when shaken with solutions of salts of the heavy metals; in the table given below, the sign + denotes that such a precipitate is formed between the corresponding base and salt.

	Piperidine.	Pyridine.	Quinoline.	Aniline.	Orthotoluidine.	Paratoluidine.	β-Naphthylamine.	α-Naphthylamine.	Phenylhydrazine.	Methylaniline.	Dimethylaniline.	Xylidine.
$AgNO_3$	+	+	+	+	+	+	+					
$CuCl_2$.....	+	+					+	+				
$HgCl$......		+	+		+		+			trace	+	
$CuSO_4$.....			+		+	+						
$ZnSO_4$									+			
$MgSO_4$									+			
$Cu(NO_3)_2$.						+						
$PbNO_3$			+		+	+					+	+
$NiCl_2$.....			+									
$CdCl_2$					+	+						

It appears that all the salts of the heavy metals with strong acids form compounds with organic bases, and that these are analogous to compounds formed from the combination of acids with bases. The various salts of the same acid have different affinities for organic bases, and the affinity varies inversely as the basicity of the metal, and inversely as the heat of formation of the salts formed from the acid and the metals. G. T. M.

Inorganic Chemistry.

Preparation of Chlorine Gas for Laboratory Purposes. By P. Klason (*Ber.*, 23, 330—337).—I. From manganese peroxide and hydrochloric acid.—According to the author's experiments, the different varieties of pyrolusite yield from 75—85 per cent. of the theoretical quantity of chlorine. For each kilo. of peroxide, about 4 litres of 36 per cent. hydrochloric acid are necessary, the greatest possible yield of chlorine being 174 grams per litre; as a general rule, however, only 125—140 grams are obtained. For the preparation of the gas in considerable quantities, the author recommends the use of an earthenware apparatus, the principle of which is similar to Kipp's. The central chamber is filled with 3 kilos. of pyrolusite in small pieces, 2 litres of concentrated hydrochloric acid added, and the whole heated on the water-bath. (In order to allow space between the apparatus and the bottom of the water-bath, the former is constructed with small feet.) The stream of chlorine can be regulated exactly, and when the gas ceases to come off, the spent acid is removed, and 2 litres of fresh acid introduced. The quantity of pyrolusite originally taken is sufficient to use up 12 litres of acid. In order to prevent chlorine entering the room when the current of the gas is stopped, the upper chamber is connected with a funnel containing soda crystals.

II. From sodium chloride, pyrolusite, and sulphuric acid.—It is usually supposed that in this reaction the whole of the chlorine is evolved in the free state; detailed experiments have, however, shown that this is not the case, but that the reaction which takes place is as follows:—

$$4NaCl + MnO_2 + 3H_2SO_4 = 2NaHSO_4 + Na_2SO_4 + MnCl_2 + 2H_2O + Cl_2.$$

The necessary proportions are, therefore, 5 parts of pyrolusite, 11 parts salt, and 14 parts of sulphuric acid diluted with an equal volume of water.

III. From pyrolusite, hydrochloric and sulphuric acids.—The instructions usually given for the preparation of chlorine by this method are to take 1 part of pyrolusite, 2 of hydrochloric acid of sp. gr. 1·14, and 1 part of sulphuric acid mixed with an equal bulk of water, the reaction being supposed to take place according to the equation—

$$MnO_2 + 2HCl + H_2SO_4 = MnSO_4 + 2H_2O + Cl_2.$$

As in the foregoing case, this equation is quite incorrect, only 65 per cent. of the chlorine being obtained in the free state.

IV. From bleaching powder and hydrochloric acid.—In this method it is unnecessary to mix the bleaching powder with gypsum (Winkler, Abstr., 1887, 442), or to compress it into cakes (Thiele, this vol., p. 6), it being quite sufficient to put it into the central bulb of a Kipp's apparatus, and bore a hole through the cake with a glass rod.

When a small quantity only of chlorine is required, and absolute purity of the gas is not necessary, this method may be with advantage employed, but in the preparation of large quantities, it is much more advantageous to obtain it by the action of hydrochloric acid on pyrolusite, in the earthenware apparatus described above.

H. G. C.

Iodine in Solution. By H. Gautier and G. Charpy (*Compt. rend.*, **110**, 189—191).—Iodine solutions are generally classed as violet or brown, but every intermediate tint can be obtained by using different solvents. The following results were obtained with 15 different solvents: *violet*, carbon bisulphide, carbon tetrachloride, chloroform; *red*, benzene, ethylene dichloride, ethylene dibromide; *red-brown*, toluene, ethyl bromide, paraxylene, ethyl iodide; *brown*, acetophenone, acetic acid, ether, alcohol, acetone. Changes in colour are accompanied by changes in the position of the absorption bands. The spectrum of the violet solutions closely resembles that of the vapour, but is displaced towards the blue.

Cryometric determinations of the molecular weight combined with

Loeb's results with benzene and carbon bisulphide gave the following results:—

Solvent.	Mol. wt.
Ether	507
Acetophenone	484
Benzene	341
Carbon bisulphide	303

$I_4 = 508$
$I_3 = 381$
$I_2 = 254$

Hence, it would seem that in the brown solutions, the molecule of iodine contains 4 atoms, but this gradually splits up until it acquires in the violet solutions a value approaching that of the iodine in the state of gas (compare next Abstr.). A rise of temperature tends to make all the solutions violet. C. H. B.

Molecular Weights of Dissolved Iodine, Phosphorus, and Sulphur. By E. BECKMANN (*Zeit. physikal. Chem.*, 5, 76—82).—The molecular weights of iodine, phosphorus, and sulphur were determined from the boiling points of their solutions by the method already described (this vol., p. 323). Iodine, both in ether and in carbon bisulphide, gave numbers corresponding with the molecule I_2, a result at variance with that formerly obtained by Loeb (Trans., 1888, 805). Phosphorus dissolved in carbon bisulphide gives a molecular weight corresponding with the molecule P_4, whilst sulphur in the same solvent has a high molecular weight, corresponding approximately with the formula S_8. H. C.

Formation of Ozone and Nitrogen Acids in Combustion. By L. ILOSVAY DE N. ILOSVA (*Bull. Soc. Chim.* [3], 2, 734—741).—Ozone is absent from oxygen obtained by the action on potassium permanganate of concentrated sulphuric acid, the indications afforded by the usual reagents being due either to traces of chlorine contained in the permanganate, or to permanganic anhydride which is carried over.

During the active combustion of coal-gas, nitrites are always formed, and vary in amount directly as the temperature of the flame. When pure air, either alone or mixed with oxygen, is burnt in coal-gas, much nitrous and nitric acids, together with ammonia, are formed, and when air mixed with nitric oxide is similarly burnt, cyanogen is also formed. These results appear to prove that at high temperatures nitrogen has some affinity for hydrogen, oxygen, and carbon.

The author passed air over different varieties of platinum at varying temperatures, and his results prove that under no circumstances is ozone formed, and that the nitrites produced do not originate from a surface condensation, but from a catalysis, which depends on the molecular structure of the platinum and on the temperature.

When air is passed over reduced iron at 190—250°, nitrous acid is formed, but is absorbed by the yellowish-brown iron oxide, since no nitrite can be detected in the air which passes over, whereas the washings of the iron oxide yield evidence of nitrites. Although reduced iron at 400° is not oxidised by dry air with incandescence, traces of moisture determine this result at once. T. G. N.

Combination of Hydrogen Phosphide with Boron Fluoride and Silicon Fluoride. By BESSON (*Compt. rend.*, **110**, 80—82).—Hydrogen phosphide and boron fluoride do not unite at the ordinary temperature, but combination begins at $-30°$, and at $-50°$ a white solid is obtained, which becomes yellow as the temperature rises, with evolution of 2 vols. of boron fluoride and 1 vol. of hydrogen phosphide, the latter being mixed with some free hydrogen, whilst some solid hydrogen phosphide is formed. The white solid has the composition $PH_3,2BF_3$, and is decomposed by water with evolution of hydrogen and hydrogen phosphide.

Hydrogen phosphide and silicon fluoride combine only under pressure, and at $-22°$ under a pressure of 50 atmos. a white, crystalline solid is obtained. The best yield is obtained with the proportion of gases given, but the solid is also formed when the gases are mixed in equal volumes or two volumes of silicon fluoride and one of hydrogen phosphide, but with one volume of the former and two of the latter, or three of the former and one of the latter, no solid is obtained even at $-40°$. The solid compound has the composition $2PH_3,3SiF_4$.
C. H. B.

Different Forms of Graphitic Carbon and their Derivatives. By BERTHELOT and P. PETIT (*Compt. rend.*, **110**, 101—106, 106—109).—Graphite formed in various ways was converted into the corresponding graphitic oxide by the method described some time ago (*Ann. Chim. Phys.* [4], **19**, 409). In the various analyses given, the ash has been deducted.

Graphite from Cast Iron.—The *graphitic oxide* has the composition C, 62·7; H, 1·3; O, 36·0; which agrees with the empirical formula $C_7H_2O_3$, and for purposes of comparison may be represented by the rational formula $C_{28}H_8O_{12}$. Saturation with baryta-water indicates mono-basicity for the empirical formula, and tetra-basicity for the rational formula. It deflagrates suddenly if heated to a certain temperature, but if carefully heated in a sealed tube, it yields pyrographitic oxide, water, carbonic oxide, and carbonic anhydride, the ratio between the two latter being 2 vols. to 3 vols.

The *pyrographitic oxide* is black, and has the composition C, 86·55; H, 0·70; O, 12·75, and may be represented by the formula $C_{46}H_6O_5$.

Amorphous Graphite or Plumbago.—The *graphitic oxide* has the composition C, 56·2; H, 1·5; O, 42·1; N, 0·1; which agrees with the formula $C_{56}H_{22}O_{31}$, or $C_{22}H_6O_{12}$. When heated in a sealed tube, it yields water, carbonic anhydride, and carbonic oxide, in the ratio of three vols. to two, and a *pyrographitic oxide*, which contains C, 83·85; H, 0·72; O, 15·43 per cent., and therefore has the formula $C_{44}H_6O_8$.

Electric Graphite.—Carbon converted into graphite in the electric arc yields a *graphitic oxide* of the composition C, 51·95; H, 1·55; O, 46·35; N, 0·15, which agrees with the formula $C_{28}H_{10}O_{19}$, or $C_{16}H_6O_{11}$.

The difference between the three graphitic oxides becomes evident if the hydrogen is assumed to be present in the form of water, and the amount of carbon is supposed to be the same in all cases.

From cast iron........	$C_{56}O_{16} + 4H_2O$
From plumbago	$C_{56}O_{20} + 5H_2O$ or $C_{44}O_{16} + 4H_2O$
From electric graphite .	$C_{56}O_{28} + 5H_2O$ or $C_{32}O_{16} + 3H_2O$

The different degrees of polymerisation of the carbon become recognisable if the results are calculated to the same amount of oxygen, the carbon-atoms being in the ratio of 56 : 44 : 32.

The graphitic and pyrographitic oxides were burnt in the calorimetric bomb in oxygen compressed to 25 atmospheres.

Graphitic Oxide from Cast Iron.—Molecular heat of combustion at constant volume, 2530·0 Cals.; at constant pressure, 2527·7 Cals., heat of formation from its elements, carbon as diamond, 388·7 Cals., carbon as graphite, 412·7 Cals. The *pyrographitic oxide:* heat of combustion at constant volume, 4479·4 Cals.; at constant pressure, 4478 8 grams: heat of formation, carbon as diamond, 66·0 Cals., carbon as graphite, 89·0 Cals.

These numbers give no exact idea of the phenomena of combustion or formation, since at the moment of formation part of the hydrogen is fixed in the form of water, with a loss of energy which cannot be estimated, but if the maximum possible value of this loss be deducted, it will be seen that the heat developed per atom of oxygen which enters into combination is only +15·3 Cals., a value much lower than the heat developed by its conversion into carbonic oxide, or still more carbonic anhydride, a fact which explains the ready decomposition of the graphitic oxide with liberation of carbonic oxide and anhydride, and the retention of part of the energy by the pyrographitic oxide, which is thus an endothermic compound, about −3·0 Cals. being absorbed per atom of carbon. The conversion of the graphitic oxide into pyrographitic oxide liberates +162·6 Cals., and if the mean specific heat of the product is taken as 0·25, the temperature of decomposition will be about 600°.

Graphitic Oxide from Plumbago.—Molecular heat of combustion at constant volume, 2637·7 Cals.; at constant pressure, 2633·8 Cals. Heat of formation from diamond, +351·6 Cals., from graphite, +365·6 Cals. The *pyrographitic oxide:* Heat of combustion at constant volume, 4157·0 Cals.; at constant pressure, 4156·1 Cals. Heat of formation from diamond +200·1 Cals., from graphite, +222·1 Cals.

Graphitic Oxide from Electric Graphite.—Molecular heat of combustion at constant volume, 2606·05 Cals.; at constant pressure, 2602·0 Cals. Heat of formation from diamond, +383 Cals., from graphite, +397 Cals.

The heats of formation of the graphitic oxides are very different, and characterise the different species. If these heats of formation are calculated to the same weight of carbon, they are represented by the numbers 13·9, 12·5, and 13·7 respectively. These values are almost equal, although the corresponding amounts of oxygen are in the ratio of 4 : 5 : 7, and this agreement in the quantity of heat developed by very different degrees of oxidation shows clearly the important differences between the various graphitic radicles and the oxides to which they give rise. C. H. B.

Combination of Alkali Metals with Ammonia. By H. W. B. ROOZEBOOM (*Compt. rend.*, **110**, 134—137).—A theoretical discussion of the observations of Joannis (this vol., p. 209) on the dissociation of sodammonium or potassammonium, which the author regards as analogous to the dissociation of a mixture of tetrahydrated calcium chloride, $CaCl_2 + 4H_2O$, and its saturated solution (*Rec. Trav. Chim.*, 8, 1—146). C. H. B.

New Hydrate of Potassium Hydrogen Sulphate. By J. B. SENDERENS (*Bull. Soc. Chim.* [3], **2**, 728).—When an aqueous solution of potassium hydrogen sulphate is evaporated at a gentle heat to such an extent that on removal of the flame a solid mass is obtained, there will appear on the surface of the mass after some time a layer of arborescent crystals, which have the composition $HKSO_4 + 5\frac{1}{2}H_2O$; these melt at 30°, and deliquesce so soon as the arborescence is completely developed. The formation is dependent on the degree of concentration of the mother liquor, and on the temperature of the laboratory. T. G. N.

Solubility of Calcium Carbonate in Fresh and Sea Water. By W. S. ANDERSON (*Proc. Roy. Soc. Edin.*, **16**, 319—324).—Iceland spar is less soluble in sea water than the other forms of carbonate, and it is less soluble in sea than in fresh water, the former dissolving 0 0082 gram per litre, whilst the latter, free from carbonic anhydride, takes up 0·251 gram; but the form in which the calcite is presented, whether massive or in powder, has no notable effect on its solubility in sea water, whereas in distilled water the powdered spar is soluble to double the amount. When sea water remains over calcite for some time, a portion of the dissolved carbonate is precipitated. Although this may not occur generally, yet it helps to account for the gradual petrifaction of the porous masses of dead coral reef in comparatively shallow waters. Carbonated water dissolves calcite readily; the more finely divided it is, the greater the solubility. Of the massive form, 0·0815 gram per litre is dissolved in 24 hours, and of the powdered, 0·472 gram. A series of experiments were undertaken with a view to throw light on the condition in which the carbonate is present in sea water, and for this purpose a hard variety of coral skeleton (*Oculina coronalis*) was finely powdered, and the solution allowed to act on portions of it separately for four days. The solubility was found to be greater in distilled than in sea water, the magnesium salts, chloride and sulphate, dissolving the largest quantity, and calcium sulphate the least; in fact this salt seems to retard solubility. Solution of magnesium chloride dissolves, and then throws out the carbonate in crystalline form, and this action shows that there is no interaction between magnesium chloride and calcium carbonate, as if there were, magnesium carbonate would be precipitated; sea water acts in a manner similar to magnesium chloride. 0·6 gram per litre being dissolved, and a portion being afterwards precipitated. This is not due to carbonic anhydride, for artificial sea water free from gas acts in the same way. Solutions of the individual salts dissolved more of the coral skeleton than did the normal or artificial sea water; this appears due to the action of calcium sulphate, as before stated. The author considers, therefore, that calcium carbonate is present in sea water as such, and is there simply owing to its solubility in the river water flowing into the sea, the salts present helping or retarding the solution, as the case may be. E. W. P.

Prolonged Action of Sea Water on Pure Natural Magnesium Silicates. By A. Johnstone (*Proc. Roy. Soc. Edin.*, 16, 172—175).—Sea water dissolves pure steatite in small quantities, with separation of silica, and this solution is attributed to the sodium chloride in the water: $Mg_4Si_5O_{14} + 8H_2O + 8NaCl = 4Na_2SiO_3,8H_2O + 4MgCl_2 + SiO_2$. Pure white talc is also slightly soluble, but the common green variety, which contains iron, is more easily dissolved.

E. W. P.

Reduction of Oxygen Compounds by Magnesium. By C. Winkler (*Ber.*, 23, 120—130).—In this paper the author gives an account of the action of magnesium on the oxides of the metals of Mendeléeff's second group; the experiments were carried out in the manner previously described (this vol., p. 331), but in some cases the behaviour of the hydroxide, as well as that of the oxide, was studied.

Beryllium oxide (2 mols.) is reduced, but only partially, by magnesium (1 mol.), and the reaction is not very energetic, although the mixture glows feebly, and some of the magnesium is volatilised. The grey mass obtained is not acted on by boiling water, but when warmed with soda, hydrogen is slowly evolved. It dissolves in hydrochloric acid and in nitric acid, hydrogen being rapidly evolved, and when heated in the air it glows brightly. When treated with chlorine at a high temperature, beryllium chloride sublimes.

In heating metallic oxides with powdered magnesium, the latter is, to a slight extent, converted into the nitride by the nitrogen of the air; the formation of nitride is proved by the evolution of ammonia, when the mixture is subsequently exposed to moist air. When magnesium wire is burnt in the air, the formation of nitride does not take place, but when powdered magnesium is heated with magnesium oxide, the product gives off ammonia on warming with potash. It seems, therefore, that the presence of substances otherwise inactive, but which absorb heat, favours the formation of magnesium nitride.

Pure magnesium oxide undergoes no change when heated with magnesium, and the formation of a lower oxide was not observed.

Calcium oxide is almost completely reduced by magnesium at a red heat; the mixture turns grey, but otherwise no apparent change takes place. The residue takes fire readily when heated, burning with a brilliant. reddish flame, and it decomposes water very energetically.

When a mixture of calcium hydroxide (1 mol.) and magne
(1 mol.) is heated in a test-tube, a brilliant, yellowish-red flame
from the mouth of the tube, but reduction is incomplete; the
decomposes water rapidly. When steam (most conveniently

by heating crystalline calcium chloride or some other salt containing water) is passed over powdered magnesium, heated to redness in a combustion-tube, the metal glows brightly, and is quickly converted into oxide with development of heat.

Strontium oxide is slowly, and as it seems completely, reduced by magnesium; the dark coloured residue takes fire in the air, and burns with an intense, red light, and it decomposes water very energetically. Strontium hydroxide is partially reduced by magnesium below a red heat, with a slight explosion.

Barium oxide is completely, or almost completely, reduced by magnesium, a very violent reaction taking place, accompanied by vivid glowing; the residue decomposes water very energetically. Barium hydroxide resembles strontium hydroxide in its behaviour with magnesium.

Zinc oxide is reduced by magnesium at a dull red heat, with explosive violence. Cadmium oxide shows a like behaviour, and reduction is complete, but the reaction is not so violent. In the case of mercuric oxide, a violent explosion takes place, and the metal produced is completely volatilised. F. S. K.

Zinc-ammonium Compounds. By H. THOMS (*Chem. Centr.*, 1889 [2], 965; from *Pharm. Centralhalle*, **30**, 629—631).—The author criticises the formula of the zinc-ammonium carbonate obtained by G. Kassner (Abstr., 1889, 1049) in relation to the constitution of the zinc-ammonium chloride described by him (Abstr., 1887, 551), in which he holds that the nitrogen is directly combined with the zinc. If Kassner's zinc oxide ammonium carbonate is similarly constituted to the author's zinc-ammonium chloride, then it must have the formula $Zn\!:\!O_2\!:\!C(OH){\cdot}O{\cdot}Zn{\cdot}NH_3O{\cdot}C(OH)\!:\!O_2\!:\!Zn$. If, however, the hydroxyl-groups are combined with the zinc, as according to Kassner they are, then the compound must have the formula

$$OH{\cdot}Zn{\cdot}O{\cdot}CO{\cdot}O{\cdot}Zn{\cdot}NH_3O{\cdot}CO{\cdot}O{\cdot}Zn{\cdot}OH,$$

and the author remarks that it is not quite clear why the excess of ammonia present in the reaction does not become combined with the zinc hydroxyl-group. J. W. L.

Cerium Hydrogen Sulphate. By G. WYROUBOFF (*Bull. Soc. Chim.* [3], **2**, 745—747).—The hydrated and anhydrous varieties of the lower cerium oxide dissolve in concentrated sulphuric acid, and the solution, on evaporation, deposits small, brilliant, transparent needles. When the evaporation is continued until no more sulphuric anhydride is evolved, care being taken that the temperature of decomposition of the salt is not reached, a perfectly pure crystalline substance is obtained, which contains in 100 parts CeO 38·69, and SO_3 55·58.

Taking the atomic weight of cerium as 94·4, this corresponds with formula $CeSO_4,H_2SO_4$, and insomuch as it is quite stable in dry ut very hygroscopic, it corresponds with the acid sulphates of nesium series, and consequently lends additional support to that cerium forms a monoxide, and has the at. wt. 94·4, as determined by Bührig, and not the at. wt. 141·4, suggested by Mendeléeff, which corresponds with its forming a sesquioxide, Ce_2O_3, since there is no sesquioxide known from which an acid sulphate is derived. T. G. N.

Preparation of Very Active Platinum-black. By O. LOEW (*Ber.*, **23**, 289—290).—Very active platinum-black can be conveniently prepared as follows:—An aqueous solution (50 to 60 c.c.) of platinic chloride (50 grams) is mixed with 40 to 45 per cent. of formaldehyde solution (70 c.c.), the mixture cooled well, and then sodium hydroxide (50 grams) dissolved in water (50 grams) gradually added; after keeping for 12 hours the solution is filtered. A yellow liquid, from which a small quantity of platinum is deposited on boiling, first passes through the filter, but as soon as most of the salts have been washed out of the residue, the filtrate assumes a deep black colour. The process is interrupted at this stage for several hours because the residue soon absorbs oxygen, the temperature rising to 36—40°, and the washings then pass through colourless. As soon as oxidation is complete, the residue is washed until completely free from sodium chloride, pressed, and dried over sulphuric acid.

If the deep-black filtrate referred to above is submitted to dialysis in absence of air, a black, transparent liquid is obtained which is stable in absence of air; on exposure to the air, however, this liquid gradually becomes colourless, and a small quantity of a black powder is deposited. The black solution decomposes hydrogen peroxide very energetically, and when mixed with alcohol or shaken with air, the odour of aldehyde is immediately perceptible. These and other experiments seem to show that this black liquid is a solution of atomic platinum containing small quantities of organic platinum compounds. F. S. K.

Mineralogical Chemistry.

Pseudomorphs of Native Copper after Azurite. By W. S. YEATES (*Amer. J. Sci.*, 38, 405—407).—The author describes some specimens of copper from Grant Co., New Mexico. The substance was very brittle, and had a sp. gr. of only 4·15. The surface of the crystals was coated with kaolin, and this mineral was also intimately mixed with the copper particles. The tabular crystals had the form of those of azurite from Arizona. This was confirmed by measurements of the angles. The copper is thus a pseudomorph after azurite. The latter must have lost its carbonic anhydride and water in the presence of some reducing agent, probably volcanic gases, leaving the copper in a spongy state, and upon it the kaolin was deposited, and forced by pressure into the pores of the spongy mass.
B. H. B.

Arsenical Pyrites. By F. v. SANDBERGER (*Jahrb. f. Min.*, 1890, i, Mem. 99—101).—The occurrence of arsenical pyrites in small crystals having the form ∞P, $\frac{1}{4}\bar{P}\infty$, at Goldkronach, has long been known. Analysis of this mineral yielded—

S.	As.	Sb.	Fe.	Ag.	Total.	Sp. gr.
20·84	41·36	3·73	34·07	0·002	100·002	6·09

The mineral is of interest on account of its unusually high percentage of antimony.

A second interesting variety of arsenical pyrites occurs at Neusorg, in the Fichtelgebirge. On analysis, it gave the following results:—

S.	As.	Fe.	Ni.	Co.	Total.	Sp. gr.
17·27	42·89	34·64	4·38	trace	99·18*	5·96

In 1848 Breithaupt directed attention to the fact that certain arsenical pyrites contain nickel, but none of the varieties he mentioned contains more than 1 per cent. of that metal. B. H. B.

Artificial Formation of Malachite. By A. DE SCHULTEN (*Compt. rend.*, 110, 202—204).—A solution of precipitated copper carbonate in ammonium carbonate is heated on a water-bath for eight days in flasks filled up to the neck, the water being renewed as it evaporates. As the ammonium carbonate volatilises, a green, crystalline crust separates on the sides of the flask, and soon becomes covered with crystals of malachite, $CuCO_3,Cu(OH)_2$, containing CuO, 71·33; CO_2, 19·72; H_2O, 8·95 = 100; sp. gr. at 15° = 3·86, that of the mineral varying from 3·7 to 4·1. Artificial malachite easily scratches calcite, but is scratched by fluorspar, and its hardness is 3·5—4·0. Its crystalline form is identical with that of the natural mineral. C. H. B.

New Variety of Aluminite. By K. FLUG (*Jahrb. f. Min.*, 1890, i, Ref. 18, from *Verh. Russ. Min. Ges.*, 23, 116—125).—The mineral examined, to which the author assigns the name of *ignatieffite*, was found in the Bachmuth district, in the government of Ekatrinoslav. On analysis it yielded—

SiO_2.	Al_2O_3.	SO_3.	P_2O_5.	FeO.	CaO.	MgO.	K_2O.	Na_2O.	C.	H_2O.
3·33	36·39	30·57	3 83	0·32	1·40	0 23	6·37	2·89	1·50	12·72

B. H. B.

Native Iron Sulphates from Chili. By J. B. MACKINTOSH (*Amer. J. Sci.*, 38, 242—245).—The author gives the results of analyses of a series of native iron sulphates, several of which have not yet been described. Four of the sulphates are well-known species. The first analysis refers to coquimbite, 1*a* being amethystine, crystalline, and transparent; 1*b*, amethystine, massive, and translucent; and 1*c*, white, massive, and opaque. The analyses of these three varieties all lead to the same formula, $Fe_2O_3,3SO_3,9H_2O$. The other well-known species are: (2) copiapite, sp. gr. 2·118, formula,

$$91\{2Fe_2O_3,5SO_3,18H_2O\} + 22\{FeSO_4 + H_2O\} + 5(Na_2SO_4 + H_2O);$$

---

* 99 27 in original.

(3) roemerite, brown, crystalline, sp. gr., 2·15, formula,

$$FeO,Fe_2O_3,4SO_3,13{\cdot}7H_2O\,;$$

(4) amarantite, red, crystalline, sp. gr. 2·005, formula,

$$Fe_2O_3,2SO_3,7H_2O.$$

Of the new minerals, the first (analysis 5) occurs associated with copiapite and amarantite, in pulverulent, orange flakes. Its formula is $Fe_2O_3,2SO_3,4H_2O$. *Ferronatrite* (analysis 6) occurs in stellate groups of a pale, whitish-green colour, associated with copiapite and coquimbite. This new mineral is analogous to kroehnkite (Abstr., 1889, 680), the relationship being shown by the formulæ—

Kroehnkite	$3(Na_2O,CuO,2SO_3,2H_2O)$
Ferronatrite	$3Na_2O,Fe_2O_3,6SO_3,6H_2O$.

Associated with these minerals are several white pulverulent sulphates, which are apparently alteration-products. The formulæ of the three powders analysed are—

(7) $4FeO,Fe_2O_3,6SO_3,19H_2O$.
(8) $428(FeSO_4,H_2O) + 71Na_2SO_4 + 40(2Fe_2O_3,5SO_3,4H_2O)$.
(9) $487(FeSO_4,H_2O) + 5Na_2SO_4 + 16(2Fe_2O_3,5SO_3,18H_2O)$.

	SO_3.	Fe_2O_3.	Al_2O_3.	FeO.	Na_2O.	K_2O.	Insol.	H_2O.

(For recent analyses of South American iron sulphates, see Abstr., 1888, 923).

B. H. B.

Minerals from Atacama. By L. DARAPSKY (*Jahrb. f. Min.*, 1890, i, Mem. 49—70).—1. *Aromite.*—In the "pampa de Aroma," in the northern portion of Tarapacá, an alum occurs which on analysis gave the following results:—

Al_2O_3.	MgO.	SO_3.	H_2O.
5·00	12·71	33·71	48·58

These results lead to the formula $Al_2O_3,6MgO,9SO_3,54H_2O$. This new variety forms with the known magnesia alums a series in which the percentage of water gradually increases:—

Pickeringite	$(MgSO_4),(Al_2O_3,3SO_3),24H_2O$
Sesquimagnesia alum.	$1\frac{1}{2}(MgSO_4),(Al_2O_3,3SO_3),26\frac{1}{2}H_2O$
Picroalaunogen......	$2(MgSO_4),(Al_2O_3,3SO_3),28H_2O$
Sonomaite..........	$3(MgSO_4),(Al_2O_3,3SO_3),33H_2O$
Aromite............	$6(MgSO_4),(Al_2O_3,3SO_3),54H_2O$.

2. *Iron Sulphates.*—The author gives the results of the analyses of seven varieties of iron sulphate. The analytical results are given in the following table:—

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*
Fe_2O_3	30·00	35·62	36·86	28·18	32·13	18·22	18·13

Total	99·96	100·15	100·58	100·03	99·88	99·74*	100·00

a. Paposite, a mineral first described by Stüven, who assigned to it the formula $Fe_2O_3,2SO_3,4H_2O$. The author's formula is

$$2Fe_2O_3,3SO_3,10H_2O.$$

b. Amarantite, first described by Frenzel. Formula,

$$Fe_2O_3,2SO_3 + 7H_2O.$$

c. Hohmannite, a mineral also described by Frenzel, is intimately mixed with a laminated mass, which gave on analysis the results stated in the table. *d.* Copiapite, formula, $Fe_2O_3.2\frac{1}{2}SO_3,8H_2O$. *e.* Fibroferrite, formula, $Fe_2O_3,2SO_3,10H_2O$. *f.* Rubrite, formula, $Fe_2O_3,2SO_3,3H_2O$. *g.* Botryogen, formula,

$$2(Fe_2O_3,3SO_3),(FeO,SO_3),32H_2O.$$

[Compare Chilian iron sulphates, preceding abstract].

3. *Thenardite.*—This mineral gave on analysis:—

SO_3.	H_2O.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	Na_2O.	Cl.	Insol.	Total.
54·24	0·73	0·06	0·20	0·22	0·07	41·66	0·36	2·46	100·00

B. H. B.

Uraninite. By W. F. HILLEBRAND (*Amer. J. Sci.*, 38, 329).—The author has noticed that on treatment of uraninite with an acid, nitrogen is given off in quantity amounting to 1 to 2 per cent. of the weight of the mineral. No clue has yet been discovered as to the reaction by which the gas is given off. B. H. B.

Barysite, a New Lead Silicate. By A. SJÖGREN and C. H. LUNDSTRÖM (*Jahrb. f. Min.*, 1890, i, Ref. 24—25; from *kong. Vetenskaps-Akad. Förhandl.*, 1888, 7).—In the iron ore vein of the Harstig mine, a lead silicate occurs, which on account of its high specific gravity has been named *barysite*. It is associated with yellow garnet, calcite, tephroite, hedyphane, and lead carbonate. Its sp. gr. is 6·55. The mean of several analyses is—

---

* 99·84 in original.

SiO_2.	PbO.	MnO.	FeO.	CaO.	MgO.
17·07	78·26	3·51	0·16	0·41	0·59

Formula, $3RO,2SiO_2$, in which RO is PbO with a small proportion of MnO, MgO, and CaO. The mineral occurs in hexagonal, silver-white crystals, with a basal cleavage, and a hardness of 3.

B. H. B.

Gadolinite, Cacoclasite, and Monazite. By F. A. Genth (*Amer. J. Sci.*, **38**, 198—203).—An examination of a shining, black mineral from Burnett Co., Texas, proved it to be *gadolinite*, a mineral which, excepting that from Colorado described by L. G. Eakins, has never been observed in the United States. Analysis gave the following results (I):—

	SiO_2.	Al_2O_3.	Ce_2O_3.	$(DiLa)_2O_3$.	$(YEr)_2O_3$.	MnO.	FeO.	BeO.	MgO.
I.	22·87	0·28	2·65	5·22	44·35	0·22	13·69	9·24	0·07
II.	22·80	0·31	2·66	5·01	44·45	0·18	12·93	9·19	0·11

	CaO.	Na_2O.	K_2O.	Ignition.	Insoluble.	Total.
I.	0·64	0·20	0·15	0·72	—	100·30
II.	0·71	0·23	0·12	0·79	0·93	100·42

II shows the results of an analysis of a similar mineral received by the author from Llano Co., Texas.

In 1883 H. Carvill Lewis described, under the provisional name of *cacoclasite*, peculiar white crystals embedded in blue calcite at Wakefield, Quebec, Canada. The author has submitted this substance to further examination, and his analyses tend to show that cacoclasite cannot be regarded as a distinct species, but that it is a mixture of quartz, calcite, apatite, and unknown minerals in various proportions. It has the form of scapolite, and has resulted from the alteration of that mineral.

At the Villeneuve Mica Mine, Quebec, Canada, an interesting variety of monazite has recently been met with. It has a sp. gr of 5·233, a reddish-brown colour, and an indistinct cleavage. Analysis gave the following results:—

H_2O.	SiO_2.	ThO_2.	P_2O_5.	Fe_2O_3.	Ce_2O_3.	$(LaDi)_2O_3$.	$(YEr)_2O_3$.
0·78	0·91	12·60	26·86	1·07	24·80	26·41	4·76

MgO.	CaO.	Total.
0·04	1·54	99·77

B. H. B.

Yttria and Thoria Minerals from Llano Co., Texas. By W. E. Hidden and J. B. Mackintosh (*Amer. J. Sci.*, **38**, 474—486).—In 1886 the first piece of gadolinite was found on the west bank of the Colorado river, Llano Co., Texas. Subsequently masses of this rare mineral were obtained, in the aggregate, not less than 500 kilos. The various ores of the rare earths are found in a coarse-textured, deep-red granite, traversed by quartz veins. The list of mineral species identified includes quartz, hyalite, orthoclase, albite, biotite, muscovite, magnetite, martite, gadolinite (several varieties due to alteration), fergusonite (three varieties of hydrous species), allanite, molybdenite, molybdite, cyrtolite, fluorspar, gummite, a carbonate of the rare earths (tengerite?), a thorium yttrium lead uranate, a hydrous uranium thoro-silicate, and a yttrium thorium silicate. The last-named mineral is termed by the authors *yttrialite*. It has a sp. gr. of 4·575 and a hardness of 5 to 5·5. When heated, it decrepitates and falls to powder. These characteristics serve to distinguish it from gadolinite, from which it differs in containing twice as much silica and no glucina. Analysis yielded—

SiO_2.	PbO.	ThO_2.	MnO.	FeO.	CaO.	Al_2O_3.	Ce_2O_3.
29·17	0·85	12·00	0·77	2·89	0·60	0·55	1·86

Yttria earths.	$(LaDi)_2O_3$.	UO_3.	Ignition.	Total.
46·50	2·94	0·83	0·79	99·75

By successive precipitations with sodium sulphate, several fractions of the yttria earths were obtained; the atomic weight of each fraction was determined, showing successive increase after each separation. The fractionation was discontinued after the fourth separation, but the atomic weight shows that the lanthanum and didymium are still mixed with an earth of higher atomic weight. The results were as follows:—

	Percentage.	Atomic weight.
(A.) Y_2O_3............	22·67	110·3
(B.) Y_2O_3............	5·30	110·5
(C.) Y_2O_3............	4·50	114·9
(D.) Y_2O_3............	14·03	120·0
$(LaDi)_2O_3$.......	2·94	162·0

The formula of the mineral appears to be $R_2O_3,2SiO_2$, in which R_2O_3 may be replaced by its equivalent in RO, RO_2, or RO_3 (Compare analysis of gadolinite in preceding abstract).

Thoro-gummite, a hydrated uranium thoro-silicate, occurs intimately associated with fergusonite and cyrtolite. It is of a dull, yellowish-brown colour, has a hardness of 4 to 4·5, and a sp. gr. of 4·43 to 4·54. The analytical results given by the authors correspond with the formula $UO_3,3ThO_2,3SiO_2,6H_2O$.

Nivenite is the name given by the authors to a hydrated thorium yttrium lead uranate found intimately associated with fergusonite and thoro-gummite. Its sp. gr. is 8·01, and its hardness 5·5. It is velvet-black, and gave on analysis—

UO_3.	UO_2.	ThO_2.	Y_2O_3.	Fe_2O_3.	PbO.	Ignition.	Insol.	Total.
46·75	19·89	7·57	11·22	0·58	10·16	2·54	1·22	99·93

The general formula is $9RO,4UO_3,3H_2O$. The mineral is allied to cleveite and bröggerite (Abstr., 1884, 1102), the relationship being as follows:—

Bröggerite..........	$3RO,UO_3$
Cleveite............	$6RO,2UO_3,3H_2O$
Nivenite	$9RO,4UO_3.3H_2O$.

The name is given in recognition of the assistance rendered by Niven in obtaining the mineral for investigation.

The heretofore rare mineral fergusonite occurs in large quantity at this new locality. The authors have found two distinct varieties. Compared with typical fergusonite, a gradation from one extreme to the other may be noted.

	Sp. Gr.	Hardness.	
Fergusonite, $R_3Nb_2O_8$...............	5·83	—	
Mono-hydro-fergusonite, $R_3Nb_2O_7(OH)_2$	5·67	6·5	pale olive-green, decrepitates.
Tri-hydro-fergusonite, $R_3Nb_2O_5(OH)_6$..	4·36	5·0	light brown, does not decrepitate.

Of other published analyses of fergusonite, that of the Ytterby variety by Nordenskjold corresponds with the di-hydrated mineral.

B. H. B.

Rhodotilite and Heliophyllite from Sweden. By G. FLINK (*Jahrb. f. Min.*, 1890, i, Ref. 22—23; from *kong. Vetenskaps-Akad. Förhandl.*, 1888, 571).—1. *Rhodotilite* occurs with rhodonite, garnet, &c., at the Harstig Mine, at Pajsberg. Analysis gave the following results:—

SiO_2.	MnO.	FeO.	MgO.	CaO.	PbO.	H_2O.	Total.
43·67	37·04	1·11	0·15	9·38	0·77	7·17	99·29

This mineral is identical with the inesite of Schneider and Scheibe (this vol., p. 345 and next abstract).

2. *Heliophyllite.*—On specimens of the so-called rhodotilite from Pajsberg a yellow mineral has been observed, which resembles a mineral described by Nordenskjöld as accompanying the ekdemite of Långban. The author names this mineral heliophyllite. It gave on analysis—

PbO.	MnO,FeO.	As_2O_3.	Cl.	Total.
80·70	0·54	11·69	8·00	100·93

Its sp. gr. is 6·886, and its hardness 2. It crystallises in the rhombic system.

B. H. B.

Manganese Ores from Dillenburg. By A. SCHNEIDER (*Jahrb. f. Min.*, 1890, i, Ref. 19—22; from *Zeit. deutsch. geol. Ges.*, **39**, 829—834; *Jahrb. kgl. preuss. geol. Landesanst.*, 1888, 472—496).—An important manganese mining industry has been carried on for several years in the valley of the Scheldebach, near Dillenburg. The ore principally worked is a mixture consisting largely of klipsteinite, and containing SiO_2, Mn_2O_3, MnO. and H_2O. It is probably the result of the alteration of a manganous silicate, which still forms part of the mass. The analysis of this silicate (analysis I) approximates to that of the stratopëite of Pajsberg. This dark amber-coloured mineral is accompanied by a dark-red ore (analysis II). Its sp. gr. is 2·675. Nests of psilomelane, manganite, and wad occur in the ore, as well as nickel-bearing iron pyrites, copper pyrites, and native copper. An anthracite is also met with. This has probably reduced the native copper, and consists of 72·67 per cent. of carbon, 3·38 per cent. of hydrogen, and 20·40 per cent. of ash-forming constituents. Anthracite is similarly met with in the neighbouring red hæmatite mines. At the contact of the manganese ore deposit with the diabase, the new mineral *inesite* (this vol., p. 345) has been met with. It is flesh-coloured, radiated, and has a hardness of 6. In composition (analysis III) inesite somewhat resembles hydrorhodonite.

	SiO_2.	Fe_2O_3.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	CO_2.	H_2O.	Total.
I.	35·64	3·02	2·59	—	39·26	1·75	1·31	0·60	13·94	98·11
II.	30·21	12·49	2·30	—	29·16	6·04	0·98	2·40	16·62	100·20
III.	43·92	—	0·29	0·69	38·23	8·00	0·28	—	8·49	99·90

B. H. B.

Theory of the Mica-group. By F. W. CLARKE (*Amer. J. Sci.*, 38, 384—393).—Ever since its publication in 1878, Tschermak's theory of the mica-group has been in vogue, and in order to replace it by something better, two fundamental conditions must be satisfied. All micas should be reducible to one general type of formula, which should express all known relations, as do the formulæ of Tschermak, and hypothetical compounds must be as far as possible avoided. In previous papers (Abstr., 1887, 347; 1888, 117), the author has shown that all orthosilicates containing aluminium may be represented as substitution-derivatives of the normal salt $Al_4(SiO_4)_3$. He is now inclined to believe that all the true micas are referable to the same general type. The normal salts $(Al_4SiO_4)_3$ and $Al_4(Si_3O_8)_3$ are the theoretical starting points for derivation. All the micas, vermiculites, chlorites, margarite, and the clintonite-group become reducible to one general type. Representing the groups SiO_4 and Si_3O_8 by the common symbol X, the micas all fall within limits indicated by the formulæ $Al_3X_3R'_4$ and $AlX_3R'_9$. The lepidolites and other low-oxygen micas are completely accounted for on the assumption that orthosilicates and polysilicates may be isomorphously mixed; a similar state of affairs is accepted among the felspars. The author tests his formulæ by application to actual examples, taking the different micas group by group. In most cases the evidence is clear, direct, and conclusive.

B. H. B.

Allanite and Epidote as Rock-forming Minerals. By W. H. HOBBS (*Amer. J. Sci.*, 38, 223—228).—The discovery of Cross and Iddings (Abstr., 1886, 317), that allanite occurs widely distributed as a constituent of many rocks, has called the attention of American geologists to its distinguishing characters. The author finds that two epidotic minerals occur as accessory constituents of the porphyritic granite of Ilchester, Howard Co., Maryland. These minerals exhibit interesting intergrowths. The granite in which they occur consists of large crystals of microcline scattered through a ground-mass consisting of monoclinic and triclinic felspar and biotite. Besides allanite and epidote, the only important accessory constituent is a colourless mica. The allanite occurs as a brownish kernel within the epidote, the two minerals being crystallographically similar. It having been suggested that the surrounding mineral might not be epidote, but merely altered allanite, an analysis was made, with the following results :—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	CaO.	MgO.	H_2O.	P_2O_5.	Total
37·63	(20 86)	15·29	0·31	22·93	0·31	2·23	0·44	100·00

These results correspond very closely with the formula

$$2H_2Ca_4Al_6Si_6O_{26} + H_2Ca_4Fe_6Si_6O_{26}.$$

Sphærolite Tachylite from the Ussuri District. By P. N. Wenjukoff (*Jahrb. f. Min.*, 1890, i, Ref. 54—55; from *Bull. Soc. Belge géol.*, 1, 165—176).—The rock described is somewhat similar to the hyalomelane of Sababurg. The sphærolites occur in a glassy mass with small globules filled with a granular mass, and are thought by the author to consist of a mixture of labrodorite, augite, olivine, and magnetite. The glass (analysis I), and the dark centre of the sphærolite (analysis II), gave on analysis the following results :—

	SiO_2.	Al_2O_3.	FeO.	Fe_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	Total.	Sp. gr.
I.	54·19	24·40	2·72	2·04	7·85	5·70	1·72	1·85	100·47	2·51
II.	53·29	21·65	4·79	2·45	7·10	6·60	1·02	2·72	99 62	2·89

B. H. B.

Rocks used in the manufacture of Chinese Porcelain. By G. Vogt (*Compt. rend.*, **110**, 43—45).—Ebelmen and Salvetat, in 1850, concluded that the materials used in the manufacture of Chinese porcelain were very similar to those used in Europe, petun-tsé being similar in composition to the pegmatite from Limousin, although its mineralogical properties brought it into the group of compact felspars.

Yeou-ko is a variety of petun-tsé, more fusible than the latter, and used principally for the preparation of the glaze. In percentage composition it is very similar to pegmatite, but hot concentrated sulphuric acid dissolves only 3·3 per cent. of the latter, whilst it dissolves 34·15 per cent. of yeou-ko. The soluble and insoluble portions have the following composition :—

	SiO_2 hydrated.	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	K_2O.
Soluble	1·01	14·20	11·28	0·46	1·14	2·97
Insoluble ..	—	62·11	2·61	—	—	0 08

	Na_2O.	CO_2.	H_2O and loss.	
Soluble	0·39	0·90	1·80	= 34·15
Insoluble	1·56	—	—	= 66·36

Almost all the sodium is in the insoluble, and almost all th sium in the soluble portion. The insoluble portion consist per cent. of quartz and 13 41 per cent. of soda felspa pegmatite frequently contains as much as 75 per cent. The soluble portion, neglecting the hydrated silica and carbonate, agrees with the formula $6SiO_2,3Al_2O_3,K_2O,2\frac{1}{2}H_2O$, which is the same as that given by Tchermak for muscovite or white mica, except that it contains $\frac{1}{2}H_2O$ more.

It follows from these results that yeou-ko consists of quartz, 52·9; muscovite, 31·3; soda felspar, 13·4; calcium carbonate, 2·0; hydrated silica, 1·0 = 100·6. Pegmatite from Limousin contains—quartz, 23·87; felspar, 72·83; soluble in sulphuric acid, 3·30 = 100·00.

Muscovite occurs in all the Chinese porcelain rocks which the author has examined; petun-tsé from different localities contained the following amounts:—

	Cheo-Ki.	Yu-Khan.	Ki-Men.	Sang-Pao-Pong.
Muscovite, p. c...	40·6	37·3	31·1	18·6

Friedel and Fouqué also proved microscopically the presence of muscovite in the materials which the authors analysed. It is obvious that the presence of such large quantities of muscovite in the materials used for the making of Chinese porcelain must exert considerable influence on the product. C. H. B.

Meteorite from Carcote, Chili. By W. WILL and J. PINNOW (*Ber.*, **23**, 345—353).—The chemical examination of a meteorite found at Carcote, in the Cordilleran desert, and described by v. Sandberger (this vol. p. 347), at whose request the authors undertook the quantitative analysis. The chief portion of the meteorite (about 80 per cent.) consists of a mixture of two silicates, one of which is readily decomposed by hydrochloric acid, and appears to belong to the olivine-group, whilst the other is insoluble in the acid, is as hard as quartz, seems to have a rectangular cleavage, and is probably a member of the diopside-group. Throughout the mass, chrome-ironstone is distributed, and also grains of an iron sulphide which cannot be distinguished from ordinary magnetic pyrites. Grains or small plates of the nickel-iron alloy are also found in considerable quantity, and a very small quantity of Rose's rhabdite. Finally, the meteorite also contains a dull, black substance of hardness 9, which consists simply of carbon in the form of black diamond. Organic matter is also present, but in unweighable quantity. The metallic constituents, the magnetic pyrites, and the decomposable silicate have been slightly weathered.

The following table gives the result of the quantitative analysis:—

	SO_3.	CaO.	MgO.	KCl,K_2SiO_3.	Cu + Sn.	Fe.	Ni + Co.	Mn.
I.	0·131	0·161	0·040	0·144	0·05	7·14	—	—
II.	—	—	—	—	—	7·28	0·74	0·12

	P.	FeS.	SiO_2.	FeO.	Al_2O_3.	MgO.	NiO + CoO.
I.	0·168	5·86	14·38	10·65	0·20	14·73	—
	—	—	14·59	11·29	0·21	13·93	0·43

O_3.	Undecomposable silicate.	Cr_2O_3,FeO.	H_2O.	C.	Total.
-	40·93	1·38	1·27	0·14	= 98·85
)	41·18	1·27	1·50	0·14	= 99·42

The composition of the portion undecomposed by hydrochloric acid is as follows:—

	SiO_2.	FeO.	Al_2O_3.	CaO.	MnO.	Na_2O.	K_2O.	Cr_2O_3,FeO.	Total.
I.	55·48	9·74	5·02	2·75	19·67	—	—	3·25	99·92

Organic Chemistry.

Products of the Distillation of Coal-tar. By H. KÖHLER (*Dingl. polyt. J.*, **274**, 79—82).—It has been observed by Staveley that after the distillation of coal-tar is complete, an oil, consisting of light paraffins mixed with water, drops from the condenser. The same chemist has found paraffins in the receivers through which the injurious gases given off during the distillation are passed before they are burnt. The author has examined German tars with a similar purpose, but failed to detect the presence of light paraffins in the distillates referred to. The results of his investigation, however, lead him to conclude that during the distillation of coal-tar at higher temperatures dissociation of oxgenated compounds, presumably phenols, takes place, resulting in the formation of light hydrocarbons which are wholly nitratable, together with the separation of water.
D. B.

Paraffin. By B. PAWLEWSKI (*Ber.*, **23**, 327—329).—This paper gives the results of an investigation of paraffin solutions by Raoult's method. The paraffin employed was a white, ozokerite paraffin of the best quality, having a sp. gr. of 0·9170 at 20°, melting at 64—65°, and solidifying at 61—63°. It was dissolved in varying proportions of glacial acetic acid, benzene, and xylene, and the freezing points of each solution determined. From the results obtained the author draws the following conclusions:—(1) The size of the normal molecule of paraffin lies between $C_{21}H_{50}$ and $C_{27}H_{56}$; (2) it has a molecule at least double this size in dilute benzene and xylene solutions; (3) that in almost saturated solutions paraffin has a molecule at least four times the size of the normal.

It further appears that paraffin behaves towards glacial acetic acid as a crystalloïd, and towards benzene and xylene as a colloïd. A solution of 2·2 grams of paraffin in 100 grams of benzene yields, on cooling, a jelly which can support a weight of several grams. A solution of 3·53 grams of the same paraffin in 100 grams of chloroform at 25—27° gave, on cooling, a jelly which was so firm that a weight of 300 grams did not alter its shape. Carbon bisulphide and turpentine oil behave in a similar manner. If fine shavings of paraffin are treated with ether, they fall to powder, partially dissolving at the same time, and the solution, on remaining for 12—20 hours, and cooling to 2°, deposits the paraffin in the form of swollen flocks. In all these cases no trace of crystallisation could be observed, whereas from acetic acid the paraffin separated in scales or small plates.

Similar results to the above have been obtained with other substances by Paternò (this vol., p. 105). H. G. C.

Action of Cupric Salts on Metallic Cyanides. By R. VARET (*Compt. rend.*, **110**, 147—149).—When cupric bromide (2 mols.) is added in successive small quantities to a boiling solution of mercuric cyanide (3 mols.), the liquid becomes black, cyanogen is evolved, and a lilac precipitate separates, which, when dried at 100°, has the composition $2HgCy_2,HgBr_2,Cu\,Cy_2$. If this precipitate is boiled with the mother liquor, it becomes paler in colour, and is converted into the compound $8HgCy_2,3HgBr_2,4Cu_2Cy_2$, and if this is boiled with mercuric cyanide solution, it loses still more mercuric bromide.

If the compound $2HgCy_2,HgBr_2,Cu_2Cy_2$ is boiled with a large excess of water, it gradually loses mercuric cyanide and mercuric bromide, and leaves a residue of cuprous cyanide, but a number of intermediate products of the type $2HgCy_2,HgBr_2,xCu_2Cy_2$ are formed, x being a function of the time and the proportion of water.

A dilute solution of mercuric cyanide added to excess of cupric bromide in the cold yields cyanogen and cuprous bromide. A cold solution of cupric bromide added to excess of mercuric cyanide produces a slight precipitate, and if the filtrate is cooled, it yields blue and green crystals of hydrates of the compounds $2HgCy_2,CuBr_2$ and $HgCy_2.CuBr_2$.

Cold solutions of cupric chloride and mercuric cyanide yield the compounds $2HgCy_2,CuCl_2,6H_2O$ and $HgCy_2,CuCl_2,6H_2O$. Hot solutions, when the cupric chloride is in excess, yield cyanogen and cuprous chloride; but if the mercuric cyanide is in excess, the compound $2HgCy_2,HgCl_2,Cu_2Cl_2$ is obtained, and is much more stable than the corresponding bromine compound.

When mercuric cyanide is boiled with cuprous iodide, it yields an orange precipitate of the compound Cu_2Cy_2,HgI_2, but no cyanogen is evolved. Cuprous bromide yields a pale-green mercuric cuprous bromocyanide, but cuprous chloride is without action under these conditions.

Silver cyanide, when boiled with cupric chloride solution, yields cyanogen and a green silver cuprous chlorocyanide which alters rapidly on exposure to light. Cupric bromide reacts more energetically and forms an unstable bromocyanide. Silver cyanide is, however, not affected when boiled with cupric nitrate or sulphate for several hours.

Haloïd cupric salts react with zinc cyanide, even at the ordinary temperature, but the salts of oxy-acids must be heated to 40° before the action becomes at all rapid. In both cases there is simply double decomposition with evolution of cyanogen.

It follows from these and previous results that haloïd cupric salts will decompose all other metallic cyanides, but cupric salts of oxyacids have no action on silver and mercuric cyanides. It is probable that the two latter salts have the formulæ Ag_2Cy_2 and Hg_2Cy_4, the cyanogen radicles being united with one another as well as with the metals. C. H. B.

Action of Hydrobromic and Sulphuric Acids on Primary Alcohols. By L. Niemilowicz (*Monatsh.*, **10**, 813—828).—The author finds that in the action between hydrobromic acid in aqueous solution and sulphuric acid, the amount of bromine liberated is inversely proportional to the temperature, and to a certain extent in direct proportion to the quantity of sulphuric acid present. Such a mixture of acids may be conveniently used in the direct preparation of bromine-derivatives of the paraffins, and gives a more satisfactory yield than any of the older methods. Methyl and ethyl alcohols yield only monobromides, isoamyl alcohol gives no dibromide, but isobutyl, normal butyl, and normal propyl alcohols give mono-, di-, and tribrominated derivatives when treated with a mixture of the acids. Alcohols which contain the isopropyl-group are much more readily attacked by the sulphuric acid mixture, and more readily form tribrominated derivatives than the normal alcohols. All the higher primary alcohols give a maximum yield of the dibrominated derivatives when heated with a mixture of the acids to a certain calculable temperature, which for propyl alcohol is 60°, for normal butyl alcohol, 50°, for isobutyl alcohol, 40°, for isoamyl alcohol, 30°, and so on. G. T. M.

Compound of Calcium Chloride with Normal Propyl Alcohol. By C. Göttig (*Ber.*, **23**, 181—182).—When commercial propyl alcohol is frequently shaken with calcium chloride, allowed to remain for some time, and then distilled, the residue in the distillation flask on cooling deposits two different substances; that which forms the lower layer is quite opaque and consists of calcium chloride, alcohol, and water; whilst the second is a transparent layer of needle-shaped crystals. These are a compound of calcium chloride with normal propyl alcohol, which, when dried, have the composition $CaCl_2 + C_3H_8O$, and may be recrystallised from dry propyl alcohol without undergoing any change in composition. The compound has almost the same specific gravity as water; small, loosely aggregated pieces float on the surface, rotating in the same manner as the compounds of the alkalis with ethyl alcohol (Abstr., 1887, 550, 636; 1888, 437, 933), and dissolving slowly with liberation of propyl alcohol. It takes up water when exposed to the air, and loses 50 per cent. of its weight over sulphuric acid in a vacuum, leaving an opaque residue, which no longer rotates on the surface of water.

H. G. C.

Cryoscopic Behaviour of the Aqueous Solutions of the Sugars obtained synthetically from Formaldehyde. By N. Klobukoff (*Zeit. physikal. Chem.*, **5**, 28—30).—Two preparations obtained by the condensation of formaldehyde in alkaline solution, the one containing about 85 per cent. of formose, and the other

20—21 per cent. of methose, were examined. Both gave reductions corresponding with the molecular weight 180, and therefore to the molecule $C_6H_{12}O_6$. H. C.

Synthesis of Mannose, Dextrose, and Levulose. By E. Fischer (*Ber.*, 23, 370—394; 799—805).—The lactone of mannonic acid (Fischer and Hirschberger, this vol.. p. 225) so closely resembles the lactone of arabinosecarboxylic acid (Kiliani, Abstr., 1887, 230) in properties, that the compounds would be regarded as identical were it not for the difference in optical activity, the former having a specific rotation of $[\alpha]_D = 53{\cdot}81$, the latter of $[\alpha]_D = -54{\cdot}8$. When mixed in equal proportions, the two substances yield an optically inactive lactone which can only be separated into its optically active constituents by special methods (*vide infra*); it is therefore evident that the two lactones are optically active isomerides of opposite rotatory power. On reduction with sodium-amalgam (compare Fischer, Abstr., 1889, 1140), the three lactones yield the corresponding glucoses and mannitols. In view of the fact that the rotation of derivatives of each isomeride is not always in the same direction—for example, the hydrazones and osazones of dextro-rotatory mannose are lævo-rotatory and *vice versâ* —it is necessary to adopt some method of indicating the optical activity of the parent glucose, and the author proposes to distinguish the derivatives of dextro- and lævo-rotatory, and of inactive mannose, irrespective of their own peculiar rotation, as derivatives of d.-, l.-, and i.-mannose respectively.

l-Mannose (lævo-rotatory mannose) is obtained when 1 part of the lactone of arabinosecarboxylic acid dissolved in 10 parts of water slightly acidified with sulphuric acid and cooled in a freezing mixture, is treated with 2½ per cent. sodium-amalgam, added in small quantities at a time with continual shaking, the solution being always kept slightly acid; hydrogen begins to make its appearance when about 15 parts of the amalgam and 1·3 parts of 20 per cent. sulphuric acid have been employed, and the reduction is complete when 2 drops of the solution completely reduce 15 drops of Fehling's solution. The product is carefully neutralised, concentrated to crystallising point, and systematically extracted with boiling alcohol in order to separate the mannose from sodium sulphate and any unattacked sodium arabinosecarboxylate; the mannose is then obtained as a syrup by the evaporation of the alcoholic solution. The yield amounts to about 50 per cent. of the theoretical. l.-Mannose is readily soluble in water, tolerably soluble in methyl alcohol, and sparingly soluble in absolute alcohol. It is lævo-rotatory, but the specific rotation could not be determined owing to lack of material. Fermentation with yeast takes place very slowly, if at all, in 5 per cent. aqueous solution, and the greater part of the mannose is found to be unaltered after 12 days' contact with the ferment. *l.-Mannosephenylhydrazone*, $C_{12}H_{18}N_2O_5$, forms slender, colourless crystals, melts, when rapidly heated, at about 195° with the evolution of gas, can be crystallised from 40 parts of boiling water, and is therefore more soluble in hot water than d.-mannosephenylhydrazone, and is dextrorotatory in hydrochloric acid solution. *l.-Mannosephenylglucosazone*,

$C_{18}H_{22}N_2O_4$, crystallises in slender, yellow needles, becomes dark, when rapidly heated, at about 195°, and melts at about 205°; its properties closely resemble those of ordinary d.-phenylglucosazone, obtained from d.-mannose, dextrose, or levulose, but it is strongly dextrorotatory in acetic acid solution. On treatment with concentrated hydrochloric acid, it is converted into the corresponding osone, which will unquestionably yield dextro-rotatory levulose (l.-levulose, *vide infra*) on reduction with zinc-dust and acetic acid.

l.-Mannitol.—The reduction of l.-mannose to l.-mannitol, which takes place much more slowly than the reduction of the lactone, is best effected by adding small quantities of 2½ per cent. sodium-amalgam to a 10 per cent. aqueous solution, neutralising the alkali between each addition, and continuing the operation until 3 drops of the solution no longer reduce 1 drop of Fehling's solution; the l.-mannitol is then extracted with alcohol by the method described under l.-mannose. It crystallises from water in slender needles, from methyl alcohol in spherical aggregates of needles, melts at 163—164°, is readily soluble in water, tolerably soluble in hot methyl alcohol, and sparingly soluble in absolute alcohol, has a sweet taste, does not reduce Fehling's solution, and is strongly lævo-rotatory in the presence of borax. The mannitol obtained by Kiliani by the reduction of the double lactone of metasaccharic acid (Abstr., 1888, 46), is in all probability identical with l.-mannitol.

i.-Mannonic acid is formed by dissolving equal parts of the lactones of d.-mannonic acid and arabinosecarboxylic acid in water. It crystallises in stellate groups of long, lustrous prisms, sinters at 149°, melts at 155°, has a sweet taste, and does not reduce Fehling's solution. It is readily soluble in water, sparingly soluble in alcohol, and is optically inactive even in a 25 per cent. solution. The *calcium* salt, $(C_6H_{11}O_7)_2Ca$, is anhydrous, and crystallises in spherical aggregates of slender needles; the crystallised salt requires 60—70 parts of boiling water for its solution, and in aqueous solution is optically inactive. The *phenylhydrazide*, $C_{12}H_{18}N_2O_6$, crystallises from water in small, lustrous, seemingly cubical forms, melts, when rapidly heated, at 230° with the evolution of gas, and is less soluble in water than the corresponding derivatives of d.-mannonic and arabinosecarboxylic acids. i.-Mannonic acid cannot be separated into its optically active components by crystallisation, and to effect this, recourse must be had to Pasteur's methods. Fermentation of the neutral ammonium i.-mannonate with *Penicillium glaucum* in a nutritive solution did not give satisfactory results, in spite of a rich growth of mycelium and occurrence of fructification, since at the end of three weeks, when further growth ceased, the solution was lævo-rotatory only to the extent of 1°. Crystallisation of the sparingly soluble strychnine salt, however, gave the desired separation. The strychnine salt was prepared by heating the i.-lactone with strychnine in molecular proportion, in 70 per cent. alcohol, for a considerable time and concentrating the alcoholic solution, whereby about 12 per cent. of the strychnine separated, whilst the corresponding amount of the lactone remained in solution; by further evaporation, the strychnine salt separated as a crystalline mass consisting of slender needles, and was freed from adhering lactone by repeated washing with alcohol. When warmed with absolute alcohol, the salt at first dissolves forming a clear solution; but in a very short time the very sparingly soluble strychnine arabinosecarboxylate crystallises out from the boiling solution, and can be purified by extraction with boiling alcohol. The salt insoluble in alcohol, amounting to about one-third of the salt of the inactive acid employed, is pure strychnine arabinosecarboxylate, and by decomposition with baryta-water and acidification with sulphuric acid, yields the corresponding lactone melting at 146—151°. The alcoholic mother liquor obtained after the separation of the strychnine arabinosecarboxylate contains chiefly strychnine d.-mannonate, together with some of the former salt; and when cooled at 0° gives a separation of the two in about equal proportions in slender, lustrous crystals amounting to about half of the salt of the inactive acid employed. A portion of the arabinosecarboxylate is removed by extracting the crystalline separation with hot alcohol, and the remainder is separated by converting the strychnine salt into the morphine salt, and crystallising the sparingly soluble morphine d.-mannonate first from water, and finally from methyl alcohol. When decomposed with baryta-water, and subsequently neutralised with dilute sulphuric acid, it is converted into the corresponding d.-lactone. The process can be reversed and the d.-lactone separated first from the i.-lactone by means of the morphine salt; the l.-lactone is then purified by conversion into the strychnine salt.

i.-Mannose is obtained by the reduction of the lactone of i.-mannonic acid by the method already described under l.-mannose. It is a colourless syrup, which is readily soluble in water, tolerably soluble in hot methyl alcohol, sparingly soluble in absolute alcohol, and, apart from its optical inactivity, has all the properties of d.- and l.-mannose. On fermentation with yeast, the solution becomes lævo-rotatory in consequence of the rapid decomposition of the dextro-rotatory component, l.-mannose being only slowly acted on by the ferment. The *i.-phenylhydrazone*, $C_{13}H_{18}N_2O_5$, is sparingly soluble, melts at about 195° with decomposition, and is optically inactive; the *i.-phenylglucosazone*, $C_{18}H_{22}N_4O_4$, crystallises in slender, lustrous, yellow needles, becomes dark at about 210°, melts at 217—218° with decomposition, is soluble in about 250 parts of boiling alcohol, is optically inactive in acetic acid solution, and has all the properties of α-acrosazone, with which the author regards it as identical. α-Acrosazone will therefore be referred to in future as i.-phenylglucosazone.

i.-Phenylglucosazone (α-acrosazone) and i.-mannitol (α-acritol) are obtained from α-acrose, and it follows therefore that this synthetical glucose must either be i.-levulose or i.-mannose, since these carbohydrates are the only two which could yield the same optically inactive osazone and mannitol. Unlike i.-mannose, α-acrose does not yield a phenylhydrazone; it must, therefore, be i.-levulose, and its production from acraldehyde bromide must be referred to the simultaneous formation of glyceraldehyde and the isomeric symmetrical dihydroxyacetone, which then undergo condensation, thus:—

$$CH_2(OH){\cdot}CH(OH){\cdot}COH + CH_2(OH){\cdot}CO{\cdot}CH_3(OH) =$$
$$CH_2(OH){\cdot}CH(OH){\cdot}CH(OH){\cdot}CH(OH){\cdot}CO{\cdot}CH_2(OH).$$

On fermentation with yeast, α-acrose is separated into its optically active constituents; the d.-levulose (ordinary lævo-rotatory levulose) is removed, and the solution becomes dextro-rotatory. The l.-levulose (that is, the dextro-rotatory modification) could not be isolated on account of the small quantity at disposal, but reacts like ordinary levulose (d.-levulose) in forming an osazone identical with l.-phenylglucosazone, but no hydrazone.

i.-Mannitol is obtained from i.-mannose by the reduction method employed in the preparation of l.-mannitol; the yield amounts to about 40 per cent. of the theoretical. It crystallises in small prisms, melts at 168° (at 170° corr.), is readily soluble in water, tolerably soluble in hot acetic acid, and very sparingly soluble in methyl and ethyl alcohol, is optically inactive, and identical with α-acritol. The name i.-mannitol will therefore be employed for both compounds. On oxidation with dilute nitric acid, i.-mannitol yields about 20 per cent. of i.-mannose, and this, by oxidation with bromine, is converted into i.-mannonic acid, which can be isolated by means of its phenylhydrazide by the method already described (Fischer and Hirschberger, *loc. cit.*); it is therefore possible to prepare synthetically all carbohydrates of the mannose and levulose series.

The synthesis of dextrose from d.-mannonic acid, and therefore from α-acrose, is described in the second paper (*Ber.*, **23**, 799—805), in which it is shown that d.-mannonic acid can be partially converted into gluconic acid, and *vice versâ*, by heating it with twice its weight of quinoline at 140° for 40 minutes; the product from either source containing about 40 per cent. of d.-mannonic acid and 60 per cent. of gluconic acid. To separate these acids, the product obtained by heating d.-mannonic acid (20 grams) with quinoline (40 grams) and water (5 grams) at 140° for 40 minutes is treated with a solution of barium hydroxide (40 grams), steam-distilled to remove all quinoline, exactly neutralised by sulphuric acid, and concentrated to 150 c.c. It is then heated with brucine (60 grams) until dissolved, allowed to remain in the cold for some time in order to remove all excess of brucine by crystallisation, then concentrated to the crystallising point, dissolved in 25 times its volume of boiling absolute alcohol, and the brucine d.-mannonate, which is only sparingly soluble in absolute alcohol, separated by crystallisation. The alcoholic filtrate from this is evaporated to a syrup, which is dissolved in water, treated with a solution of barium hydroxide (20 grams) to liberate the brucine, and the filtrate carefully precipitated with sulphuric acid. The clear solution is now concentrated to 30 c.c., and heated at 100° for an hour with phenylhydrazine (3 grams) in the form of acetate, in order to convert the gluconic acid into its phenylhydrazide, which crystallises out on cooling, and can be reconverted into the acid by the method already described (Fischer and Hirschberger, *loc. cit.*). Gluconic acid, so prepared, has all the properties of ordinary gluconic acid.

To obtain dextrose from gluconic acid, the aqueous solution is evaporated to a thick syrup on the water-bath, with the object of forming as much lactone as possible, and then reduced by adding sodium-amalgam to the cold 10 per cent. aqueous solution in the way already described. The yield is not so good as that obtained when any of the

gluconic acid
[by reduction]
d.-dextrose (ordinary dextro-rotatory dextrose)
[by reduction (Abstr., 1889, 484)]
d.-glucosone
[by reduction]
isoglucosamine
[by nitrous acid]
d.-levulose (ordinary lævo-rotatory levulose).

three mannonic acids are reduced; this is due in all probability to the fact that gluconic acid is only incompletely converted into its lactone, since the property of undergoing reduction by sodium-amalgam is seemingly intimately associated with that of forming lactones in acids of this class. The synthetical dextrose has a specific rotatory power of $[\alpha]_D = 52$, yields d.-phenylglucosazone, and is identical with ordinary dextrose. It follows therefore that, with the exception of l.-gluconic acid, which the author is attempting to prepare from l.-mannonic acid (arabinosecarboxylic acid) by heating with quinoline, l.-dextrose, and the optically inactive forms of these compounds, all the carbohydrates of the mannitol series have been prepared synthetically; the relation of these carbohydrates to α-acrose is shown in the table (p. 470).

W. P. W.

Matezite and Matezo-dambose. By C. Combes (*Compt. rend.*, **110**, 46—47).—Girard (*Compt. rend.*, **77**, 995) obtained from Madagascar caoutchouc, a saccharine substance, matezite, which, when treated with hydriodic acid, yields methyl iodide and matezo-dambose, an isomeride of glucose. β-Pinite, obtained by Maquenne from *Pinus lambertiana*, behaves in a similar manner, and with hydriodic acid yields methyl iodide and β-inosite (this vol., p. 244). Matezite and β-pinite both crystallise in radiating nodules, and matezo-dambose and β-inosite are precipitated in tetrahedra on addition of alcohol to their aqueous solutions. Both the latter give Scherer's reaction, and have a molecular weight of 171 as determined by Raoult's method. These facts and the following measurements show that β-pinite and β-inosite are not distinct chemical species, but are identical with matezite and matezo-dambose respectively.

	Matezite.	β-pinite.	Matezo-dambose.	β-inosite.
Melting-point ..	187°	186·5°	246°	246°
Rotatory power.	66·0°	65·7°	67·6°	68·4°

C. H. B.

Rotatory Power of Matezite and Matezo-dambose. By A. Girard (*Compt. rend.*, **100**, 84—86).—The value of the rotatory power given in an earlier paper was erroneous, and the author has recalculated the numbers from his old data—

Matezite $[\alpha]_D = + 65·2°$. Matezo-dambose $[\alpha]_D = + 65·4°$.

New determinations give very similar results.

Matezite $[\alpha]_D = + 64·7°$. Matezo-dambose $[\alpha]_D = + 64·7°$.

The rotatory-powers are therefore identical, and not different as was formerly supposed (compare Combes, preceding abstract).

C. H. B.

Racemo-inosite. By Maquenne and C. Tanret (*Compt. rend.*, **110**, 86—88).—Inosite from quebrachite is lævogyrate, and inosite from pinite dextrogyrate, their rotatory powers being exactly equal, but of opposite sign. For the hydrated compounds, $[\alpha]_D = \pm 65°$; and for the anhydrous, $[\alpha]_D = \pm 55°$. Both soften without decomposing above 210°, and melt at 247°; both crystallise in hemihedral rhomboidal prisms, give the same reactions, and have the same solubilities both in the hydrated and anhydrous forms. Their acetates soften in the hand, and have equal but opposite rotatory powers (10°); the benzoates crystallise in comparatively insoluble, brilliant needles which melt at 252°.

When solutions of equal quantities of the two inosites are mixed, an abundant crystalline precipitate of *racemo-inosite* is obtained. It is optically inactive, melts at 253° without softening, is much less soluble than the active varieties, and separates from solution only in the anhydrous form. It does not affect Fehling's solution in the cold. The acetate is crystalline and melts at 111°, and the benzoate forms bulky, microscopic needles which melt at 217°.

Racemo-inosite has the same composition as the active inosite, to which it stands in the same relation as racemic acid does to the active tartaric acids. It is the first example of physical isomerism amongst the sugars. C. H. B.

Xylose and Wood-gum from Straw and other Materials. By E. W. Allen and B. Tollens (*Ber.*, 23, 137).—When loofah, straw, or cherry-wood is extracted with soda, and the extract mixed with alcohol, a gum is precipitated; in the case of straw, the yield of crude gum is 16 per cent., and, on hydrolysis, it gives xylose.

F. S. K.

Derivatives of Propylamine. By S. Gabriel and W. E. Lauer (*Ber.*, 23, 87—96).—Continuing Gabriel's previous work on the derivatives of fatty amines, the authors have investigated some more of the derivatives of propylamine.

When γ-bromopropylphthalimide (Abstr., 1888, 1292) is digested with potash, the potassium salt of *hydroxypropylphthalamic acid* is formed. If the syrupy acid is heated for 3—4 hours at 135—145°, water is separated, and *γ-hydroxypropylphthalimide*,

$$C_8H_4O_2{:}N{\cdot}C_3H_6{\cdot}OH,$$

is produced. This crystallises from water in colourless needles.

Propylmercaptophthalimide, $C_8H_4O_2{:}N{\cdot}C_3H_6{\cdot}SH$, is formed when bromopropylphthalimide is heated with alcoholic potassium hydrosulphide in sealed tubes at 100°. It is soluble in alcohol and light petroleum, insoluble in water. crystallises in colourless needles, and melts at 46—48°. When heated with fuming hydrochloric acid, it decomposes into phthalic acid and γ-amidopropylmercaptol.

γ-Thiocyanopropylphthalimide, $C_8H_4O_2{:}N{\cdot}C_3H_6{\cdot}SCN$, is formed when bromopropylphthalimide is heated with alcoholic potassium thiocyanate at 100°. It crystallises from alcohol in colourless needles melting at 96—98°. When this compound is digested with potash, it yields *dipropyldisulphide-γ-diphthalamic acid*, $S_2(C_3H_6{\cdot}NH{\cdot}CO{\cdot}C_6H_4{\cdot}COOH)_2$; this crystallises in colourless scales melting at 136°, is soluble in glacial acetic acid, ammonia, and alkalis, insoluble in water. When digested with concentrated hydrochloric acid at 200°, it is decomposed into phthalic acid and *dipropylamido-γ-disulphide hydrochloride*,

$$S_2(C_3H_6{\cdot}NH_2)_2,2HCl,$$

which crystallises in white needles melting at 218—219°, and yields a sparingly soluble picrate, $C_6H_{16}N_4S_2.2C_6H_2(NO_2)_3\cdot OH$, which crystallises from alcohol in yellow scales melting at 145—146°.

γ-Amidopropyl hydrogen sulphate, $NH_2\cdot C_3H_6\cdot O\cdot SO_3H$, is formed when γ-bromopropylamine hydrobromide is added to a hot aqueous solution of silver sulphate. It forms crystals, soluble in hot water, and melting at 221°.

μ-Mercaptopenthiazoline,  $CH_2{<}\begin{smallmatrix}CH_2\cdot S\\ CH_2\cdot N\end{smallmatrix}{>}C\cdot SH$, is formed by the action of carbon bisulphide on γ-bromopropylamine hydrobromide. It is easily soluble in hot water and alcohol, insoluble in acids, forms colourless crystals, and melts at 132°. When oxidised by heating with bromine-water, this compound yields *γ-amidopropylsulphonic acid*, $NH_2\cdot C_3H_6\cdot SO_3H$, which crystallises from alcohol in needles, and does not melt below 300°. This acid is isomeric with β- and ν-methyltaurine. The mother liquors from this acid contain a less oxidised derivative of the thiazoline, which forms fibrous crystals, very soluble in water.

Trimethylene-ψ-thiocarbamide,  $CH_2{<}\begin{smallmatrix}CH_2-S\\ CH_2\cdot NH\end{smallmatrix}{>}C{:}NH$, is formed by the action of potassium thiocyanate on γ-bromopropylamine hydrobromide. It is a strongly-smelling oil, with strong alkaline reaction, and is less stable than the corresponding ethylene-derivative. Its *hydrobromide*, $C_4H_9N_2SBr$, is soluble in water, and forms crystals melting at 135—136°; its *picrate* forms long needles melting at 128°.

Trimethylene-ψ-carbamide,  $CH_2{<}\begin{smallmatrix}CH_2-O\\ CH_2\cdot NH\end{smallmatrix}{>}C{:}NH$, is formed when potassium cyanate is substituted for thiocyanate in the above reaction. It is a thick, strongly basic oil, yielding a *picrate*, crystallising in yellow needles, and melting at 200°. L. T. T.

New Hexylamine and a New Hexyl Alcohol. By M. Freund and P. Herrmann (*Ber.*, **23**, 189—196).—The starting point for these compounds is diethylacetic acid, obtained by Conrad's method from ethyl malonate: for every 100 grams of the latter employed, 25 grams of diethylacetic acid was obtained.

Diethylacetic chloride, $CHEt_2\cdot COCl$, is obtained by acting on the acid with phosphorus trichloride at the ordinary temperature, and then carefully distilling. It is a fuming liquid, having a pungent odour, and boiling at 134—137°. It readily acts on sodium diethylacetate, forming *diethylacetic anhydride*, $O(CO\cdot CHEt_2)_2$, a colourless liquid, which has a faint odour, and boils at 230°.

Diethylacetamide, $CHEt_2\cdot CO\cdot NH_2$, is prepared by passing ammonia gas into the free acid, and heating the ammonium salt thus obtained in a sealed tube at 240—250° for 5—6 hours. It crystallises from absolute alcohol in long needles which melt at 105°, boils without decomposition at 230—235°, and is readily soluble in water, alcohol, and ether.

Diethylacetanilide, $CHEt_2\cdot CO\cdot NHPh$, is obtained from the foregoing compound by boiling it with aniline and a little hydrochloric acid. It crystallises from alcohol in slender needles which melt at 124°, and are almost insoluble in water.

Diethylacetonitril, $CHEt_2 \cdot CN$, is formed when the amide is mixed with phosphorus pentoxide and carefully distilled. It is a somewhat volatile liquid of pleasant odour, boils at 144—146°, and mixes with alcohol and ether, but is almost insoluble in water.

β-Diethylethylamine hydrochloride, or *pseudohexylamine hydrochloride*, $CHEt_2 \cdot CH_2 \cdot NH_2,HCl$, is prepared by adding sodium to a boiling alcoholic solution of diethylacetonitril, and distilling the liquid formed in a current of steam. The distillate is collected in hydrochloric acid, the solution evaporated to dryness, and any ammonium chloride present removed by digestion with absolute alcohol. On evaporation, the filtered solution leaves pseudohexylamine hydrochloride as a white, somewhat hygroscopic powder. It crystallises from alcohol containing a little ether or light petroleum in a network of fine needles, melting with decomposition at 187°, and very readily soluble in water and alcohol. The *platinochloride*, $(CHEt_2 \cdot CH_2 \cdot NH_2)_2,H_2PtCl_6$, is very insoluble, and forms golden-yellow, brilliant scales.

The free base is obtained by adding a slight excess of concentrated potash solution to the hydrochloride suspended in ether, drying the ethereal solution over solid caustic potash, and distilling. *Pseudohexylamine* is a liquid of ammoniacal odour, which boils at 125·3° (corr.), and rapidly absorbs carbonic anhydride from the air.

Pseudohexylcarbamide, $NH_2 \cdot CO \cdot NH \cdot CH_2 \cdot CHEt_2$, is prepared by evaporating a solution of equal weights of pseudohexylamine hydrochloride and potassium cyanate; from the potassium chloride also formed, it is separated by digesting with absolute alcohol, evaporating the solution, washing with a little water, and recrystallising several times from hot water. It forms small plates which melt at 116·5°, and are sparingly soluble in cold, readily in hot water or alcohol.

Pseudodihexyloxamide, $C_2O_2(NH \cdot CH_2 \cdot CHEt_2)_2$, is formed by warming pseudohexylamine and oxamide in ethereal solution. It crystallises from alcohol in beautiful needles melting at 144°.

Symmetrical phenylpseudohexylcarbamide, $NHPh \cdot CO \cdot NH \cdot CH_2 \cdot CHEt_2$, and *symmetrical phenylpseudohexylthiocarbamide*,

$$NHPh \cdot CS \cdot NH \cdot CH_2 \cdot CHEt_2,$$

are obtained when a solution of pseudohexylamine in absolute alcohol is heated with phenyl cyanate and phenylthiocarbimide respectively. The former crystallises in fascicular groups of needles, and melts at 70°, whereas the latter separates from solution as an oil, but may be obtained in the crystalline state by precipitating its alcoholic solution with water, adding a solid particle, and scratching with a glass rod. After repeating this process several times, it crystallises in small prisms which melt at 52—53°, and still contain traces of phenylthiocarbamide.

Pseudohexyl alcohol, $CHEt_2 \cdot CH_2 \cdot OH$.—To prepare this alcohol, pseudohexylamine hydrochloride is digested with an excess of silver nitrite and a little water, and the filtrate distilled. The alcohol swims on the aqueous distillate as a yellow oil, and is freed from traces of the amine by hydrochloric acid, dried over ignited potassium carbonate, and finally over baryta, and fractionated. It is a colourless liquid, having an odour resembling that of camphor and of fusel oil, and boils at 139—143°. Between the boiling-points of the alcohol and the acid there is, therefore, approximately the same difference as between the other known hexyl alcohols and the corresponding acids.

H. G. C.

Derivatives of Ammonium Chloride. By J. A. LE BEL (*Compt. rend.*, **110**, 144—147).—If it is admitted that the atoms or radicles in a substituted ammonia are capable of movement round the central nitrogen-atom, and have not fixed and definite relative positions, it is possible to imagine the existence of two isomeric derivatives, without assuming that they have been formed in different ways, as for example by the union of RCl with NR'_3, or R'Cl with NRR'_2.

Amongst the platinochlorides of the amines there is a remarkable group of cubic salts, formed from chlorides of the type NRR'_3Cl. To this group belong methyltripropylammonium platinochloride and trimethylpropylammonium platinochloride, but the limit is passed by the trimethylisobutylammonium salt. As a rule, if a platinochloride does not differ from the cubic salts by more than a single methyl-group, its crystalline form will be so nearly a cube that very careful goniometric and optical examination will be necessary to prove that it is not cubic.

Trimethylisobutylammonium platinochloride was first obtained in highly birefractive needles, distinctly not cubic, but when these were recrystallised in order to obtain larger crystals, octohedra were obtained very closely resembling regular octohedra, and their character was not altered by recrystallisation. All attempts to reconvert the octohedral platinochloride into the prismatic form failed, but when the salt was agitated with pure precipitated silver oxide, the platinum and chlorine were precipitated together, and if the compound ammonia in the filtrate was neutralised with hydrochloric acid and concentrated rapidly in a vacuum, the hydrochloride was obtained partly in needles and partly in octohedra. It follows that there are not only two platinochlorides, but two hydrochlorides, the prismatic hydrochloride being more stable than the corresponding platinochloride. The octohedral hydrochloride changes into the prismatic form in presence of excess of the original hydrochloride, especially if a little free acid is present.

C. H. B.

Action of Ammonia and of Ethylenediamine on Tetrachlorodiacetyl. By S. LEVY (*Annalen*, **254**, 374—376).—The compound (m. p. 127°) obtained by treating tetrachlorodiacetyl with ammonia (this vol., p. 233) is identical with the amide of trichloropropyleneoxidecarboxylic acid obtained from tetrachloracetone; probably it has the constitution

$\begin{matrix}ClHC\\ | \\ O\end{matrix}\!\!>C(CONH_2)\cdot CHCl_2.$

If such is the case, the compound obtained from tetrachlorodiacetyl and ethylenediamine probably has the constitution

$$\begin{matrix}ClHC\\ | \\ O\end{matrix}\!\!>C(CHCl_2)\cdot CO\cdot NH\cdot C_2H_4\cdot NH\cdot CO\cdot C(CHCl_2)\!<\!\!\begin{matrix}CHCl\\ | \\ O\end{matrix}.$$

F. S. K.

Diethylenediamine. By J. SIEBER (*Ber.*, 23, 326—327).—Diethylenediamine is formed when ethylenediamine is treated with ethylene bromide; the product is decomposed with potash, the resulting oil dried, fractionated, and the portion passing over at 168—175° collected separately. The base could not be obtained in an anhydrous condition. The *hydrochloride*, $C_4H_{10}N_2,2HCl$, crystallises in small, colourless needles, and is readily soluble in water, but insoluble in alcohol. The *platinochloride*, $C_4H_{10}N_2,H_2PtCl_6$, crystallises in small, yellow needles, and is moderately easily soluble in hot water, but only very sparingly in hot alcohol. The *mercurochloride*, $C_4H_{10}N_2,H_2HgCl_4$, crystallises in concentrically grouped needles, and is readily soluble in hot water, but is reprecipitated on adding alcohol. The *picrate*, $C_4H_{10}N_2,C_6H_3N_3O_7$, crystallises from water in yellow needles, and is almost insoluble in alcohol. F. S. K.

Propylthiocarbimide and some New Thiocarbamides. By O. HECHT (*Ber.*, 23, 281—288).—*Propylammonium propyldithiocarbamate* separates in colourless crystals, when normal propylamine is mixed with ether and treated in the cold with the theoretical quantity of carbon bisulphide. It is readily soluble in water and alcohol, and melts at 102° with decomposition.

Propylthiocarbimide, $NPr{:}CS$, is obtained when the preceding compound is dissolved in alcohol, the solution shaken with a concentrated aqueous solution of mercuric chloride, and then distilled with steam. The yield is 42 per cent. of the theoretical quantity. It is a colourless, highly refractive liquid, with a strong odour of mustard oil; it boils at 152·7° (743 mm.), has a sp. gr. of 0·9304 at 99·4°, (water at 99·4° = 1) and is only sparingly soluble in water, but miscible with alcohol, ether, acetone, benzene, chloroform, and light petroleum.

Propylthiocarbamide, $NHPr{\cdot}CS{\cdot}NH_2$, prepared by dissolving propylthiocarbimide in ammonia, separates from alcohol in colourless, quadratic plates, melts at 110°, and is moderately easily soluble in water. The *methyl*-derivative, $NHPr{\cdot}CS{\cdot}NHMe$, prepared by treating propylthiocarbimide with methylamine, or by treating methylthiocarbimide with propylamine in alcoholic solution, crystallises in colourless plates, melts at 79°, and is very easily soluble in alcohol, acetone, and chloroform, and readily in ether, benzene, and carbon bisulphide, but only sparingly in water and light petroleum. The *ethyl*-derivative, $NHPr{\cdot}CS{\cdot}NHEt$, crystallises in small, colourless plates, and melts at 52°; it is moderately easily soluble in water, and behaves like the corresponding methyl-derivative with other solvents. The *propyl*-derivative, $CS(NHPr)_2$, crystallises in colourless, nacreous plates, melts at 71°, and is only sparingly soluble in cold, but moderately easily in hot, water.

Dipropylcarbamide, $CO(NHPr)_2$, prepared by treating an alcoholic solution of the thiocarbamide with mercuric oxide, crystallises from hot water in needles, and melts at 105°.

Propylallylthiocarbamide, $NHPr{\cdot}CS{\cdot}NH{\cdot}C_3H_5$, can be obtained by treating propylthiocarbimide with allylamine, or by treating allylthiocarbimide with propylamine; it crystallises in large, transparent plates, melts at 60°, and is only very sparingly soluble in cold, but moderately easily in hot, water.

Propylphenylthiocarbamide, $NHPr\cdot CS\cdot NHPh$, crystallises from alcohol in colourless, nacreous plates, melts at 63°, and is only sparingly soluble in hot water.

Dimethylthiocarbamide, $CS(NHMe)_2$, is a colourless. crystalline compound melting at 51·5°; it is very readily soluble in alcohol, chloroform, and acetone, but only sparingly in ether, benzene, carbon bisulphide, and light petroleum.

Methylallylthiocarbamide, $NHMe\cdot CS\cdot NH\cdot C_3H_5$, is a colourless, crystalline compound melting at 52°; *ethylallylthiocarbamide* forms large, transparent crystals, and melts at 47°.

Diallylthiocarbamide, $CS(NH\cdot C_3H_5)_2$, crystallises in large, transparent plates, and melts at 49·5°. F. S. K.

Thioaldehydes. By E. Baumann (*Ber.*, **23**, 60—69).—Baumann and Fromm showed (this vol., p. 25) that when acetaldehyde is treated with hydrogen sulphide in the presence of hydrochloric acid, two isomeric trithioaldehydes are formed, and that benzaldehyde in like manner yields two isomeric thiobenzaldehydes. The author has tried the same reaction with formaldehyde, but in all cases the trithioformaldehyde, $C_3H_6S_3$, described by Hofmann (*Annalen*, **145**, 357) was alone produced. As this compound is also formed in so many other ways, and as no isomeride of it has been obtained, there can be little doubt that the peculiar isomerism occurring with the higher members of this class does not extend to the simplest member thereof.

In text-books it is stated that trithioformaldehyde is formed when hydrogen sulphide is passed into a solution of formaldehyde. This is not the case; this and the homologous aldehydes only being formed in the presence of strong acids or dehydrating agents. The first action of hydrogen sulphide on aldehydes seems to be the formation of a compound $SH\cdot R\cdot OH$, two or more molecules of which then unite with separation of water and formation of more or less complicated compounds of a mercaptan-like character, the reactions being probably represented by the equations—

$$2SH\cdot R\cdot OH = SH\cdot R\cdot O\cdot R\cdot SH + H_2O;$$
$$2SH\cdot R\cdot OH = SH\cdot R\cdot S\cdot R\cdot OH + H_2O;$$
$$SH\cdot R\cdot OH + OH\cdot R\cdot OH = OH\cdot R\cdot S\cdot R\cdot OH + H_2O;$$

and so on. These compounds are very difficult to isolate, and under the influence of hydrochloric acid, &c., are converted into trithioaldehydes. With formaldehyde, the intermediate products were obtained as a semi-crystalline mass easily soluble in caustic soda solution, from which it was reprecipitated by acids. Its alcoholic solution gives with lead salts a bright yellow precipitate, which on heating yields lead sulphide. By passing hydrogen sulphide into a 40 per cent. aqueous solution of formaldehyde acidified with hydrochloric acid, the author has obtained one compound apparently tolerably pure. Crystallised from ether, it melts at 97—103°, volatilises seemingly unchanged, and gives numbers corresponding approximately with the formula $C_4H_8S_3O$ or $C_3H_6S_3 + CH_2O$. It is not, however, a simple additive-product of trithioformaldehyde and formaldehyde, as it decolorises iodine solution and does not yield a sulphone on oxidation. With lead and copper salts, it gives precipitates, which when warmed with alkalis easily decompose into metallic sulphides. Its general behaviour is thus that of a mercaptan, and when heated with concentrated hydrochloric acid or other dehydrating agents, it yields trithioformaldehyde. When a solution of formaldehyde is saturated with hydrogen sulphide, it remains clear, but on the addition of concentrated hydrochloric acid the solution solidifies suddenly to a crystalline magma consisting mainly of the compound just described. If excess of hydrochloric acid is added, and the whole warmed, the crystalline mass is converted into trithioformaldehyde. Trithioformaldehyde is odourless when pure.

With acetaldehyde similar but liquid products are formed, which have been investigated by Weidenbusch, Klinger, and others. These products yield a more stable, yellow lead-derivative, decolorise iodine solutions, dissolve in caustic soda, and generally have the character of mercaptans. Marckwald has also shown (Abstr., 1886, 864) that thioacetaldehyde unites with water to form hydroxyethylmercaptan, SH·CHMe·OH, which under water gradually changes to the oily products just described. L. T. T.

Thioaldehydes. By E. BAUMANN and R. CAMPS (*Ber.*, 23, 69—73).—Baumann and Fromm showed (this vol., p. 25) that α- and β-trithioaldehydes were both oxidised by potassium permanganate in acid solutions to a stable trisulphone, $C_6H_{12}S_3O_6$. The authors have now investigated the oxidation of trithioformaldehyde. The oxidation is best effected by making a paste of the aldehyde with dilute sulphuric acid and adding gradually thereto a concentrated solution of potassium permanganate. *Trimethylenetrisulphone*,  $CH_2<\begin{matrix}SO_2\cdot CH_2\\ SO_2\cdot CH_2\end{matrix}>SO_2$, forms a crystalline powder insoluble in water, alcohol, ether, chloroform, glacial acetic acid, or dilute acids. It dissolves in caustic soda, warm aqueous ammonia, and also in boiling sodium carbonate solution, from which it expels carbonic anhydride. Neither concentrated nitric nor sulphuric acid acts on it in the cold or when gently warmed with it, but the latter dissolves it when strongly heated, the unchanged substance crystallising out again on cooling. Only at its boiling point does sulphuric acid cause partial decomposition. When the trisulphone is heated alone, a part sublimes, the remainder charring without previous fusion. The trisulphone has the character of a hexabasic acid, all six atoms of hydrogen being replaceable by basic radicles. When it is dissolved in a large excess of soda and the solution treated with excess of methyl iodide, triacetonetrisulphone, $C_9H_{18}S_3O_6$ (this vol, p. 26), is formed. With less alkali and methyl iodide, less highly methylated compounds are formed.

Compounds less highly oxidised than the trisulphone were also present in small quantities among the oxidation-products, and were less soluble in soda. One of these appeared to be a disulphone, but was not obtained in a pure state. L. T. T.

Anhydride Formation in Acids of the Succinic Series. By K. AUWERS and V. MEYER (*Ber.*, **23**, 101—103).—The readiness with which anhydride formation takes place in acids of the succinic series is increased by the presence of methyl-groups in the molecule.

Tetramethylsuccinic acid, for example, is converted into the anhydride on distilling, when heated with hydrochloric acid under pressure, or when distilled with steam; in the last case the change is not complete.

Trimethylglutaric acid gives an anhydride far more readily than glutaric acid, but not so easily as tetramethylsuccinic acid; it is not acted on by boiling water, but on distillation it yields the anhydride.

When trimethylglutaric acid is brominated according to Hell's method, it yields bromotrimethylglutaric anhydride.

Trimethylsuccinic acid has been prepared. F. S. K.

Tetramethylsuccinic Acid and Trimethylglutaric Acid. By K. AUWERS and V. MEYER (*Ber.*, **23**, 293—311; compare Abstr., 1889, 1145, and Zelinsky, this vol., p. 132).—The two acids, melting at 97° and 190° respectively, which are obtained by treating ethyl α-bromisobutyrate with finely divided silver and hydrolysing the fraction of the product boiling at 200—250° with concentrated hydrobromic acid at 100°, have been proved to be trimethylglutaric acid and tetramethylsuccinic acid respectively. The two compounds can be easily separated by distillation with steam. The tetramethylsuccinic acid passes over for the most part in the form of the anhydride, and is best isolated by evaporating the distillate to a small volume with alkali, then acidifying, and separating the precipitated acid by filtration. The non-volatile trimethylglutaric acid is extracted with ether, the ether evaporated, and the residue recrystallised from hot water. The yield of the two products together is about 15 per cent. of the theoretical quantity, and they are obtained in about equal quantities.

Tetramethylsuccinic acid, $C_8H_{14}O_4$, melts at 190—192° when heated slowly, but when heated quickly the temperature may rise to about 200° before it becomes liquid; it forms short, dendritic crystals, is readily soluble in alcohol and benzene, and moderately easily in ether, chloroform, carbon bisulphide, and hot water, but only sparingly in cold water, and is almost insoluble in light petroleum. Molecular weight determinations by Beckmann's method in ethereal solution, and by Raoult's method in glacial acetic acid solution, gave results in accordance with the molecular formula given above. An examination of the electrical conductivities of tetramethylsuccinic acid and trimethylglutaric acid proved that the higher melting compound only is a substituted succinic acid, and measurements of the electrical conductivities of the sodium salts of the two acids gave results which showed that both compounds are dicarboxylic acids.

Tetramethylsuccinic anhydride, $C_8H_{12}O_3$, is best prepared by distilling the acid or heating it for a short time at its boiling point. It crystallises from hot light petroleum in small, colourless needles, melts at 147°, and boils at 230·5°. It is very readily soluble in most ordinary solvents, but only sparingly in cold light petroleum, and almost insoluble in cold water or sodium carbonate. It is quickly decomposed by hot alkalis, and on acidifying, the acid is precipitated.

When tetramethylsuccinic acid is treated with bromine and amorphous phosphorus by Hell-Volhard's method, and the product dropped on to ice, the anhydride is obtained, but not a trace of any brominated acid is formed.

Trimethylglutaric acid, $COOH\cdot CMe_2\cdot CH_2\cdot CHMe\cdot COOH$, crystallises from hot water in plates, melts at 97°, and is very readily soluble in most ordinary solvents, but less readily in carbon bisulphide and light petroleum. Molecular weight determinations by Beckmann's method in ethereal solution, and by Raoult's method in glacial acetic acid solution, gave results in accordance with the molecular formula $C_8H_{14}O_4$.

The *anhydride*, $C_8H_{12}O_3$, can be prepared by boiling the acid for a long time, or by treating it with acetic chloride. It crystallises from hot light petroleum in compact, colourless needles, melts at 95—96°, and boils at 262°. It is much more readily decomposed by water and sodium carbonate, but in other respects it resembles the anhydride of tetramethylsuccinic acid.

α-Bromotrimethylglutaric anhydride,  $CH_2<\begin{matrix}CMe_2-CO\\CBrMe\cdot CO\end{matrix}>O$, is obtained as follows:—The acid is mixed with a little amorphous phosphorus, and bromine gradually added to the mixture; the product is kept for 24 hours, then heated for a short time on the water-bath, and, when cold, gradually mixed with ice. The precipitate is washed, dried, and recrystallised from hot light petroleum. It forms colourless needles, melts at 114°, sublimes without decomposition, and is readily soluble in all ordinary organic solvents except light petroleum.

Hydroxytrimethylglutaric acid lactone,  $\begin{matrix}CMe_2\cdot CH_2\\|\\CO\text{——}O\end{matrix}>CMe\cdot COOH$, is obtained when the preceding compound is treated with soda, boiling water, or sodium carbonate; the solution is acidified if necessary, and the product extracted with ether. It separates from ether in transparent, well-defined crystals, melts at 103—104°, and is readily soluble in water, alcohol, ether, benzene, and chloroform, but less readily in carbon bisulphide, and only sparingly in light petroleum. It sublimes without decomposition, but it is not volatile with steam. The *silver* salt, $C_8H_{11}O_4Ag$, is a colourless, crystalline compound.

F. S. K.

Tricarballylates. By E. Guinochet (*Compt. rend.*, **110**, 47—49). —The tricarballylates closely resemble the aconitates, but the tribasic salts of tricarballylic acid are neutral to litmus and phenolphthaleïn, whilst those of aconitic acid are alkaline.

The *monopotassium* salt crystallises with 2 mols. H_2O in colourless, transparent films which become anhydrous in a dry vacuum. The *sesquipotassium* salt, $C_6H_7KO_6,C_6H_6K_2O_6 + \frac{1}{2}H_2O$, is a crystalline powder which loses water at 100° and decomposes at 130°; the *tripotassium* salt forms very deliquescent nodules containing 1 mol. H_2O, which is given off at 215°, the salt decomposing at 240°. The *monosodium* salt crystallises with 1 mol. H_2O in transparent prisms which become anhydrous at 100°; the *disodium* salt forms crystalline crusts which contain 1 mol. H_2O, become anhydrous at 110°, and decompose at 135°; the *trisodium* salt forms very soluble, prismatic needles which contain ½ mol. H_2O, and when dried do not decompose below 160°. The *sesquiammonium* salt forms anhydrous, striated, nacreous, hexagonal plates; the *triammonium* salt crystallises with 1 mol. H_2O in very deliquescent, slender needles. The *trilithium* salt crystallises with 2 mols. H_2O in very soluble, prismatic needles which lose one-half their water at 130°, become anhydrous at 185°, and do not alter at 250°. The *monocalcium* salt forms slender needles which contain 1 mol. H_2O and decompose at 125°; the *tricalcium* salt forms a white, amorphous powder which contains 3 mols. H_2O, one-third being given off at 100°, and the remainder at 150°, whilst the salt decomposes at 200°. If this latter salt is made by neutralising tricarballylic acid with lime-water, a precipitate only forms in concentrated solutions; if concentrated solutions of tripotassium tricarballylate and calcium chloride are mixed, no precipitate forms until the liquid is boiled. The *tribarium* salt, after being dried in a vacuum, contains 7 mols. H_2O, one of which is expelled at 100°, and the remainder at 200°; but the salt does not decompose even at 250°. The *trimagnesium* salt crystallises with 3 mols. H_2O, loses one at 100°, and the remainder at 165°, and decomposes at 200°.

The *aluminium* salt, obtained by double decomposition, is a gelatinous precipitate which when dry forms a bulky, white, very hygroscopic powder; it is a hydrated, basic salt, and has the composition $(C_6H_5O_6)_2Al_2 + Al_2O(OH)_4$, becomes anhydrous at 150°, and decomposes at 200°. The *chromium* salt is prepared in a similar manner, has a similar composition, and forms a very hygroscopic, grey-blue powder. The *nickel* salt crystallises with 5 mols. H_2O, loses one at 100°, three at 200°, the last at 225°, and decomposes at 210°; its solution becomes turbid at 60°, and at 100° deposits an abundant precipitate of a lower hydrate containing 3 mols. H_2O; this becomes anhydrous at 150° and decomposes at 200°. The *cobalt* salt is a wine-red, hygroscopic powder, which when dried at the ordinary temperature contains $4H_2O$, but decomposes above 200°; if the solution is heated, it deposits a precipitate, which after drying at 100° is violet-blue, contains 1 mol. H_2O, and decomposes at 110°. The *zinc* salt forms prismatic crystals, and if its solution is heated, a crystalline powder is deposited which contains $\frac{1}{2}H_2O$ and becomes anhydrous at 100°; the addition of alcohol to the cold aqueous solution precipitates a monohydrated salt which becomes anhydrous at 190°, and decomposes at 220°. The *cupric* salt is obtained by double decomposition as a blue, flocculent precipitate which when dry contains 2 mols. H_2O and decomposes above 140°. The *lead* salt is a dense, white, insoluble powder, and the *silver* salt is dense and white, and alters but little when exposed to light. C. H. B.

Action of Oxygen on Zinc Ethyl. By R. DEMUTH and F. MEYER (*Ber.*, **23**, 394—398).—In the course of his classical researches on zinc ethyl, Frankland studied the action of oxygen on this substance, and obtained a white compound which he regarded as a mixture of zinc oxide, ethoxide, and acetate (*Annalen*, **95**, 46). This result appeared to the authors very remarkable, as in processes of oxidation the oxygen is not as a rule interposed between two atoms which are directly connected. (The formation of acids from aldehydes is only an apparent exception, as this reaction probably always takes place in presence of water.) They have therefore re-examined the subject, and find that when oxygen or air is passed through zinc ethyl diluted with light petroleum, a beautiful white powder is obtained which contains no acetic acid. Its composition is not constant, but varies in the different preparations. As previously stated by Frankland, it decomposes on heating with violent evolution of gas, scattering white flocks around, and sometimes exploding violently. These properties can hardly belong to a substance having the constitution $Zn(OC_2H_5)_2$, and the authors regard it as a peroxide of the formula ZnEt·O·OEt. In favour of this view is the fact that it causes separation of iodine from an acid solution of potassium iodide even in absence of air, and yields ethyl alcohol on distillation with dilute sulphuric acid, but no ethane. The latter result shows that it cannot have the constitution ZnEt·OEt.

Zinc ethoxide is also stated by Butlerow and Lissensko (*Jahresb.*, 1864, 467, 470) to be formed by the action of zinc ethyl on absolute alcohol. A white powder is indeed thus obtained, which decomposes quietly on heating, but yields no alcohol on distillation with dilute sulphuric acid, and cannot, therefore, be zinc ethoxide. This compound has, therefore, not yet been prepared. H. G. C.

Chloropyromucic Acids. By H. B. HILL and L. L. JACKSON (*Amer. Chem. J.*, **12**, 22—51).—Ethyl pyromucate was made by warming a solution of 3 parts of pyromucic acid in 5 parts of absolute alcohol with 3 parts of concentrated sulphuric acid (sp. gr. 1·84) for four hours on a water-bath, allowing the mixture to cool, and treating it with water. The crude ether thus obtained was washed with sodium carbonate, dried by exposure to air, and purified by distillation; the yield was 68 per cent. of the theoretical. The distillate was treated with chlorine at 0° until it ceased to gain in weight, and then fractionally distilled at a pressure of 15 mm. Some ethyl chloropyromucate [COOH : Cl = 2 : 5] was formed, but the main product was ethyl pyromucate tetrachloride, $C_4H_3Cl_4O·COOEt$, which formed the fraction distilling between 150° and 160°.

Chloropyromucic acid [COOH : Cl = 2 : 5] was obtained in the following manner:—Ethyl pyromucate was heated at 145°, and chlorine passed through it until the gain in weight corresponded with the substitution of an atom of chlorine for one atom of hydrogen. The viscous liquid was added to a concentrated alcoholic solution of soda, and the sodium salt of chloropyromucic acid thus obtained was decomposed with dilute acid, and the crude acid formed crystallised from benzene; the yield was 38 per cent. of the theoretical. It melts at 176—177°, dissolves readily in alcohol and ether, and also in benzene or water when hot but not when cold; 100 parts of water dissolve 0·28 part of it at 19·5°. The *barium* (with 1 mol. H_2O) and *calcium* (with $3H_2O$) *salts* were prepared; 100 parts of water at 19·5°

dissolve 5·67 and 1·12 parts respectively of these salts. The *potassium* and *silver salts* were also prepared; the latter is only slightly soluble in water.

Ethyl chloropyromucate (2 : 5) was prepared by treating the acid with alcohol and sulphuric acid; it is a heavy, colourless oil, melting at 1—2°, and boiling at 216—218° at a pressure of 77 mm. By treating it with ammonia, *chloropyromucamide* (2 : 5) was obtained; it can, however, be better prepared from the acid chloride and solid ammonium carbonate. It crystallises from water in slender needles melting at 154—155°. This chloropyromucic acid, when treated with bromine and water, yields fumaric acid, the reaction taking place according to the equation $C_5H_3ClO_3 + 2Br_2 + 3H_2O = C_4H_4O_4 + CO_2 + 4HBr + HCl$. When oxidised with nitric acid, it also yields fumaric acid. This shows that it must have the formula [COOH : Cl = 2 : 5].

Chloropyromucic acid [COOH : Cl = 2 : 3] was made from dichloropyromucic acid [COOH : $(Cl)_2$ = 2 : 3 : 5] by dissolving it in 20 parts of dilute ammonia, adding an equal weight of zinc-dust, and boiling the solution for 10 hours, taking care to keep it strongly alkaline. The solution was filtered, cooled, and treated with dilute sulphuric acid, the crude acid which separated was dissolved in dilute ammonia, and calcium chloride added to the solution as long as a sparingly soluble calcium salt was precipitated. The acid was then obtained by filtering the solution and acidifying it with hydrochloric acid; it was recrystallised from water; the yield was 80 per cent. of the theoretical. It was also obtained, though less easily, by reducing dichloropyromucic acid (2 : 3 : 4) with sodium amalgam. It melts at 145—146°, and dissolves in alcohol, ether, and in hot benzene, chloroform, and water; 100 parts of water dissolve 0·8 part of it at 19·8°. The *barium* (with 1 mol. H_2O) and *calcium* (with $3H_2O$) *salts* were prepared; of these 100 parts of water dissolve 2 and 3·1 parts respectively at about 19·5°. *Ethyl chloropyromucate* [2 : 3] forms crystals melting at 29—30° and boiling at 217°. This chloropyromucic acid, when treated with bromine and water, gives a *mucochlorobromic acid* melting at 121—122°, according to the equation $C_5H_3ClO_3 + 3Br_2 + 2H_2O = C_4H_2BrClO_3 + CO_2 + 5HBr$. Nitric acid oxidises it in part to chlorofumaric acid.

Dichloropyromucic acid [COOH : $(Cl)_2$ = 2 : 3 : 4] was prepared by passing chlorine over ethyl pyromucate at 0° until it ceased to gain in weight, expelling the excess of chlorine by a current of air, and decomposing the product with excess of alcoholic soda. The sodium salt thus obtained was decomposed with hydrochloric acid, and the dichloropyromucic acid formed was recrystallised from benzene; the yield was 39 per cent. of the theoretical. It melts at 168—169°, and dissolves in alcohol and ether, and in water, benzene, and chloroform when hot; 100 parts of water at 19·5° dissolve 0·27 part of the acid. The *barium* (with $3H_2O$), *calcium* (with $4H_2O$), *potassium*, and *silver salts* were prepared; of the first two, 100 parts of water at 19·5° dissolved 0·46 and 1·21 parts respectively. *Ethyl dichloropyromucate* [2 : 3 : 4] was prepared by acting on the acid with alcohol and sulphuric acid; it crystallises from alcohol in large needles melting at 63—64°. When treated with strong aqueous ammonia, it forms *dichloropyromucamide*

[2 : 3 : 4], melting at 176—177°. This dichloropyromucic acid yields mucochloric acid melting at 124—125°, when treated with bromine and water, according to the equation $C_5H_2Cl_2O_3 + 2Br_2 + 2H_2O = C_4H_2Cl_2O_3 + CO_2 + 4HBr$. When oxidised with nitric acid, it yields both mucochloric and dichlormaleic acids, and must therefore have the formula [COOH : Cl_2 = 2 · 3 : 4].

Dichloropyromucic acid [COOH : Cl_2 = 2 : 3 : 5] was obtained by distilling ethyl pyromucate tetrachloride at 16 mm. pressure, and formed the greater part of the fraction boiling between 110° and 113°. Another dichloropyromucic acid of unknown formula, and chloropyromucic acid [2 : 5] were also formed; the separation of these acids was a tedious matter, and reference must be made to the original paper for details. Dichloropyromucic acid [2 : 3 : 5] melts at 155—156°, and sublimes unaltered at a higher temperature. It dissolves in ether, in alcohol, and in hot water, benzene, or chloroform; 100 parts of water at 19·5 dissolve 0·26 part of the acid. The *barium* (with $4H_2O$) and *calcium* (with $3H_2O$) *salts* were prepared; 100 parts of water at 19·5° dissolve 0 42 and 0 22 part respectively of these salts. *Ethyl dichloropyromucate* [2 : 3 : 5] was prepared by the action of ethyl iodide on the silver salt of the acid; it is a heavy liquid, melts at 2—3°, and boils at 116—118° at 16 mm. pressure. When treated with concentrated aqueous ammonia at 100°, it yields *dichloropyromucamide* [2 : 3 : 5] melting at 153—154°. The acid itself is but slowly attacked by nitric acid, but when treated with bromine and water, it yields chlorofumaric acid according to the equation $C_5H_2Cl_2O_3 + 2Br_2 + 3H_2O = C_4H_3ClO_4 + CO_2 + HCl + 4HBr$; hence it must have the constitution [COOH : Cl_2 = 2 : 3 : 5].

C. F. B.

Dependence of Substitution Phenomena on the Atomic or Molecular Weights of certain Atoms or Groups. By F. KEHRMANN (*Ber.*, 23, 130—136; compare *J. pr. Chem.* [2], 40, 257).—The study of substitution phenomena, especially in the aromatic series, shows that the so-called orientation rules are dependent on the atomic or molecular weight of the atom or radicle which dominates or directs the position taken up by the substituting-group, as well as on the law of affinity. Monhydroxy- and monamido-derivatives of benzene, for example, give both ortho- and para-substitution products, but when the molecular weight of the hydroxy- or amido-group is increased by an alkyl or an acid radicle, the para-substitution compound is the principal, or the sole product.

The lack of data makes it impossible as yet to formulate any general law, but in a few cases the observed facts are sufficient to show the influence of atomic or molecular weight. In the substitution of the homologues of benzene with two different alkyls, the entering group takes up with preference the ortho-position to that radicle which has the lower molecular weight. Parethyltoluene, for example, yields a brominated derivative [Me : Br : Et = 1 : 2 : 4]; paracymene gives a sulphonic acid [Me : SO_3H : Br = 1 : 2 : 4], and only small quantities of the isomeride.

In the substitution of dihalogen benzene-derivatives with two different halogens, the greater negative influence of the halogen of lower atomic weight is overcome by the influence due to the atomic weight *per se*. Metachlorobromobenzene, for example, probably gives a mixture of two nitro-compounds, but the substance [$Cl : NO_2 : Br = 1 : 2 : 5$] is formed in larger quantity; parachloriodobenzene gives most probably, the compound [$Cl : NO_2 : I = 1 : 2 : 4$].

F. S. K.

Nitro-derivatives of Metabromotoluene. By W. B. Bentley and W. H. Warren (*Amer. Chem. J.*, **12**, 1—7).—Metabromodinitrotoluene, melting at 103—104°, has been prepared by Grete (*Annalen*, **168**, 258) by acting on metabromotoluene or metabromomononitrotoluene with fuming nitric acid, and more recently by Jackson and Robinson (this vol., p. 377) by the decomposition of ethyl bromodinitrophenylmalonate.

The authors have determined its constitution to be

$$[Me : Br : (NO_2)_2 = 1 : 3 : 4 : 6]$$

from the following reasons:—(1) Grete obtained it from a mononitrometabromotoluene, which he showed must have the NO_2-group in the *ortho*-position, because when reduced it gave a bromotoluidine identical with that obtained by acting on *ortho*acetotoluide with bromine; (2) Nevile and Winther (Trans., 1880, 429) showed that when in the metabromotoluidine mentioned above, the NH_2-group is displaced by bromine, a dibromotoluene is obtained identical with that obtained by v. Richter (this Journal, 1875, 73) from *para*dibromobenzene; the nitrobromotoluene from which it is derived must therefore have the formula [$Me : Br : NO_2 = 1 : 3 : 6$]; (3) the authors heated this nitrobromotoluene with alcoholic ammonia, and converted it into a dinitrometatoluidine melting at 193—194°. The latter substance was then dissolved in a mixture of acetone and alcohol and treated with sulphuric acid and sodium nitrite; dinitrotoluene [$Me : (NO_2)_2 = 1 : 4 : 6$], melting at 71°, was thus obtained. This shows that the two NO_2-groups occupy respectively the *ortho*- and *para*-positions with regard to the methyl, and hence that the metabromodinitrobenzene under consideration must have the formula [$Me : Br : (NO_2)_2 = 1 : 3 : 4 : 6$]. The dinitrotoluidine mentioned above had been previously prepared by Hepp by acting on γ-trinitrotoluene with alcoholic ammonia, and by Kolb from dinitrocresol ether. Hepp's γ-trinitrotoluene must therefore have the formula [$Me : (NO_2)_3 = 1 : 3 : 4 : 6$].

Metabromotrinitrotoluene [$Me : Br : (NO_2)_3 = 1 : 3 : 2 : 4 : 6$] was prepared by treating metabromodinitrotoluene with a mixture of fuming nitric acid and sulphuric acid; the yield was about 60 per cent. of the theoretical. It crystallises from alcohol in small, white needles melting at 143°. It is insoluble in water or light petroleum, nearly insoluble in cold alcohol, sparingly soluble in carbon bisulphide, soluble in ether, methyl alcohol, benzene, chloroform, glacial acetic acid, and acetone. It is not acted on by aqueous soda, or by strong acids, but the bromine is easily removed by the action of alcoholic ammonia or aniline. When treated with alcoholic ammonia, it gives a trinitrotoluidine melting at 136°, identical with that obtained from trinitrometacresol ether by Nölting and Salis (Abstr., 1885, 59), who assigned to it the formula [Me : NH_2 : $(NO_2)_3$ = 1 : 3 : 2 : 4 : 6]. Hence metabromotrinitrotoluene must have the formula given above.

Anilidotrinitrotoluene [Me : NHPh : $(NO_2)_3$ = 1 : 3 : 2 : 4 : 6] was prepared by treating metabromotrinitrotoluene with aniline. It crystallises from a mixture of alcohol and benzene in well-developed, shining, yellow plates melting at 151°. It is insoluble in water or light petroleum, sparingly soluble in ethyl or methyl alcohol, soluble in ether, chloroform, benzene, carbon bisulphide, glacial acetic acid, and acetone. It dissolves in aqueous soda, giving a red solution from which hydrochloric acid precipitates the original substance unaltered. It dissolves in strong sulphuric or strong nitric acid, but not in strong hydrochloric acid. C. F. B.

Derivatives of Paranitrobenzyl Chloride. By A. HAFNER (*Ber.*, **23**, 337—345).—In agreement with Salkowski's results (Abstr., 1889, 1174), the author finds that paranitrobenzyl chloride may be readily converted into paranitrobenzylamine, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH_2$, by Gabriel's method (Abstr., 1887, 1037). It forms a strongly basic oil which absorbs carbonic anhydride from the air, solidifying to white crystals. Its *hydrochloride* crystallises in colourless needles which are soluble in water, and commence to decompose at 220°, whilst the *nitrate* forms citron-yellow, flat needles which decompose at 200°. The *platinochloride* and *picrate* have also been prepared.

Paranitrobenzyl alcohol, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}OH$, is prepared by warming a dilute solution of the hydrochloride with sodium nitrite. It separates in slender, colourless needles which melt at 93°. This compound has been previously prepared by Beilstein and Kuhlberg (*Annalen*, **147**, 343), and by Basler (Abstr., 1884, 310).

Paranitrobenzylacetamide, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NHAc$, is obtained by heating the hydrochloride with acetic anhydride and sodium acetate. It forms colourless needles, soluble in water, and melting at 133°. Amsel and Hofmann (Abstr., 1886, 698) found the melting point to be 125°.

The corresponding *paranitrobenzoylbenzamide*, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NHBz$, formed by the action of benzoic chloride on paranitrobenzylamine hydrochloride, crystallises from alcohol in fascicular groups of needles which melt at 155—156°.

Paranitrobenzylcarbamide, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}NH_2$.—In order to prepare this compound, paranitrobenzylamine hydrochloride is treated with freshly prepared silver cyanate at 100°, the mixture evaporated to dryness, and extracted with alcohol. It separates from the solution in pale-yellow, lance-shaped needles melting at 196—197°. If potassium cyanate be substituted for silver cyanate, no reaction takes place.

By the action of carbon bisulphide on an ethereal solution of paranitrobenzylamine, it is converted into the *dithiocarbamate*,

$$NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH{\cdot}CSSH,NH_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}NO_2,$$

a yellow, crystalline mass which darkens at 120°, melts at 193°, and is converted on boiling with excess of alcohol into hydrogen sulphide and *paradinitrobenzylthiocarbamide*, $CS(NH\cdot C_7H_6\cdot NO_2)_2$. This crystallises in brown, nodular groups of needles which melt with decomposition at 202°, are sparingly soluble in alcohol, and somewhat more readily in acetic acid. Mercuric oxide converts it into the corresponding *paradinitrobenzylcarbamide*, which is also formed by mixing an ethereal solution of paranitrobenzylamine with a solution of carboxyl chloride in benzene. It crystallises from acetic acid in silvery needles which begin to decompose at 224°, and melt completely at 234°. They dissolve in alcohol with difficultly, and are insoluble in ether.

Ethyl paranitrobenzylcarbamate, $NO_2\cdot C_7H_6\cdot NH\cdot COOEt$, is readily produced by mixing an ethereal solution of the amine with ethyl chlorocarbonate. It crystallises from ether in concentrically grouped needles melting at 116—117°.

When paranitrobenzylphthalimide is reduced by tin and hydrochloric acid, it is converted into a base, $C_{15}H_{14}N_2O$, which has the constitution  $C_6H_4\left<\begin{matrix}CO-\\CH_2\end{matrix}\right>N\cdot C_7H_6\cdot NH_2$ or $CH_2\left<\begin{matrix}C_6H_4\\-O-\end{matrix}\right>C{:}N\cdot C_7H_6\cdot NH_2$, and is therefore *paramidobenzylphthalimidine*. It forms colourless plates which have a mother-of-pearl lustre, and melt at 187—188°. A white, crystalline *hydrochloride* was obtained which had the composition $C_{15}H_{14}N_2O,HCl$; but this compound could not be prepared again, a salt being obtained containing a larger quantity of chlorine. The *hydrobromide* has the formula $(C_{15}H_{14}N_2O)_2,3HBr$, is readily soluble in water, and melts with decomposition at 215°. The *platinochloride*, *picrate*, and *stannochloride* have also been prepared and analysed.

Acetylparamidobenzylphthalimidine, $C_8H_6O{:}N\cdot C_7H_6\cdot NHAc$, is obtained by boiling the base with acetic anhydride. It forms a brown, crystalline powder which is readily soluble in acetic acid, less so in alcohol, and melts at 226—227°.

Parahydroxybenzylphthalimidine, $C_8H_6O\cdot N\cdot C_7H_6\cdot OH$, is prepared by the careful addition of dilute solution of sodium nitrite to a solution of paramidobenzylphthalimidine in hydrochloric acid, and gentle warming. It crystallises from water in long, red, sparingly soluble needles, melts at 187—198° (?), and is readily soluble in alcohol, acetic acid, and fixed alkalis, but insoluble in ammonia.

This compound is split up by hydrochloric acid, with formation of a new base and resinous matter. The former appears to have the composition $C_8H_9NO_2$, and forms a platinochloride which crystallises well.

H. G. C.

Orthonitrobenzyl Sulphide. By R. JAHODA (*Monatsh.*, 10, 874—883).—Lellmann and Stickel have shown (Abstr., 1886, 793) that orthobenzylenimide is formed on reduction of orthonitrobenzylic chloride with tin and hydrochloric acid. The author has extended their investigation, using an ammoniacal alcoholic solution of the chloride, and hydrogen sulphide as a reducing agent, and has isolated the following products:—

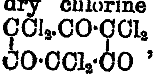
Orthonitrobenzyl sulphide, $S(CH_2\cdot C_6H_4\cdot NO_2)_2$, is insoluble in water, but dissolves readily in hot alcohol, benzene, chloroform, and acetic acid, and crystallises from these solvents in monoclinic, pale-yellow plates, $a : b : c = 0·53623 : 1 : 1·04866$; it melts at 124°. On reduction with tin and hydrochloric acid, the corresponding amidobenzyl sulphide is formed, which is readily soluble in alcohol and ether, melts at 70°, and gives a hydrochloride very soluble in water and alcohol; this decomposes at 200° without previously melting. Orthonitrobenzyl sulphide is slowly attacked when heated in a water-bath with nitric acid of sp. gr. 1·3; but may be more readily oxidised by heating at 100° in sealed tubes with concentrated nitric acid, or by treating a solution in acetic acid with potassium permanganate, the sulphoxide, $SO(CH_2·C_6H_4·NO_2)_2$, being formed. It is readily soluble in alcohol and ether, and on oxidation with a large excess of fuming nitric acid or with permanganate is converted into the sulphone, $SO_2(CH_2·C_6H_4·NO_2)_2$, which crystallises in slender, white, silky needles melting at 200°.

Orthonitrobenzyl bisulphide, $S_2(CH_2·C_6H_4·NO_2)_2$, is readily soluble in warm alcohol, from which it separates on cooling as a seemingly amorphous mass melting at 47°. It may be obtained in the crystalline form by allowing the alcoholic solution to evaporate very slowly, is volatile in a current of steam, and has a very irritating odour. On reduction with tin and hydrochloric acid, it gives a hydrosulphide which produces a red colour with ferric chloride. On treatment with mercuric chloride, the bisulphide forms a heavy white precipitate. G. T. M.

Compounds of Volatile Fatty Acids with Phenols. By M. v. Nencki (*Monatsh.*, **10**, 906—907; compare Perkin, Trans., 1889, 546—549).—The author directs attention to the fact that several compounds of volatile fatty acids with phenols have been previously described by him (Abstr., 1881, 591, 811; 1882, 1201); he now finds that propionic, butyric, and valeric acids, when heated with phenols and zinc chloride, form the corresponding hydroxyketones, which mostly crystallise well, are insoluble, or nearly insoluble in water, and dissolve readily in alcohol.

Phenyl propionate is readily obtained by heating together propionic acid (1 part), phenol (1 part), and zinc chloride (2 parts), for from 5 to 10 minutes. It dissolves in 30 parts of hot, and 2,900 parts of cold water; gives phenol and parahydroxybenzoic acid on fusion with potash, and consequently has the propionyl-group in the para-position (compare Perkin, *loc. cit.*). Phenyl propionate gives with bromine a crystalline dibromo-derivative, and with nitric acid a characteristic nitro-compound. G. T. M.

Action of Chlorine on Phloroglucinol. By T. Zincke and O. Kegel (*Ber.*, **23**, 230—248).—It has been shown in a previous paper (Abstr., 1889, 967) that the final product of the action of dry chlorine on phloroglucinol is hexachlorotriketohexamethylene,



$$\begin{array}{l} CCl_2·CO·CCl_2 \\ | \qquad\qquad\quad | \\ CO·CCl_2·CO \end{array}$$

, and that this is decomposed by water with formation of carbonic anhydride, tetrachloracetone, and dichloracetic acid. It seemed probable that two intermediate products must be formed, having the formulæ $CHCl_2\cdot CO\cdot CCl_2\cdot CO\cdot CCl_2\cdot COOH$ and

$$CHCl_2\cdot CO\cdot CCl_2\cdot CO\cdot CHCl_2.$$

No evidence of the formation of these compounds could be obtained, and the further investigation of the action of water has yielded only negative results. If, however, the compound be treated simultaneously with either chlorine or bromine and water, persubstitution-products of acetylacetone are obtained. The action of ammonia and methyl and ethyl alcohols on the compound has also been investigated.

When hexachlorotriketohexamethylene is dissolved in acetic acid, treated with excess of bromine, and 50—60 times the quantity of ice-cold water gradually added, carbonic anhydride is immediately evolved, and a granular-crystalline mass of *hexachlorodibromacetylacetone*, $CBrCl_2\cdot CO\cdot CCl_2\cdot CO\cdot CBrCl_2$, separates This crystallises from light petroleum in thick, colourless needles or in well-developed prisms which melt at 57—58°; it boils under 25—26 mm. pressure at 200—201°, and is soluble in most of the ordinary solvents with the exception of water. This liquid has no action on the substance in the cold, but, on warming, decomposes it into *tetrachlorobromacetone*, dichlorobromomethane, and carbonic anhydride. The first-named compound is a colourless, refractive oil which has a penetrating odour, boils at 112—114° (30 mm.), and forms a solid hydrate with water. Ammonia converts hexachlorodibromacetylacetone into *dichlorobromacetamide*, $CCl_2Br\cdot CO\cdot NH_2$, which forms large, quadratic tables or thick needles melting at 139°. Aniline gives a mixture of compounds amongst which is dichloracetanilide; whilst with alkali, a mixture of the potassium salts of dichloracetic and dichlorobromacetic acids, together with dichlorobromomethane, appears to be the chief product.

Chlorine and water act on an acetic solution of hexachlorotriketohexamethylene in exactly the same manner as bromine and water, *octochloracetylacetone* being formed. This crystallises from light petroleum in thick needles or prisms, melts at 42—43°, and boils at 165—168° (30—32 mm) It is decomposed by hot water into pentachloracetone, and trichloracetic acid or its decomposition-products, whilst ammonia converts it into trichloracetamide; this crystallises from water in thick, colourless needles or tablets melting at 141°, and is identical with the compound prepared from trichloracetic acid.

The action of the halogen and water on hexachlorotriketohexamethylene may be readily explained if the formation of hypochlorous acid is presupposed, in the manner shown by the following equations:—

I. 
$$\begin{array}{l} CO\cdot CCl_2\cdot CO \\ | \qquad\qquad\quad | \\ CCl_2\cdot CO\cdot CCl_2 \end{array} + ClOH = CCl_3\cdot CO\cdot CCl_2\cdot CO\cdot CCl_2\cdot COOH.$$

II. $$CCl_3\cdot CO\cdot CCl_2\cdot CO\cdot CCl_2\cdot COOH + ClOH = CCl_3\cdot CO\cdot CCl_2\cdot CO\cdot CCl_3 + OH\cdot CO\cdot OH.$$

When ammonia gas is passed into a solution of hexachlorotriketohexamethylene in benzene, the reaction takes place very quietly, *dichloracetamide* being the sole product. This forms hard, prismatic crystals melting at 98—99°.

The action of aniline is much more complicated: dichloracetanilide is the chief product, but monochloracetanilide, a bromacetanilide, aniline hydrobromide, and probably a brominated aniline, are also formed.

Methyl alcohol acts on hexachlorotriketohexamethylene with formation of tetrachloracetone and methyl dichloromalonate. The reaction is represented by the equation

$$\begin{matrix}CCl_2\cdot CO\cdot CCl_2\\ | \qquad\qquad | \\ CO\cdot CCl_2\cdot CO\end{matrix} + 2MeOH = CHCl_2\cdot CO\cdot CHCl_2 + COOMe\cdot CCl_2\cdot COOMe.$$

The latter compound cannot be obtained pure by fractionation, and probably contains a small quantity of a compound analogous to that formed by ethyl alcohol, and described below. With ammonia, however, it yields dichloromalonamide, $CCl_2(CO\cdot NH_2)_2$; this crystallises in rhombic tables, frequently aggregated to broad needles or plates, melts at 203°, and is identical with the compound prepared directly from malonic acid.

Ethyl alcohol acts on hexachlorotriketohexamethylene in a different manner. A smaller quantity of tetrachloracetone is formed, and another compound is obtained boiling at 133—134° under 19—20 mm. pressure, and at 239° with slight decomposition under the ordinary pressure. The constitution of this substance has not yet been proved, but it appears probable that it has the formula

$$CHCl_2\cdot C(OH)(OEt)\cdot CCl_2\cdot COOEt.$$

With caustic potash, it gives dichloracetic acid only, with ammonia dichloracetamide, and with aniline dichloracetanilide, which agrees with the above formula.

H. G. C.

Behaviour of Aniline with Substituted Hydroxybenzoic Acids at a High Temperature. By R. Seifert (*Ber.*, **23**, 118—120).—Remarks on Limpricht's paper (this vol., p. 158). The compounds obtained by Limpricht and described as new substances have been previously prepared. Limpricht's phenylimidophenol, diacetylphenylimidophenol, and diphenylimidophenylene are the well-known compounds phenylparamidophenol, diacetylphenylparamidophenol, and diphenylparaphenylenediamine respectively. The reaction studied by Limpricht probably takes places in two phases, both of which, when taken singly, are well-known reactions.

F. S. K.

Formation of Triphenodioxazine by the Oxidation of Orthamidophenol. By P. Seidel (*Ber.*, **23**, 182—189).—The garnet-red dye obtained by G. Fischer (Abstr., 1879, 924) by the oxidation of orthamidophenol hydrochloride in aqueous solution with potassium ferricyanide, is best prepared by passing a rapid current of air for many days through the hydrochloride dissolved in 30—40 times its weight of water, and heated in a reflux apparatus on a water-bath; a brownish-red, granular precipitate is obtained at first, but this becomes darker in colour and less pure towards the end of the reaction. The dye can only be purified by careful sublimation, and has the composition $C_{18}H_{10}N_2O_2$, being regarded by the author as *triphenodioxazine*,  $C_6H_4{<}\substack{N\\O}{>}C_6H_2{<}\substack{N\\O}{>}C_6H_4$, a view which derives confirmation from the fact that it can be prepared synthetically by carefully heating a mixture of anhydrous symmetrical diamidoresorcinol sulphate (1 mol. prop.) with orthamidophenol (2 mol. prop.) to its fusing point. The dye is almost insoluble in water, alcohol, ether, acetone, carbon bisulphide, pyridine, benzene, &c., but gives with all these solvents, except water, solutions which show a beautiful green fluorescence. From xylene (solubility 1 in 1000 at 140°), nitrobenzene (solubility 1 in 100 at 200°), aniline, azobenzene, naphthalene, &c., it crystallises in dark-red forms showing a bluish lustre. When rapidly heated, it can be fused; at 250° it begins to sublime, and at temperatures above 300° is converted into a beautiful, pure green vapour. The dye is not affected by prolonged boiling with concentrated aqueous or alcoholic alkalis, does not form an acetyl-derivative when heated with acetic anhydride, is not oxidised by chlorine or a hot solution of chromic acid in acetic acid, but yields orthamidophenol on reduction with concentrated hydriodic acid at 170°. When warmed with concentrated sulphuric acid, it is converted into a sulphonic acid, which forms sparingly soluble, cantharides-green potassium and sodium salts, whilst with concentrated nitric acid in acetic acid solution it yields a sparingly soluble nitro-derivative crystallising in brown, bronze-lustred crystals. The *hydrochloride*, $C_{18}H_{10}N_2O_2,2HCl$, crystallises in beautiful, dark cantharides-green needles, and decomposes on treatment with water. The *leuco*-base, $C_{18}H_{12}N_2O_2$, is formed when the dye is heated at 120° with a solution of phenylhydrazine in xylene. It crystallises in colourless scales, is sparingly soluble in the ordinary solvents, and when heated either alone at 250—300°, or in solution in nitrobenzene, aniline, or pyridine, is reconverted into the red dye. Its *diacetyl*-derivative, $C_{18}H_{10}N_2O_2Ac_2$, crystallises in colourless scales, melts at 295°, decomposes at higher temperatures with the production of the red dye, and is somewhat more soluble in nitrobenzene, aniline, pyridine, &c., than the leuco-base. W. P. W.

Formation of Alkyl-derivatives of Amides. By J. TAFEL and C. ENOCH (*Ber.*, **23**, 103 108).—*Silver benzamide*, C_7H_6NOAg, prepared by dissolving benzamide (1 mol.) and silver nitrate (1 mol.) in warm water, and gradually adding the calculated quantity of soda, is a colourless, semi-crystalline powder, which is decomposed by warm water. When treated with ethyl iodide in the cold, it yields benzimido ethyl ether, NH:CPh·OEt, identical with the compound obtained by Pinner (Abstr., 1883, 1089) from benzonitrile and alcoholic hydrogen chloride. When silver benzamide is covered with ether, and treated with hydrogen chloride or hydrogen sulphide, it is reconverted into benzamide.

Anisamide melts at 161—162°, and not at 137—138°, as stated by Henry. The *silver*-derivative has the composition $C_8H_8O_2NAg$.

Anisimido ethyl ether, $OEt{\cdot}C(NH){\cdot}C_6H_4{\cdot}OMe$, prepared by treating silver anisamide with ethyl iodide at 40°, crystallises in long, colourless needles, melts above 30°, and boils without decomposition under greatly reduced pressure. It is soluble in alcohol and ether, and is decomposed by boiling water. The *hydrochloride*, $C_{10}H_{13}O_2N,HCl$, melts at 130° with decomposition, and is soluble in water and alcohol, but insoluble in ether. The *oxalate*, $C_{10}H_{13}O_2N,C_2H_2O_4$, crystallises in colourless needles, melts at 136°, and is soluble in water and alcohol, but insoluble in ether. The *platinochloride*, $(C_{10}H_{13}O_2N)_2,H_2PtCl_6$, crystallises in yellow needles, and is only sparingly soluble in hot alcohol, but soluble in, and partially decomposed by water.

Anisamidine hydrochloride, $NH_2 \cdot C(NH) \cdot C_6H_4 \cdot OMe,HCl$, prepared by treating finely divided anisimido ethyl ether hydrochloride with alcoholic ammonia at 30°, separates from alcohol in colourless crystals, begins to decompose at about 220°, and is readily soluble in water and alcohol, but only sparingly in ether. The free *base*, $C_8H_{10}ON_2$, is a crystalline, hygroscopic compound, very readily soluble in alcohol, but insoluble in ether; the aqueous solution has a strongly alkaline reaction. The *platinochloride*, $(C_8H_{10}ON_2)_2,H_2PtCl_6$, crystallises from hot water in yellow needles. F. S. K.

Identity of Hoffmann's Dibenzylphosphine with Tribenzylphosphine Oxide, &c. By E. A. Letts and R. F. Blake (*Proc. Roy. Soc. Edin.*, **16**, 193—200).—During a previous investigation, Letts found reason to believe that the A. W. Hofmann's dibenzylphosphine (this Journal, 1872, 423) was, in reality, an oxide of tribenzylphosphine, $P(C_7H_7)_3O$. He now finds the melting point to be 215—215·5° (corr.) when recrystallised from alcohol. To estimate the phosphorus, a new method has been devised, the usual processes not being trustworthy when applied to phosphines. A combustion is made with pure copper oxide, and afterwards the contents of the combustion-tube dissolved in nitric acid, and the phosphorus precipitated with ammonium molybdate; figures are given which show the great differences in the percentages as obtained by various processes.

The bromide, chloride, iodide, hydriodide, hydrobromide, platinochloride, nitro-compound, and a double salt with zinc iodide, have been prepared both of Hofmann's compound and of tribenzylphosphine oxide, and in all cases the results were identical. Dibenzylphosphinic acid (m. p. 192°) was also produced by the action of fused potash on both compounds. It seemed probable that the production of the oxide in Hofmann's sealed tube reaction was due to the oxidation of tribenzylphosphine; therefore, the authors sought for the tertiary product in the original product. After much trouble, they isolated a liquid which grew hot on exposure to the air with production both of tribenzylphosphine oxide and of dibenzylphosphinic acid, which was precipitated by hydriodic acid, forming solid compounds, and which in contact with sulphur gives rise to a crystalline compound, believed to be tribenzylphosphine sulphide; the liquid also acts energetically on crystallised benzyl iodide, forming tetrabenzylphosphonium iodide, and is probably a mixture of secondary and tertiary phosphines. From this liquid two solids have been obtained, the one, almost insoluble in ether, having the formula $(C_7H_7)PO_2$, or $(C_7H_7)_3PS$. The second compound was undoubtedly tribenzylphosphine, and crystallises easily from alcohol, and unites with sulphur and oxygen at the ordinary temperature.

The authors, therefore, consider that in Hofmann's sealed tube reaction hydrogen phosphide acts on benzyl chloride as ammonia does on an alkyl iodide:—(1) $C_7H_7Cl + PH_3 = C_7H_7{\cdot}PH_2,HCl$; (2) $2C_7H_7Cl + PH_3 = (C_7H_7)_2PH,HCl + HCl$; (3) $3C_7H_7Cl + PH_3 = (C_7H_7)_3PHCl + 2HCl$; (4) $4C_7H_7Cl + PH_3 = (C_7H_7)_4PCl + 3HCl$.

It is probable that Hofmann's "dibenzylphosphine" is a product of the reaction of potash on tetrabenzylphosphonium chloride or iodide, an action which Lillie has proved possible—

$$(C_7H_7)_4PCl + KHO = (C_7H_7)_3PO + KCl + C_7H_8.$$

All the possible oxidised derivatives have been isolated from the products of Hofmann's reaction, and they are: benzylphosphinous acid, benzylphosphinic acid, dibenzylphosphinic acid, and tribenzylphosphine oxide.

When benzylphosphine acts on benzyl iodide at the ordinary temperature, the secondary, tertiary, and quaternary compounds are formed.

E. W. P.

Action of Hydroxylamine Hydrochloride on Paradihydroxyparaquinones. By F. KEHRMANN and W. TIESLER (*J. pr. Chem.* [2], **41**, 87—91).—*Chlorhydroxyamidohydroxyquinone oxime*,

$$OH{\cdot}C_6HClO(NOH){\cdot}NH{\cdot}OH,$$

is formed when finely-powdered chlorodihydroxyquinone is left in contact with water and hydroxylamine hydrochloride for several days; the quinone particles change into nearly white, horn-shaped crystals, which decompose without melting, and are almost insoluble in the usual solvents, but soluble in alkalis. When reduced with stannous chloride and hydrochloric acid, it is converted into chlorodiamidoresorcinol. Nitric acid of sp. gr. 1·30 converts it into chlorodinitroresorcinol (m. p. 181°).

A. G. B.

Action of Ethylmalonic Chloride on Ethylbenzene in presence of Aluminium Chloride. By A. BÉHAL and V. AUGER (*Compt. rend.*, **110**, 194—197).—The action of ethylmalonic chloride (45 grams) on ethylbenzene (200 grams) in presence of aluminium chloride (100 grams) yields metadiethylbenzene, which on oxidation is converted into isophthalic acid; sp. gr. at 0° = 0·8812, refractive index at 14° = 1·472. At the same time, a diketone, diethyl-benzoyl ethylmethane, $CHEt(CO{\cdot}C_6H_4Et)_2$ is formed. It boils between 270° and 275° in a vacuum, melts at 88—89°, and crystallises readily from alcohol in needles grouped in nodules. When treated with alkalis, it splits up into paraethylbenzoic acid and ethylphenyl propyl ketone, $PrCO{\cdot}C_6H_4Et$, which boils at 150° under a pressure of 20 mm.; sp. gr. at 0° = 0·9800, refractive index at 14° = 1·499.

C. H. B.

Occurrence of Isocinnamic Acid in the Alkaloïds of Cocaine. By C. LIEBERMANN (*Ber.*, 23, 141—156).—The decomposition-products of the alkaloïds occurring together with cocaine contain isocinnamic acid, which can be isolated in the following manner:—The crude product obtained by decomposing the alkaloids (38 kilos.) with hydrochloric acid is filtered from the solid acids, and the filtrate extracted with ether; on evaporating the ether there remains a semi-solid mass (700—800 grams). This residue is filtered to separate the solid acids, which consist principally of cinnamic acid, together with small quantities of α- and β-truxillic acids and benzoic acid, the oily filtrate is kept for some days at 0°, and again filtered from the crystals which are deposited. The filtrate (300—400 grams) is dissolved in cold sodium carbonate, the solution shaken with ether to remove ethereal salts which may be present, and the acids reprecipitated. The acid mixture is then extracted with warm light petroleum, and the solution evaporated. The crude isocinnamic acid (about 120 grams), obtained in this way in a crystalline condition, is further purified and separated from cinnamic acid by repeatedly extracting it with small quantities of light petroleum, in which cinnamic acid is only very sparingly (0·095 in 100), isocinnamic acid, on the other hand, readily (17 in 100) soluble. It is then converted into the calcium salt, and the latter extracted with water, in which calcium cinnamate is only very sparingly (1 in 430), but calcium isocinnamate readily (1 in 8) soluble. These two processes are repeated many times until the calcium salt obtained is completely soluble in a small quantity of cold water. The salt is then decomposed with hydrochloric acid, and the acid, which is precipitated as an oil, extracted with ether, and recrystallised from light petroleum.

Isocinnamic acid, $C_9H_8O_2$, separates from cold light petroleum in transparent crystals melting at 45—47°; if the acid be coarsely powdered and treated with a small quantity of cold light petroleum in such a way that the more compact crystals remain undissolved, the latter melt at 57°, which is the true melting point of the acid. It is very readily soluble in light petroleum, carbon bisulphide, alcohol, and all ordinary solvents, except water, whereas cinnamic acid and atropic acid are only sparingly soluble in light petroleum and carbon bisulphide. Molecular weight determinations by Raoult's method, in glacial acetic acid solution, gave results in accordance with the molecular formula given above; on evaporating the acetic acid solution on the water-bath, the isocinnamic acid was deposited unchanged. It is immediately oxidised by potassium permanganate in cold sodium carbonate solution, with formation of benzaldehyde, but it does not reduce Fehling's solution, and it is not changed by boiling alcoholic potash. Crystalline measurements showed that this acid is not identical either with cinnamic acid or with atropic acid.

The *calcium* salt, $(C_9H_7O_2)_2Ca + 3H_2O$, separates from cold water in crystals which effloresce on exposure to the air; the salt then contains 3 mols. H_2O, which are expelled at 125°. The *barium* salt is not quite so readily soluble in water as the calcium salt. The *silver* salt, $C_9H_7O_2Ag$, is colourless, and undergoes no change on exposure to light. In aqueous solutions of the ammonium salt, cobalt, manganese, and zinc acetate produce no precipitation, but copper acetate gives a green, and mercuric nitrate a colourless precipitate. The *methyl* salt is a colourless liquid.

Isocinnamic acid begins to boil at 265°, but the boiling point gradually rises to 300°. The distillate consists principally of cinnamic acid (90 per cent.), but on prolonged boiling cinnamene is also produced. Isocinnamic acid is almost quantitatively converted into cinnamic acid when it is boiled for about a minute under the ordinary pressure.

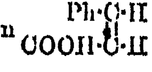
Hydrocinnamic acid (m. p. 48°) is obtained when isocinnamic acid is dissolved in soda, and the solution treated in the cold with 3 per sodium amalgam; the yield is almost quantitative. When isocinnamic acid is treated with bromine in cold carbon bisulphide solution, it is converted into phenyl-$\alpha\beta$-bromopropionic acid (m. p. 196°); the yield is on the average 45—50 per cent. of the acid employed. Methyl isocinnamate, under the same conditions, is converted into methyl phenyl-$\alpha\beta$-bromopropionate (m. p. 117°). Isocinnamic acid is not changed when treated with iodine in cold carbon bisulphide solution, but on warming it is converted into cinnamic acid.

Isocinnamic acid dissolves almost completely in hydrobromic acid, and in about 24 hours it is completely converted into phenyl-β-bromopropionic acid (m. p. 137°); it is completely converted into phenyl-β-chloropropionic acid (m. p. 126°) when it is dissolved in a saturated solution of hydrogen chloride in glacial acetic acid and the solution kept for three to four days, whereas cinnamic acid under the same conditions is only very partially converted into the same additive compound.

Isocinnamic acid and cinnamic acid both require the same quantity (4 mols.) of potassium permanganate for complete oxidation to benzoic acid.

Isocinnamic acid occurs in storax; from about 2 kilos. of crude cinnamic acid from this source, the author isolated about 2 grams of pure isocinnamic acid by the method described above.

The relationship existing between cinnamic acid and isocinnamic acid can be explained by accepting Wislicenus' hypothesis; in accordance with this view, the acids would have the constitution



$$\begin{array}{c}\mathrm{Ph{\cdot}C{\cdot}H}\\ \|\\ \mathrm{COOH{\cdot}C{\cdot}H}\end{array}$$

and

$$\begin{array}{c}\mathrm{Ph{\cdot}C{\cdot}H}\\ \|\\ \mathrm{H{\cdot}C{\cdot}COOH}\end{array}$$

respectively.

The behaviour of isocinnamic acid is in complete accordance with the view that it is a labile form of cinnamic acid. F. S. K.

Benzallevulinic Acid and its Dibromide. By E. ERLENMEYER, Jun. (*Ber.*, **23**, 74—76).—This acid is best prepared as follows:—11·6 grams of levulinic acid is dissolved in 200 grams of water, a solution of 8 grams of sodium hydroxide in 160 grams of water added, and the whole mixed with 10·2 grams of benzaldehyde and 100 grams of alcohol. The mixture is heated on the water-bath for about 20 minutes, then cooled, and the calculated quantity of hydrochloric acid added. The yield is about 50 per cent. of the theoretical. The acid crystallises in quadratic scales or needles. *Benzallevulinic acid dibromide*, $C_{12}H_{12}O_3Br_2$, is readily formed when an acetic acid solution of bromine is added to an acetic acid solution of the acid. It crystallises in white prisms, which turn brown at about 150°, melts with decomposition at 153°, and dissolves in concentrated sulphuric acid with a yellow coloration which changes to bluish-green on warming.

L. T. T.

Coumarone in Coal Tar. By G. KRAEMER and A. SPILKER (*Ber.*, 23, 78—83).—The authors have isolated considerable quantities of coumarone from coal tar. The fraction boiling between 168 and 175° was purified with caustic alkalis and by acids, and then treated gradually with bromine, care being taken not to let the temperature rise above 0°. *Coumarone dibromide*, $C_8H_6Br_2O$, is thus formed, and at 5° to 10° crystallises out in large, prismatic crystals melting at 88—89°. A kilo. of the tar fraction yields about 80 grams of coumarone dibromide. It is easily soluble in chloroform. When heated with alcoholic potash, *bromocoumarone*, C_8H_5BrO, is formed. This crystallises in prisms, melts at 39°, boils at 219—220°, and is volatile in steam. It is insoluble in water and dilute alkalis, soluble in organic solvents. When treated in alcoholic solution with sodium amalgam, coumarone, C_8H_6O, is gradually formed. This boils at 758 mm. pressure at 170—171° (uncorr.), and has a sp. gr. of 1·089 at 150°. It is resinified by concentrated sulphuric acid. The vapour-density determination by V. Meyer's method gave 118·4 (theory 118°). The above properties differ slightly from some of those given by Fittig, who probably only had very small quantities of the substance.

Coumarone dichloride, $C_8H_6Cl_2O$, was obtained by passing chlorine into a solution of coumarone in dry ether. It is a yellowish oil, boils at 245—248° with slight decomposition, and is volatile in steam, but even then slight separation of hydrogen chloride occurs. When treated with alcoholic potash, it yields *chlorocoumarone*, C_8H_5ClO, which crystallises in glistening prisms, melts at 74—75°, boils at 215—217°, and is volatile in steam.

No iodo-derivatives could be obtained, and coumarone was found to be very stable, distilling almost unchanged even when dropped on to fused potash, and being only very slightly decomposed when its vapour is passed through a red-hot tube. Oxidising agents cause complete decomposition. Strong mineral acids convert it into *paracoumarone*, a resinous substance easily soluble in ether, benzene, and chloroform, sparingly in alcohol, its solutions forming good varnishes owing to its stability towards acids and alkalis. A second solid and insoluble polymeride seems to be formed at the same time, and both seem to yield sulphonic acids when heated with strong sulphuric acid.

L. T. T.

Action of Benzamidine on Ethyl Acetylmalonate. By A. PINNER (*Ber.*, 23, 161—166).—*Benzamidine benzamidylacetylmalonate*, $NH{:}CPh{\cdot}NH{\cdot}CO{\cdot}CHAc{\cdot}COOH,NH_2{\cdot}CPh{:}NH$, separates in colourless crystals, when a mixture of benzamidine hydrochloride (2 mols.), a concentrated solution of potassium carbonate (1 mol.), and ethyl acetylmalonate (1 mol.) is kept for some time at the ordinary temperature (compare this vol., p. 69). The crystals are washed with water, alcohol, and ether consecutively, and then repeatedly recrystallised from acetone in order to remove the ethyl phenylmethylhydroxypyrimidinecarboxylate which is also produced in the reaction. The pure product, when dried in the air, melts at 71°, and contains 1 mol. H_2O, which it loses over sulphuric acid. When heated gradually to 200°, it is converted into diphenylhydroxykyanidine with evolution of ammonia, carbonic anhydride, and acetone.

Diphenylhydroxykyanidine,  $OH{\cdot}C{<}{\substack{N{\cdot}CPh\\N{:}CPh}}{>}N$, crystallises from alcohol or pyridine in colourless needles, melts at 289°, and is very sparingly soluble in alcohol and insoluble in water. It dissolves moderately easily in dilute soda, but is reprecipitated on the addition of concentrated soda or acids; it is also soluble in concentrated hydrochloric acid, but is reprecipitated on adding water.

F. S. K.

Action of Ethyl Sodiomalonate on Tribromotrinitrobenzene.

By C. L. JACKSON and G. D. MOORE (*Amer. Chem. J.*, **12**, 7—21).—Tribromotrinitrobenzene was prepared by treating 20 grams of tribromodinitrobenzene with 500 c.c. of nitric acid of sp. gr. 1·52 and 200 c.c. of fuming sulphuric acid; a much better yield (40 per cent.) was obtained in this way than with the proportions recommended in an earlier paper. This tribromotrinitrobenzene was dissolved in benzene and treated with a slight excess of ethyl sodiomalonate; the liquid became dark-red in colour. It was allowed to remain for two or three days, and then treated with water and acidified with dilute sulphuric acid; this decomposed the red salt and liberated ethyl bromotrinitrophenylmalonate, which was extracted from the solution by means of ether and recrystallised from hot alcohol. The yield varied from 50 to 60 per cent.

Ethyl bromotrinitrophenylmalonate,

$$C_6HBr(NO_2)_3{\cdot}CH(COOEt)_2\ [= 3 : 2 : 4 : 6 : 1],$$

crystallises in slender, white needles arranged in radiating groups, and melts at 104—105°, becoming red and giving off gas at 160°. It is but slightly soluble in water, light petroleum, and ether, and in cold ethyl or methyl alcohol, but dissolves freely in these last two substances when hot, as also in benzene, carbon bisulphide, glacial acetic acid, chloroform, and acetone. It dissolves in potash, soda, or ammonia, giving red solutions, and the solution in ammonia forms reddish precipitates with the salts of many metals. The *sodium*-derivative, $C_6HBr(NO_2)_3{\cdot}CNa(COOEt)_2$, was prepared, and also a *copper*-derivative, which was found to explode when heated. All the salts seem to decompose rather easily. The ethereal salt itself, when boiled with dilute sulphuric acid, loses 2 mols. of carbonic anhydride, and forms a bromotrinitrotoluene shown by Bentley and Warren (this vol. p. 484) to have the formula $[Me : Br : (NO_2)_3 = 1 : 3 : 2 : 4 : 6]$. This, as well as its formation from symmetrical tribromotrinitrobenzene, shows that ethyl bromotrinitrophenylmalonate has the formula assigned to it above. The action of nitric acid on it gives rise to at least two different substances, but these have not yet been fully investigated.

It is shown that the action of ethyl sodiomalonate on tribromotrinitrobenzene is represented by the following equations, all the bromine being eliminated as sodium bromide, and ethyl acetylenetetracarboxylate being formed:—

$$\begin{aligned}
&C_6Br_3(NO_2)_3 + 3CHNa(COOEt)_2,\\
&\quad = C_6Br_2(NO_2)_3{\cdot}CH(COOEt)_2 + NaBr + 2CHNa(COOEt)_2\\
&\quad = C_6Br_2(NO_2)_3{\cdot}CNa(COOEt)_2 + CH_2(COOEt)_2 + CHNa(COOEt)_2 + NaBr\\
&\quad = C_6HBr(NO_2)_3{\cdot}CNa(COOEt)_2 + CHBr(COOEt)_2 + CHNa(COOEt)_2 + NaBr\\
&\quad = C_6HBr(NO_2)_3{\cdot}CNa(COOEt)_2 + C_2H_2(COOEt)_4 + 2NaBr.
\end{aligned}$$

Ethyl trinitrophenylenedimalonate, $C_6H(NO_2)_3[CH(COOEt)_2]_2$, is formed by the further action of ethyl sodiomalonate on ethyl bromotrinitrophenylmalonate. It crystallises in long prisms melting at 123°, and resembling ethyl bromotrinitromalonate in solubility. It dissolves slightly in potash and soda, readily in ammonia, is not acted on by sulphuric or hydrochloric acid, but with nitric acid behaves in a similar manner to the bromotrinitrophenylmalonate.

C. F. B.

Metaxylylmalonic Acid. By O. Poppe (*Ber.*, 23, 108—113).—*Ethyl metaxylylmalonate*, $C_6H_4Me{\cdot}CH_2{\cdot}CH(COOEt)_2$, is obtained, together with ethyl metadixylylmalonate, when metaxylyl bromide is treated with ethyl sodiomalonate; it is a thick, colourless oil boiling at 320° (250°; 150 mm.). The corresponding *methyl salt*,

$$C_6H_4Me{\cdot}CH_2{\cdot}CH(COOMe)_2,$$

is a colourless liquid boiling at about 300°.

Metaxylylmalonic acid, $C_{11}H_{12}O_4$, separates from a mixture of benzene and light petroleum in rhombic crystals, melts at 133° with evolution of carbonic anhydride, and is soluble in benzene, ether, and chloroform, but only sparingly in water and light petroleum. The *potassium* salt crystallises in slender needles, and is very hygroscopic. The *silver* salt and the *lead* salt are colourless, the *copper* salt is green.

Ethyl metaxylylmalonamate, $C_6H_4Me{\cdot}CH_2{\cdot}CH(CONH_2){\cdot}COOEt$, prepared by heating ethyl metaxylylmalonate with alcoholic ammonia at 150°, crystallises from alcohol or benzene in microscopic needles, and melts at 184—186°; when treated with water, it is converted into the *ethyl ammonium* salt, $C_{13}H_{19}O_4N$, which crystallises from alcohol in needles and melts at 77°.

Ethyl metaxylylmalonmethylamate,

$$C_6H_4Me{\cdot}CH_2{\cdot}CH(CO{\cdot}NHMe){\cdot}COOEt,$$

prepared by heating ethyl metaxylylmalonate with a 33 per cent. solution of methylamine at 150°, crystallises from alcohol in microscopic needles, and melts at 118—120°.

Metaxylylmalonanilide, $C_6H_4Me\cdot CH_2\cdot CH(CO\cdot NHPh)_2$, crystallises from benzene or alcohol in needles melting at 188°.

Metaxylylacetic acid, $C_6H_4Me\cdot CH_2\cdot CH_2\cdot COOH$, is formed when metaxylylmalonic acid is heated at 133°; it could not be obtained in a crystalline condition. The *silver* salt has the composition $C_{10}H_{11}O_2Ag$.

Ethyl metaxylylchloromalonate, $C_6H_4Me\cdot CH_2\cdot CCl(COOEt)_2$, prepared by treating ethyl sodiochloromalonate with xylyl bromide, or by treating ethyl xylylmalonate with chlorine at about 200°, is a colourless liquid boiling at 260° (150 mm.).

Metaxylyltartronic acid, $C_6H_4Me\cdot CH_2\cdot C(OH)(COOH)_2$, is formed when the preceding compound is boiled with alcoholic potash; the acid cannot be isolated, as it immediately decomposes with evolution of carbonic anhydride. The *calcium* salt has the composition $C_{11}H_{10}O_5Ca$.

Metaxylylglycollic acid, $C_6H_4Me\cdot CH_2\cdot CH(OH)\cdot COOH$, is a syrup; the *calcium* salt has the composition $(C_{10}H_{11}O_3)_2Ca$. F. S. K.

Experiments to Determine the Constitution of Tautomeric Compounds. By H. GOLDSCHMIDT and A. MEISSLER (*Ber.*, 23, 253—280).—The methods hitherto employed for determining the constitution of tautomeric compounds do not, as is well known, give trustworthy results, because the reagents employed in forming the alkyl, acetyl, or metallic derivative may themselves bring about intramolecular change. The phenomena of intramolecular change can be explained in most, if not in all cases, by assuming that in the reactions of tautomeric compounds which take place under the influence of electrolytes, the intramolecular change is brought about by the free ions. If, then, the constitution of a tautomeric compound is to be ascertained experimentally, solutions of electrolytes must be excluded.

Starting from this point of view, the authors have studied the action of phenylcarbimide on a number of tautomeric compounds; in their opinion, the presence or absence of hydroxyl-groups is shown by the formation or non-formation of a carbanilido-derivative.

Ethyl succinylsuccinate and ethyl quinonedihydrodicarboxylate do not react with phenylcarbimide under the most varied conditions, a fact which seems to show that both compounds are diketo- and not hydroxy-derivatives.

Ethyl dicarbanilidodichlorohydroquinonedicarboxylate,

$$C_6Cl_2(O\cdot CO\cdot NHPh)_2(COOEt)_2,$$

is formed in small quantity when ethyl dichlorohydroquinonedicarboxylate (1 mol.) is heated for several hours with phenylcarbimide (2 mols.) and a little benzene at 150°. In absence of benzene the reaction takes place at 100°, but in presence of a large quantity of benzene no reaction takes place even at 200°, as the carbanilido-compound is decomposed by benzene at this temperature. It is a colourless, crystalline powder, melts at 195°, and is decomposed by soda, yielding aniline and the hydrate of dichlorohydroquinonedicarboxylic acid. The formation of this carbanilido-derivative shows that ethyl dichlorohydroquinonedicarboxylate is not a quinone, but a hydroxy-derivative of benzene; its formation in benzene solution proves that Hantzsch and Herrmann's assumption (compare *Ber.*, **20**, 2801), that the green solutions contain a tautomeric quinone-derivative, is not correct.

Ethyl dicarbanilidodibromohydroquinonedicarboxylate,

$$C_6Br_2(O\cdot CO\cdot NHPh)_2(COOEt)_2,$$

is formed in small quantities when ethyl dibromohydroquinonedicarboxylate is heated at 140° with phenylcarbimide and a little benzene or light petroleum; it is a colourless, crystalline compound melting at about 200°. The conditions of formation are the same as in the case of the corresponding chloro-compound, as this carbanilido-derivative is also decomposed by benzene at 200°.

Phenylcarbimide has no action on ethyl dihydroxyquinonedicarboxylate (Hantzsch and Löwy, Abstr., 1886, 354) or on dihydroxyquinone.

Ethyl tetracarbanilidotetrahydroxyterephthalate,

$$C(O\cdot CO\cdot NHPh)_4(COOEt)_2,$$

is obtained when ethyl tetrahydroxyterephthalate is heated at 170° with phenylcarbimide and a little chloroform. It is an orange, crystalline powder, melts at 258—260°, and is insoluble in most ordinary solvents; it is decomposed by boiling soda. Attempts to prepare a dicarbanilido-derivative were unsuccessful. This behaviour shows that ethyl tetrahydroxyterephthalate contains four hydroxy-groups, all of which react with the same readiness.

Tricarbanilidophloroglucinol, $C_6H_3(O\cdot CO\cdot NHPh)_3$, is obtained when phloroglucinol is heated at 200° with phenylcarbimide and a little benzene. It separates from a mixture of benzene and light petroleum as a yellowish powder, and melts at 123°.

Ethyl tricarbanilidophloroglucinoltricarboxylate,

$$C(O\cdot CO\cdot NHPh)_3(COOEt)_3,$$

obtained from ethyl phloroglucinoltricarboxylate in like manner, separates from a mixture of benzene and light petroleum as a yellowish powder, begins to decompose at 155° and melts at 195°; it is decomposed by boiling soda, yielding phloroglucinol, aniline, and carbonic anhydride.

When ethyl mercaptan is heated with phenylcarbimide at 100°, ethyl phenylthiocarbamate, $NHPh\cdot CO\cdot SEt$, is formed, a fact which shows that the hydrosulphuryl-group behaves like the hydroxyl-group with phenylcarbimide.

Diphenylcarbamide and phenylthiocarbimide are formed when thiocarbanilide is heated at 180° for several hours with phenylcarbimide and a little benzene. Thiocarbanilide and paratolylcarbimide, under the same conditions, yield paratolylphenylcarbamide and phenylthiocarbimide. These experiments show that thiocarbanilide does not combine with phenylcarbimide, from which fact it may be assumed that thiocarbanilide has the constitution $CS(NHPh)_2$.

When $\alpha\alpha'$-lutidone is heated with phenylcarbimide and a little benzene at 150°, carbonic anhydride is evolved, and phenylamidolutidine, identical with the compound obtained by Conrad and Epstein (Abstr., 1887, 501) from γ-chlorolutidine and aniline, is formed.

α-Quinolyldiphenylcarbamide, $C_{22}H_{17}N_3O$, is formed in small quantities with evolution of carbonic anhydride, when carbostyril is heated at 220° with phenylcarbimide and a little benzene. It crystallises from benzene in small, colourless needles, and melts at 150°. It is decomposed by concentrated hydrochloric acid at 200° yielding carbonic anhydride, aniline, and phenylquinolineamine, identical with the compound obtained by Friedländer and Weinberg (Abstr., 1885, 989) from α-chloroquinoline and aniline. These experiments seem to show that lutidone and carbostyril are analogously constituted.

Sulphoncyanamides. By P. HEBENSTREIT (*J. pr. Chem.* [2], **41**, 97—120).—*Sodium benzenesulphoncyanamide*, $C_6H_5\cdot SO_2\cdot NNa\cdot CN$, is made by acting on benzenesulphonic chloride with sodium cyanamide; the latter is suspended in acetone (7—8 parts), and the chloride added by degrees, the reaction being completed on the water-bath, and the new substance afterwards precipitated by ether; the yield was 54 grams, theoretically 61 grams. It forms small, white needles (with 1 mol. H_2O) which decompose at 140°, and are soluble in alcohol and water, but not in benzene. It is also obtained by the action of cyanamide on benzenesulphonic chloride in aqueous soda solution, but not by the action of cyanamide and sodium ethoxide on benzenesulphonic chloride. The *silver* compound, the *barium* compound (with 1 mol. H_2O), and the *lead* compound (with 2 mols. H_2O) are described. *Benzenesulphoncyanamide*, $SO_2Ph\cdot NH\cdot CN$, obtained by the action of hydrochloric acid on the silver compound, crystallises in needles (with 1 mol. H_2O) which melt with decomposition at 158°, are sparingly soluble in cold water, chloroform, and benzene, insoluble in ether, and soluble in alcohol and acetone; the aqueous solution is strongly acid.

Sodium-α-naphthalenesulphoncyanamide, $C_{10}H_7{}^{\alpha}\cdot SO_2\cdot NNa\cdot CN$, is prepared by suspending sodium cyanamide (8 grams) in ether (200 c.c.), adding α-naphthalenesulphonic chloride (14 grams), and heating on the water-bath for 24 hours, when the new substance remains as a white powder. It crystallises in lustrous, anhydrous leaflets, sparingly soluble in hot alcohol, easily soluble in acetone, and insoluble in ether. The *silver*, *lead*, and *barium* compounds have been obtained. *α-Naphthalenesulphoncyanamide*, obtained by decomposing the silver compound with hydrochloric acid, or the sodium compound with sulphuric acid, crystallises in white needles (with 1 mol. H_2O), decomposes at 115°, and is sparingly soluble in water to an acid solution, more freely soluble in alcohol, and insoluble in ether.

Sodium β-naphthalenesulphoncyanamide is similarly obtained; it crystallises in brilliant leaflets (with 2 mols. H_2O) of the same solubility as the α-compound. The *silver* compound, *barium* compound (with 2 mols. H_2O), and *lead* compound are described. *β-Naphthalenesulphoncyanamide* crystallises (with 1 mol. H_2O) in needles which decompose at 120°, and are soluble in hot alcohol, but insoluble in ether.

Sodium ethylsulphoncyanamide, $SO_2Et·NNa·CN$, is prepared by adding sodium cyanamide (1 mol.) to a solution of sodium hydroxide (1 mol.), and mixing it with ethylsulphonic chloride (1 mol.); the water is evaporated, the residue dissolved in alcohol and precipitated by ether. It crystallises in long, silky needles (with 1 mol. H_2O) which melt at 88°, and are soluble in water, and alcohol sparingly in acetone and glacial acetic acid, but insoluble in ether. The *silver*, *lead*, and *barium* compounds are described. *Ethylsulphoncyanamide* forms anhydrous crystals which melt at 134°, and are freely soluble in hot alcohol, but only sparingly in cold water, and insoluble in ether.

When benzene- and α-naphthalenesulphoncyanamides are heated to 115° and 95° respectively, they decompose, forming benzenesulphonamide and α-naphthalenesulphonamide respectively, which sublime, and cyanuric acid, which is left in the residue of still undecomposed cyanamide. A. G. B.

Nitrotoluidinesulphonic Acids. By R. NIETZKI and B. POLLINI (*Ber.*, **23**, 138—140).—*Nitrotoluidinesulphonic acid*

$$[NH_2 : NO_2 : SO_3H : Me = 1 : 2 : 4 : 6]$$

can be prepared by nitrating acetyltoluidinesulphonic acid

$$[NHAc : Me : SO_3H = 1 : 2 : 4]$$

in sulphuric acid solution as previously described (compare Nietzki and Benckiser, Abstr., 1885, 535). It can also be obtained by dissolving orthacetotoluidide in fuming sulphuric acid, diluting with concentrated sulphuric acid, and then nitrating the product. It is best purified in both cases by converting it first into the barium salt, and then into the potassium salt. It crystallises in light-yellow needles. The *potassium* salt crystallises in orange needles, and is readily soluble in water, but only moderately easily in potash; when heated with dilute (1 : 1) sulphuric acid at 170—180° for about three hours, and the product treated with ammonia, nitrotoluidine [$NH_2 : NO_2 : Me = 1 : 2 : 6$] is obtained. The acid yields a sparingly soluble, very explosive diazo-compound, which can be combined with phenols to form azo-dyes.

Diamidotoluenesulphonic acid, $SO_3H·C_6H_2Me(NH_2)_2$, prepared by reducing the nitramido-acid with stannous chloride and hydrochloric acid, crystallises from water in colourless needles, and combines readily with orthodiketones, yielding azine-derivatives. The *azine* obtained with croconic acid forms a potassium salt which crystallises in almost black needles, and has the composition

$$C_5H_2O_3<\overset{N}{\underset{N}{|}}>C_6H_2Me·SO_3K + H_2O.$$

Nitrotoluidinesulphonic acid [$NH_2 : NO_2 : Me : SO_3H = 1 : 2 : 4 : 6$] can be obtained from paratoluidinesulphonic acid [$NH_2 : Me : SO_3H = 1 : 4 : 6$], as described above; when paratoluidinesulphonic acid

[$NH_2 : SO_3H : Me = 1 : 3 : 4$] is treated in like manner, it yields a nitrotoluidinesulphonic acid [$NH_2 : NO_2 : SO_3H : Me = 1 : 2 : 3 : 4$]. Both compounds can be decomposed into nitrotoluidine

$$[NH_2 : NO_2 : Me = 1 : 2 : 4],$$

and on reduction they both yield diamido-compounds analogous to that described above. F. S. K.

Normal Propylbenzenesulphonic Acids. By A. CLAUS and O. WELZEL (*J. pr. Chem.* [2], **41**, 152—158).—α- and β-Propylbenzenesulphonic acids are propylbenzeneorthosulphonic and parasulphonic acids respectively; the authors doubt if Paternò and Spica (Abstr., 1877, 707) really obtained the latter, as the salts described by these chemists have properties differing from those now obtained. When the product of the reaction (*loc. cit.*) is gradually diluted with water, the first crystallisation consists chiefly of the ortho-acid. To completely separate the two acids, they are converted into the nickel salts; that of the ortho-acid crystallises from its hot aqueous solution, whilst that of the para-acid does not.

Propylbenzeneorthosulphonic acid [$Pr : SO_3H = 2 : 3$] crystallises in needles or small prisms (with 1 mol. H_2O), very soluble in water and alcohol, insoluble in other solvents. The *nickel salt* and the *chloride* were obtained. The *amide*, $C_6H_4Pr{\cdot}SO_2NH_2$, formed from the chloride by the action of ammonia, crystallises from water in colourless needles, and from other solvents in pearly leaflets; both forms melt at 104·5—105° (uncorr.). When brominated, the acid yields *orthobromopropylbenzene*, a yellow oil which boils at 222° (uncorr.), and yields orthobromobenzoic acid when oxidised. The bromopropylbenzenesulphonic acids are being investigated.

Propylbenzeneparasulphonic acid [$Pr : SO_3H = 1 : 4$] crystallises in needles which are more soluble than the ortho-acid; its salts are also more soluble than those of the ortho-acid, but do not crystallise so well. The *amide* crystallises in pearly, flattened needles or leaflets melting at 109—110° and soluble in most solvents. By brominating the acid, *parabromopropylbenzene* is obtained as an oil boiling at 220° (uncorr.), and solidifying in the cold; it is converted into parabromobenzoic acid by oxidation. A. G. B.

Paratolylphenylketoxime. By K. AUWERS (*Ber.*, **23**, 399—403).—Paratolylphenylketoxime was first prepared by Beckmann and Wegerhoff in the usual manner (Abstr., 1889, 1067). In view of the fact that, according to Hantzsch and Werner's hypothesis (this vol., p. 348), two stereometric isomerides of this compound, having the formulæ  $\begin{matrix} C_7H_7{\cdot}C{\cdot}C_6H_5 \\ \| \\ N{\cdot}OH \end{matrix}$ and  $\begin{matrix} C_7H_7{\cdot}C{\cdot}C_6H_5 \\ \| \\ HO{\cdot}N \end{matrix}$, should exist, the author has endeavoured to obtain a second oxime by methods similar to those successfully employed in the case of benzil (Abstr., 1888, 549, 597). In all cases, however, the result has been negative, the raw product obtained in each case being identical. This invariably contained an impurity, which could be removed by repeated crystallisation from alcohol, benzene, or light petroleum, the melting point being finally found to be 153—154° instead of 140°, as given by Beckmann and Wegerhoff. That this impurity does not represent the second oxime is shown by the fact that acetic anhydride converts the crude product into the *acetyl*-derivative of paratolylphenylketoxime, $C_7H_7\cdot C_6H_5\cdot C{:}N\cdot OAc$, which is obtained quite pure by one recrystallisation from alcohol. It forms large lustrous prisms melting at 123—124°. It cannot be assumed that an intramolecular change of the second oxime by means of acetic anhydride takes place, as even the unstable benzil-γ-dioxime undergoes no such change with this reagent. The impurity is probably due to the unstable nature of the oxime, which decomposes, as already mentioned by Beckmann and Wegerhoff, even on remaining exposed to the air.

An attempt to bring about an intramolecular change in the oxime by treating it with alcohol at a high temperature likewise gave negative results. H. G. C.

Formation of Dibenzyl-derivatives. By O. Poppe (*Ber.*, 23, 113—118).—*Ethyl cyanodiphenylsuccinate*,

$$COOEt\cdot CHPh\cdot CPh(CN)\cdot COOEt,$$

is formed, together with ethyl diphenylsuccinate, when ethyl phenylchloracetate or ethyl phenylbromacetate is digested with an alcoholic solution of potassium cyanide (2 mols.), until the odour of hydrogen cyanide is no longer perceptible. (Compare Franchimont, this Journal, 1873, 390.) The solution is then extracted with ether, and the product repeatedly recrystallised; the yield is 4 per cent. of the ethyl salt employed. It separates from alcohol in prisms, melts at 105°, and is readily soluble in hot alcohol, ether, benzene, chloroform, and glacial acetic acid, but only sparingly in cold alcohol, and insoluble in water. When treated with sodium in alcoholic solution, it is converted into ethyl diphenylsuccinate. The corresponding *methyl* salt, $C_{19}H_{17}O_4N$, obtained in like manner from methyl phenylchloracetate, crystallises from alcohol in colourless plates, and melts at 101°. The *amyl* salt, $C_{27}H_{33}O_4N$, is an oil.

The compound $COOEt\cdot CHPh\cdot CPh(CONH_2)\cdot COOEt$, is obtained when ethyl cyanodiphenylsuccinate is heated for a short time at 50—60° with concentrated sulphuric acid. It crystallises from a mixture of benzene and light petroleum in needles and melts at 157°. The free *acid*, $C_{17}H_{15}O_5N$, prepared by heating the ethyl salt at 100° with hydrochloric acid. crystallises from benzene and alcohol, melts at 190°, and is insoluble in water. When boiled with alcoholic potash, it is converted into diphenylsuccinic acid. F. S. K.

The Euxanthone Group. By C. Graebe (*Annalen*, 254, 265—303; compare Abstr., 1887, 272; 1889, 886).—In this paper the author gives a more complete account of his investigations on euxanthone and its derivatives.

Piuri (purrée) or Indian-yellow is obtained in Bengal from the urine of cows which are fed exclusively on the leaves of the mango tree and water; the urine is heated, the precipitated dye separated and dried. The fact, observed by Kostanecki (Abstr., 1887, 272), that euxanthone is converted into euxanthic acid in the animal organism, shows that mango-leaves contain some substance nearly related to euxanthone.

The author's analyses of very pure samples of piuri gave the following results in percentages:—Euxanthic acid, 51; silica and alumina, 1·5; magnesium, 4·2; calcium, 3·4; water and volatile substances, 39. His analyses differ from those of Stenhouse and Erdmann in showing the presence of considerable quantities of calcium. The poorer qualities contain a considerable quantity of euxanthone, partly in the free, partly in the combined state. The euxanthic acid and the euxanthone in piuri can be estimated and isolated as follows:—The dye is triturated with dilute hydrochloric acid until the whole has assumed the bright yellow colour of the free acid; it is then washed well with cold water to remove inorganic compounds, and the euxanthic acid extracted with a solution of ammonium carbonate; the residual euxanthone is dissolved in soda, reprecipitated with an acid, and dried at 100°.

Euxanthic acid melts at about 156—158°, but immediately afterwards begins to decompose, so that the melting point is difficult to observe. It forms two series of salts, of the composition $C_{19}H_{17}O_{11}M'$ and $C_{19}H_{16}O_{11}M'_2$ respectively. The magnesium salt, when dried in the air, has the composition $C_{19}H_{16}O_{11}Mg + 5H_2O$.

Accepting Schmiedeberg and Meyer's view of the constitution of glycuronic acid, the constitution of euxanthic acid may be expressed by the formula

$$OH{\cdot}C_6H_3{<}{\overset{O-}{\underset{CO}{}}}{>}C_6H_3{\cdot}O{\cdot}CH(OH){\cdot}[CH(OH)]_4{\cdot}COOH.$$

In accordance with this view, the decomposition of euxanthic acid into glycuronic acid and euxanthone may be represented by the equation $C_{19}H_{18}O_{11} = C_{13}H_8O_4 + C_6H_{10}O_7$.

In this decomposition the atomic complex $[CH(OH)]_2$ would be converted into the aldehyde-group, with elimination of 1 mol. H_2O, a view which would account for the fact that the decomposition of euxanthic acid takes place without the addition of the elements of water. The constitutional formula given above would also explain why euxanthic acid does not reduce Fehling's solution, whilst the liberated glycuronic acid does so. Glycuronic acid combines readily with phenylhydrazine; euxanthic acid, on the other hand, is not acted on even when heated with phenylhydrazine in alcoholic solution for two hours at 100°.

The hydroxyxanthone (m. p. 146°) prepared by Michael (Abstr., 1884, 310), by heating salicylic acid and resorcinol with zinc chloride, has the constitution $C_6H_4{<}{\overset{O-}{\underset{CO}{}}}{>}C_6H_3{\cdot}OH\ [O:OH = 2:6]$, this same compound can be prepared by heating salicylic acid and β-resorcylic acid with acetic anhydride. It is not acted on by hydroxylamine, or by phenylhydrazine, and when heated with zinc-dust it gives diphenylenemethane oxide (m. p. 100·5°). When fused with soda at 250—270° it is converted into trihydroxybenzophenone (m. p. 133°). This substance combines with phenylhydrazine, yielding a crystalline *hydrazone*, $OH{\cdot}C_6H_4{\cdot}C(N_2HPh){\cdot}C_6H_3(OH)_2$.

Erdmann's statement that euxanthone is converted into trinitroresorcinol (styphnic acid) by nitric acid is confirmed by the author's experiments; considerable quantities of oxalic acid are also formed in the reaction. When euxanthone is fused with soda or potash, it yields quinol, as previously observed by Baeyer, but resorcinol is also produced, and seemingly in about an equal quantity.

Euxanthone can be prepared by boiling a mixture of β-resorcylic acid (5 grams), hydroquinonecarboxylic acid (6 grams), and acetic anhydride (12 grams) for four hours in a small retort. The whole is then distilled, the neck of the retort being placed almost vertically, whereon, towards the end of the operation, most of the euxanthone sublimes. The acetic acid which passes over towards the end of the distillation is saturated with soda, and the solution treated with carbonic acid to precipitate the euxanthone; the sublimed euxanthone is dissolved in warm soda, and the filtered solution precipitated with carbonic anhydride; the yield of the pure product is 1 gram. Euxanthone prepared in this way melts at 240° (corr.), and is identical with the natural product (compare Abstr., 1889, 886). When it is warmed with water and sodium amalgam, the solution gradually becomes lighter in colour, and on adding an acid, a substance is precipitated which quickly turns violet on exposure to the air, and dissolves in concentrated sulphuric acid with an intense red coloration; this reaction is characteristic of the naturally occurring euxanthone. The *diacetyl*-derivative melts at 185°.

β-Isoeuxanthone, prepared from dinitroxanthone (m. p. 260°) gives a *diacetyl*-derivative which crystallises from alcohol in colourless needles melting at 175°. 3 : 6 Isoeuxanthone (m. p. 245—246°) prepared by Bistrzycki and Kostanecki, gives a *diacetyl*-derivative, $C_{13}H_6O_2(OAc)_2$, which melts at 124—130°. When isoeuxanthone is heated with potash and a little water, it is converted into an euxanthonic acid, which melts at about 200°, being reconverted into isoeuxanthone.

F. S. K.

ac.-Tetrahydro-β-naphthol and Secondary Closed Chain Alcohols. By E. Bamberger and W. Lodter (*Ber.*, **23**, 197—213).—*ac.-Tetrahydro-β-naphthol*, $C_{10}H_{11}\cdot OH$, is prepared by gradually adding 20 grams of sodium shavings in quantities of 4—5 grams to a boiling solution of 10 grams of β-naphthol in 200 grams of amyl alcohol, and heating until the whole is dissolved. The hot solution is poured into water and the alcoholic layer separated, washed several times with aqueous soda to remove as much ar.-tetrahydro-β-naphthol and unattacked β-naphthol as possible, then with water, and finally with dilute hydrochloric acid, and distilled under the ordinary atmospheric pressure until the temperature rises to 150—160°; the distillation at higher temperatures being conducted in a vacuum. The fraction boiling at 160—205° under a pressure of 40 mm. is a viscid, orange-yellow oil, and contains the whole of the "alicyclic" derivative together with noteworthy quantities of ar.-tetrahydro-β-naphthol and β-naphthol. The β-naphthol and the greater portion of the "aromatic" derivative can be removed by mixing the fraction with 15 per cent. aqueous soda and steam-distilling until the distillate dissolves completely in aqueous soda. The oily ac.-tetrahydro-β-naphthol is extracted from the distillate by ether, and freed from the last traces of the "aromatic" derivative by treatment with a solution of diazotised sulphanilic acid in aqueous sodium carbonate; this converts the latter derivative into an azo-dye insoluble in ether, but is without action on the former. The yield amounts to about 30 per cent. by weight of the β-naphthol employed. ac.-Tetrahydro-β-naphthol is a colourless, transparent, extremely viscid, non-fluorescent oil with an odour resembling that of sage, it boils without decomposition at 264° under a pressure of 716 mm., and at 176·5—178° under a pressure of 53 mm. It is very slightly soluble in water, readily soluble in alcohol, ether, benzene, carbon bisulphide, and chloroform, and insoluble in alkalis. It does not react with diazo-compounds, and like ac.-tetrahydro-β-naphthylamine (Abstr., 1888, 712), yields hydrocinnamorthocarboxylic acid on oxidation. On treating its ethereal solution with sodium, hydrogen is evolved and the compound is converted into the sodium-derivative, behaving therefore like an alcohol under similar conditions. When warmed with solid potassium hydroxide, it readily yields dihydronaphthalene with the elimination of water.

Sodium ac.-tetrahydro-β-naphthyl carbonate, $C_{10}H_{11}O{\cdot}CO{\cdot}ONa$, is formed by passing carbonic anhydride through a well-cooled ethereal solution of the sodium-derivative of the hydronaphthol. It is a white, gelatinous, very unstable compound, undergoing decomposition on exposure to moist air. Acids decompose it at once with the evolution of carbonic anhydride and separation of the hydronaphthol.

ac.-Tetrahydro-β-naphthyl acetate, $CH_3{\cdot}CO{\cdot}OC_{10}H_{11}$, is obtained by heating the hydronaphthol either with 3—4 times the quantity of acetic acid for some hours at 140—150°, or, better, with acetic anhydride, to which some fused sodium acetate has been added. It is a pale-yellow, extremely viscid oil with a fruity odour, and boils at 169° under a pressure of 34 mm. When distilled under atmospheric pressure, it boils at 268—280°, with partial decomposition into acetic acid and dihydronaphthalene.

ac.-Tetrahydro-β-naphthyl benzoate, $COPh{\cdot}OC_{10}H_{11}$, prepared by heating the hydronaphthol with benzoic acid at 170° for 48 hours, crystallises from alcohol in well-formed, lustrous tablets, melts at 62—63°, boils at 254—255° under a pressure of 40 mm., but decomposes partially into dihydronaphthalene and benzoic acid when distilled under atmospheric pressure; it is readily soluble in benzene, chloroform and warm alcohol, sparingly soluble in hot light petroleum.

ac.-Tetrahydro-β-naphthyl chloride, $C_{10}H_{11}Cl$, is obtained by warming the hydronaphthol with about 10 times its weight of concentrated hydrochloric acid. It was not, however, found possible to purify the product by distillation, since it decomposes on heating into dihydronaphthalene and hydrogen chloride. When ac.-tetrahydro-β-naphthol is treated at the ordinary temperature with colourless, fuming hydriodic acid (sp. gr. = 1·9), an oil is obtained which seems to be the corresponding *iodide*, but like the chloride it decomposes on distillation with the elimination of hydrogen iodide.

ac.-Tetrahydro-β-naphthyl phenylcarbamate, $NHPh{\cdot}CO{\cdot}OC_{10}H_{11}$, formed by treating the hydronaphthol with phenyl cyanate at the ordinary temperature, crystallises in tufts of silky needles, melts at 98·5°, and is readily soluble in ether, benzene, chloroform, and boiling light petroleum.

Sodium ac.-tetrahydro-β-naphthylxanthate, $C_{10}H_{11}O{\cdot}CS{\cdot}SNa$, is readily prepared by treating the ethereal solution of the sodium derivative of the hydronaphthol with carbon bisulphide, and forms an ochre-yellow mass which dissolves readily in water and closely resembles sodium ethylxanthate in properties From the aqueous solution, copper sulphate precipitates the brownish-black cupric salt, and this, like cupric ethylxanthate, slowly undergoes change into the ochre-yellow *cuprous* salt, $C_{10}H_{11}O{\cdot}CS{\cdot}SCu$, which crystallises from carbon bisulphide in bright-yellow crusts.

ac.-Tetrahydro-β-naphthol, like borneol and menthol, gives the reaction, therefore, of a true secondary alcohol, and a comparison of the properties of the three compounds makes it evident that hydroxyl-radicles can assume alcoholic functions not only in open but also, under certain conditions, in closed chain compounds. Like ac.-tetrahydro-β-naphthol, borneol and menthol (compare Arth, Abstr., 1886, 892) form chlorides which readily decompose into hydrogen chloride and camphene and menthene respectively, both readily eliminate water with the formation of camphene and menthene respectively, both yield xanthic acids resembling ethylxanthic acid in properties (compare Bamberger and Lodter, this vol., p. 516), and menthol benzoate decomposes partially into menthene and benzoic acid on distillation. It is noted that the oxidation-products of these three compounds—hydrocinnamorthocarboxylic acid, camphoric acid, and oxymenthylic acid respectively—contain the same number of carbon-atoms as the substances from which they are derived, thus differing from those of open chain secondary alcohols; such a difference, however, is only to be expected in the case of closed chain secondary alcohols. It is especially noteworthy that the products of partial oxidation in both closed and open chain secondary alcohols are ketones: borneol and menthol are known to give camphor and menthone on oxidation, and the authors have obtained evidence which points to the formation of an unstable ketone when ac.-tetrahydro-β-naphthol is oxidised by means of potassium dichromate and sulphuric acid, since, in addition to phthalic acid and hydrocinnamorthocarboxylic acid, a neutral oil is formed in small quantity which is readily volatile with steam and yields a well crystallised, nitrogenous compound on treatment with phenylhydrazine.

W. P. W.

ar.-Tetrahydro-α-naphthol. By E. Bamberger and F. Bordt (*Ber*, **23**, 215—218).—*ar.-Tetrahydro-α-naphthol*, $C_{10}H_{11}{\cdot}OH$, is obtained as the sole product when α-naphthol in amyl alcohol solution is reduced with sodium, and is isolated by pouring the amyl alcohol solution into water, separating the alcoholic layer which contains the greater part of the product in the form of sodium salt, distilling off the alcohol, dissolving the yellowish-brown residue in water, acidifying, and extracting with ether; the ether is then removed by distillation and the resulting tetrahydro-α-naphthol purified by distillation under the ordinary pressure. It crystallises in silvery white tables resembling naphthalene in appearance, melts at 68·5—69°, boils at 264·5—265·5° under a pressure of 705 mm. and is therefore identical with the product obtained from ar.-tetrahydro-α-naphthylamine by the diazo-reaction (compare Bamberger and Althausse, Abstr., 1888, 960). Adipic acid could not be obtained by oxidising the compound; cautious oxidation with potassium permanganate resulted only in the formation of oxalic and phthalic acids. On ethylation, it yields *ar-tetrahydro-α-ethoxynaphthalene*, $C_{10}H_{11}·OEt$, a viscid, heavy oil which distils at 259° under a pressure of 705 mm. and has a pleasant odour.

Phenylazo-ar.-tetrahydro-α-naphthol, $N_2Ph·C_{10}H_{10}·OH$, prepared by the action of diazobenzene chloride on ar.-terahydro-α-naphthol in alkaline solution, crystallises from alcohol in beautiful, cantharides-green tablets showing a metallic lustre, and is insoluble in water, sparingly soluble in benzene, soluble in acetic acid, and readily soluble in chloroform.

Sulphophenylazo-ar.-tetrahydro-α-naphthol, $SO_3H·C_6H_4·N_2·C_{10}H_{10}·OH$, forms scarlet-red flocks. The sodium salt crystallises in orange-red scales showing a bronze lustre. W. P. W.

Derivatives of Nitro-β-naphthaquinone. By R. ZAERTLING (*Ber.*, 23, 175—180).—*Nitronaphthaphenazine*, $C_6H_4\!:\!N_2\!:\!C_{10}H_5·NO_2$, is produced by treating nitro-β-naphthaquinone (1 mol. prop.) dissolved in acetic acid with a solution of orthophenylenediamine hydrochloride (1 mol. prop.) and sodium acetate (2 mol. prop.) in dilute acetic acid. It crystallises from a mixture of phenol and acetic acid in well-formed, greenish-yellow prisms, melts at 221—222°, and is sparingly soluble in alcohol, benzene, ether, and acetic acid, insoluble in light petroleum. It dissolves in concentrated sulphuric acid with a carmine-red colour, and is precipitated unchanged from the solution on addition of water. *Amidonaphthaphenazine*, $C_6H_4\!:\!N_2\!:\!C_{10}H_5·NH_2$, is formed when the nitro-derivative is reduced by heating with alcoholic ammonium sulphide for 2 hours at 100°, and crystallises from aniline in small, dark brownish-red crystals which yield a cherry-red powder. It sublimes in woolly, carmine-red flocks consisting of microscopic hair-like needles, melts at 191°, and is sparingly soluble in alcohol and ether, more soluble in benzene, and readily soluble in boiling aniline and phenol; the solutions, unlike those of the majority of eurhodines, are destitute of fluorescence. Concentrated sulphuric acid dissolves it with a brown colour, and the solution becomes yellow on dilution with water. The hydrochloride is sparingly soluble in boiling water, and, like all the salts of the base, is yellow in colour.

Nitro-β-naphthaquinol, $NO_2·C_{10}H_5(OH)_2$, is best prepared from the quinone by reduction with stannous chloride and hydrochloric acid (Groves, Trans., 1884, 299), the yield amounting to 95 per cent. of that theoretically possible. It can also be obtained by dissolving powdered nitro-β-naphthaquinone in a saturated aqueous solution of sulphurous anhydride, and concentrating the solution on a water-bath to the crystallising point; the yield by this method, however, amounts only to about 60 per cent. of the theoretical, owing to the carbonisation which occurs in concentrated solutions by the action of the sulphuric acid formed in the reduction. In view of the fact that nitro-β-naphthaquinol is almost insoluble in water, and that ether extracts nothing from the orange-red sulphurous acid solution, the author suggests that the quinol may combine either with sulphurous or sulphuric acid, forming a soluble compound which decomposes into its constituents when its solutions are concentrated. Nitro-β-naphthaquinol is also obtained on treating the quinone with phenylhydrazine, and in this reaction benzene, azobenzene, aniline, and nitrogen constitute the decomposition-products of the hydrazine. It sublimes in beautiful, long, red needles resembling sublimed alizarin in appearance, melts at 159·5°, is slightly volatile with steam, has an odour recalling that of juglone, and dissolves sparingly in boiling water. It is insoluble in cold concentrated sulphuric acid, but dissolves in aqueous alkalis forming deep-green solutions which, when shaken with air, become brighter in colour and cannot afterwards be precipitated by the addition of acids. Carbonic anhydride is eliminated when nitro-β-naphthaquinol is boiled in aqueous solution with barium or an alkaline carbonate. The quinol has feeble tinctorial powers, and with iron mordants gives yellowish-brown, with chromium mordants pale indigo-blue, and with aluminium mordants red colours which are not fast to soap.

Nitro-β-naphthaquinone reacts with hydroxylamine in the cold forming a pale-yellow, hygroscopic additive-compound,

$$NO_2{\cdot}C_{10}H_5O_2,NH_2{\cdot}OH,$$

which melts at 140—141° with decomposition, and decomposes into nitro-β-naphthaquinol with the evolution of nitrogen when boiled with acetic acid, phenol, alcohol, or water. W. P. W.

Di-β-naphthylketone Oxide. By A. CLAUS and W. RUPPEL (*J. pr. Chem.* [2], 41, 48—54).—*Di-β-naphthylketone oxide*, $CO{:}(C_{10}H_6)_2{:}O$, is obtained when ethylidene di-β-naphthyl oxide (Abstr., 1887, 271) is dissolved in boiling glacial acetic acid (10 grams in 150 grams), and a glacial acetic solution of chromic acid (15 grams in 100 grams) added thereto; after 10 minutes' heating, the mixture is cooled, when the oxide crystallises. It forms light-grey, silvery leaflets which melt at 149° (uncorr.), and sublime at a higher temperature in slender, colourless needles which soon become yellowish-grey; it dissolves in the usual solvents except water. It is not changed by concentrated hydrochloric acid or by alcoholic potash, and forms no compound with phenylhydrazine.

Dinitrodi-β-naphthylketone oxide, obtained by nitrating the above, is precipitated on adding water to its solution in strong acid as an amorphous powder which aggregates at 268°, and is insoluble in all solvents except nitrobenzene, from which it is precipitated by alcohol in leaflets melting at 275° (uncorr.). By reduction, it yields crystals of an amido-compound (?) melting at 182°.

Barium di-β-naphthylketoneoxidedisulphonate was obtained by sulphonating the oxide, &c.

Dibromodi-β-naphthylketone oxide crystallises in beautiful, lustrous needles which melt at 181° (uncorr.), and are soluble in ether, acetone, and glacial acetic acid.

Methylene-di-β-naphthyl oxide, $CH_2{:}(C_{10}H_6)_2{:}O$, is the product of the reduction of the ketone oxide; it crystallises in small, lustrous, yellowish needles melting at 165° (uncorr.), and soluble in the usual solvents. When the reducing agent is concentrated hydriodic acid and the temperature 180°, a *dinaphthylmethane* is obtained: this forms glittering leaflets which melt at 137° (uncorr.), and are soluble in hot alcohol and ether; it is not identical with Richter's dinaphthylmethane (Abstr., 1881, 281). A. G. B.

Decomposition of ac.-1 : 4′-Tetrahydronaphthylenediamine into its Optically Active Components. By E. BAMBERGER (*Ber.*, **23**, 291—292).—The lævo-rotatory modification of ac-1 : 4′-tetrahydronaphthylenediamine is obtained by concentrating an aqueous solution of the hydrogen tartrate of the optically inactive base to a thick syrup, and adding a minute fragment of conine dextrotartrate. Slender needles of the salt of the lævo-rotatory modification at once begin to crystallise out. The hydrochloride crystallises in transparent, compact, lustrous prisms, and in aqueous solution has a specific rotatory power of $[\alpha]_D = -7° 29′ 50″$.

The hydrogen salt of the dextro-rotatory modification forms lustrous needles which crystallise with extreme slowness from the syrupy mother liquor. The hydrochloride in aqueous solution has a specific rotatory power of $[\alpha]_D = +8° 8′ 49″$. W. P. W.

Homologues of Anthracene and Anthraquinone. By K. ELBS (*J. pr. Chem.* [2], **41**, 1—32 and 121—151).—This paper consists chiefly of descriptions of the preparation of the methylanthracenes and methylanthraquinones, together with their dicarboxylic acids, given in greater detail than heretofore (compare Abstr., 1885, 261; 1886, 461, 557; 1887, 841, 940).

β-Methylanthracene melts at 199—200° and β-methylanthraquinone (Abstr., 1886, 557, 1029) at 176—177°.

The *ammonium*, *calcium*, *lead*, and *silver* salts, and the *anhydride* both of 2 : 3-anthraquinonedicarboxylic acid and of 2 : 3-anthracenedicarboxylic acid are described; the salts are all anhydrous, amorphous precipitates.

When 1 : 3-dimethylanthracene is treated with bromine in carbon bisulphide, a crystalline *dibromo*-1 : 3-*dimethylanthracene* is produced; it melts at 175°—180° with decomposition.

"*Metadimethylanthracylene*" is the name given by the author to the hydrocarbon $C_{16}H_{12}$ =  $C_6H_4{:}C_2H{<}\begin{matrix}CH_2\\C_6H_3Me\end{matrix}$ [CH₂ : Me = 1 : 3], obtained by reducing 1 : 3-dimethylanthraquinone with zinc-dust and ammonia (Abstr., 1887, 841). When treated with bromine, it yields a crystalline *dibromo-derivative*, $C_{16}H_{10}Br_2$, melting at 175°, soluble in acetone and in carbon bisulphide, and converted by nitric acid into 1 : 3-anthraquinonedicarboxylic acid, and by alcoholic potash into 1 : 3-*dimethylanthranol*; the latter crystallises in slender, colourless needles which melt at 155°.

The *ammonium*, *potassium*, *sodium*, *calcium*, *barium*, *lead*, *copper*, and *silver* salts, and the *chloride* of 1 : 3-anthraquinonedicarboxylic acid are described; as are also the *ammonium*, *copper*, and *silver* salts, and the *chloride* of 1 : 3-anthracenedicarboxylic acid.

1 : 4-Dimethylanthraquinone has been prepared by Gresly (Abstr., 1886, 1029); it melts at 118—119°. When reduced by zinc-dust and ammonia, it yields a hydrocarbon, $C_{16}H_{12}$ (compare above), which crystallises in leaflets melting at 63°, and gives a *picrate* which melts at 129°.

1 : 4-*Anthraquinonedicarboxylic acid*, obtained by oxidising 1 : 2-dimethylanthraquinone with nitric acid, forms crystals which are still solid at 300°, and are insoluble in water, but soluble in alcohol; its *alkali* salts, and its *calcium*, *lead*, and *silver* salts are described. 1 : 4-*Anthracenedicarboxylic acid*, obtained by reducing the preceding compound, separates from alcohol on dilution as a light-brown, crystalline powder melting at about 320°; its *alkali* salts and its *calcium*, *lead*, and *silver* salts are described.

1 : 2 : 4-Trimethylanthracene (Gresly, Abstr., 1886, 1029), when added to a solution of picric acid in benzene, forms a *picrate* which crystallises in brownish-red needles melting at 145°, and immediately decomposed by alcohol.

Gresly's method for obtaining 1 : 2 : 4-trimethylanthraquinone (*loc. cit.*) is best carried out as follows:—Pseudocumoylorthobenzoic acid (10 grams) is shaken with strong sulphuric acid (100 c.c.) and slowly heated to 115°, at which temperature it is kept for one hour; it is then cooled to 70—80° and phosphoric anhydride (10 grams) added, the temperature being again raised to 115—120° and kept there for two hours, after which the mixture is allowed to cool and poured into much water. The precipitated quinone is washed with cold water, hot aqueous soda solution, and hot water, dissolved in xylene, and precipitated by absolute alcohol. Thus obtained, it forms long, yellow needles which melt at 162—163° and sublime.

"*Trimethylanthracylene*," $C_{17}H_{14}$, =  $C_6H_4{:}C_2H{<}\begin{array}{l}CH_2\\ \vert\\ C_6HMe_2\end{array}$?, is obtained when 1 : 2 : 4-trimethylanthraquinone is reduced with zinc-dust and ammonia; it crystallises in colourless leaflets which melt at 64°. Its *picrate* forms dark-red needles melting at 134°. When brominated, it yields a *dibromo-derivative*, $C_{17}H_{12}Br_2$, which crystallises in yellow, transparent prisms melting at 105° with decomposition, and sparingly soluble in alcohol.

Anthraquinone-1 : 2 : 4-*tricarboxylic acid*, prepared by oxidising 1 · 2 : 4-trimethylanthraquinone with dilute nitric acid according to the method already given, crystallises in yellowish-white nodules not melting or decomposing at 320°, and soluble in alcohol, but nearly insoluble in water. The ammonium salt was not obtained pure, but the *monosodium salt* (with 2 mols. H_2O), the *disodium salt* (with 3 mols. H_2O), the *normal sodium salt*, and the *normal calcium*, *copper*, *lead*, and *silver salts* are described; the *ethyl salt* forms small, lustrous, yellow leaflets melting at 125°.

Anthracene-1 : 2 : 4-*tricarboxylic acid* is made by reducing the preceding acid with zinc-dust and ammonia; it is a deep yellow precipitate, insoluble in water, but soluble in light petroleum, benzene, and alcohol; at 260° it yields a red sublimate, apparently an anhydride. The *alkali salts* and the *silver salt* have been obtained.

There are two *nitro*-1 : 2 : 4-*trimethylanthraquinones*, designated by the author as I and II.

I is obtained when 1 : 2 : 4-trimethylanthraquinone (5 grams) is dissolved in strong sulphuric acid (100 grams) at the ordinary temperature, and powdered potassium nitrate (2·2 grams) gradually added; the mixture is allowed to remain for some hours and then poured into much water. The nitro-derivative is thus separated as a red powder, freely soluble in boiling benzene and xylene, which deposit it as an impure, crystalline mass melting with decomposition at 195—200°. The corresponding *tricarboxylic acid* forms small crystals which melt with decomposition at 308—310°, and are soluble in most solvents except water; its three *sodium salts*, and its *neutral calcium*, *strontium*, *barium*, *nickel*, *cobalt*, *lead*, *copper*, and *silver* salts were obtained. The corresponding *amido-tricarboxylic acid* crystallises in small, dark-red leaflets melting at 210°, and soluble in hot water and in alcohol.

II is formed when 1 : 2 : 4-trimethylanthraquinone (5 grams) is dissolved in nitric acid of sp. gr. 1·52 (100 c.c.), cooled by ice, and, after six hours, poured into much water; it is a pale-red powder, soluble in glacial acetic acid, benzene, and xylene; it cannot be purified, and decomposes at 180°. The corresponding *tricarboxylic acid* forms a dubiously crystalline, red-yellow powder, soluble in alcohol and benzene, and melting with decomposition between 360° and 370°; its three *sodium salts*, its *calcium*, *barium*, *strontium*, *nickel*, *lead*, and *silver salts* were obtained; the *copper salt* forms red needles dissolving in ammonia with a red colour, whereas the copper salt of the I-tricarboxylic acid forms green needles soluble in ammonia with an emerald-green colour. The corresponding *amido-tricarboxylic acid* crystallises in deep-red leaflets melting at 255°, soluble in water and alcohol. The corresponding *amido-quinone* forms a red precipitate, which is obtained as a crystalline mass by decomposing its saturated alcoholic solution with water; it melts at 154—155°, and sublimes in slender, lustrous, dark-red needles.

Dinitro-1 : 2 : 4-*trimethylanthraquinone* is the ultimate product of the action of nitric acid (sp. gr. 1·54) on the above quinones; it is a dark-yellow powder, soluble in boiling glacial acetic acid, benzene, and xylene, and melting with decomposition between 240 and 260°. The corresponding *tricarboxylic acid* and its *silver salt* were obtained.

2 : 1′ : 4′-*Trimethylanthraquinone*, obtained by oxidising 2 : 1′ : 4′-trimethylanthracene (Abstr., 1887, 941) with chromic acid in glacial acetic solution, crystallises in yellow needles which melt at 184° and sublime; it dissolves sparingly in alcohol. When it is oxidised with chromic acid, a mixture of di- and tricarboxylic acids is produced; the *silver dicarboxylate* was obtained.

3 : 1′ : 3′-*Trimethylanthracene*, obtained by the condensation of dimetaxylyl ketone (Cosack, *Diss.*, *Freiburg i. B.*, 1889; compare Abstr., 1887, 941), melts at 222°, and is sparingly soluble in alcohol and light petroleum, but more freely in other solvents. When

brominated in carbon bisulphide solution, it yields *γ-dibromo-3 : 1′ : 3′-trimethylanthracene*, $C_6H_2Me_2{:}C_2Br_2{:}C_6H_3Me$, which crystallises in leaflets melting at 142°.

3 : 1′ : 3′-*Trimethylanthraquinone* crystallises in yellow needles melting at 190°, subliming and soluble in glacial acetic acid, and sparingly in alcohol; the corresponding *tricarboxylic acid* crystallises in yellow leaflets nearly insoluble in water and melting above 300°; its *ammonium* and *barium salts* are described.

Phenylbenzoylorthobenzoic acid, $COOH{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_4Ph$, is obtained by heating diphenyl with phthalic anhydride in the presence of aluminium chloride in light petroleum (b. p. 90—100°); the petroleum is distilled off with steam, and the residue dissolved in weak soda solution and fractionally precipitated by hydrochloric acid; the flocks thus obtained are crystallised from alcohol, when only the first portions that come down are crystalline, the rest separating as flocks; the last portions, therefore, are dissolved in weak ammonia and converted into the copper salt by adding copper sulphate and evaporating off the ammonia; from the copper salt the acid is separated by hydrogen sulphide. It crystallises in small, yellowish-white needles melting at 225°, and is sparingly soluble in light petroleum, but soluble in other solvents. The *ammonium*, *nickel*, *copper*, *lead*, and *silver* salts are described, as are also the *sulphonic acid*-derivative and its *barium* salt.

When phenylbenzoylorthobenzoic acid is heated with zinc-dust and ammonia, *phenylbenzhydrylorthobenzoic lactone*,

$$CO{<}{}^{C_6H_4}_{-O-}{>}CH{\cdot}C_6H_4Ph,$$

is formed; it crystallises in colourless nodules, and melts at 204°; when heated to a higher temperature, a part sublimes, the sublimate melting at 205—206°; it is soluble in most solvents. By carrying the reduction still further, *phenylbenzylorthobenzoic acid*,

$$C_6H_4Ph{\cdot}CH_2{\cdot}C_6H_4{\cdot}COOH,$$

is obtained; it forms well-formed, colourless, or slightly red crystals which melt at 184—185° without decomposition, and are soluble in alcohol and in ether; the *silver salt* was obtained. A. G. B.

Truxene- and Truxone-derivatives. By C. LIEBERMANN and O. BERGAMI (*Ber.*, 23, 317—322; compare Abstr., 1889, 698, and Hausmann, *ibid.*, 1172).—The quinone-like compound obtained by oxidising truxene is identical with tribenzoylenebenzene (Gabriel and Michael, Abstr., 1878, 734). The molecular formula of truxone has not yet been ascertained, but it is probably a tribenzoylenehexahydrobenzene $(C_9H_6O)_3$.

When truxone is boiled with hydroxylamine in glacial acetic acid solution, it is gradually but completely converted into a colourless, insoluble powder which contains nitrogen; this compound is only very sparingly soluble in boiling alkalis, and is, probably, the anhydride of the oxime. When heated at 100° for a short time with concentrated sulphuric acid, it is converted into the *oxime*, which is precipitated on adding water. The oxime is, however, unstable, and is almost completely reconverted into the anhydride when it is dried. The *acetyl*-derivative, $(C_9H_6{:}N{\cdot}OAc)_3$, can be obtained by boiling the oxime with acetic anhydride. It crystallises in small needles, melts at 261°, and is moderately easily soluble in glacial acetic acid; when boiled with alcoholic potash, or when heated at 100° with concentrated sulphuric acid, it is reconverted into the oxime.

Dihydrodiphenylenehydroxyanthraquinone,

$$\mathrm{CHPh}<\begin{matrix}\mathrm{CH{:}C}\\ \mathrm{CH_2{\cdot}C}\end{matrix}>\mathrm{CH}\quad\mathrm{CO}<\begin{matrix}\mathrm{C_6H_3}\\ \mathrm{C_6H_2(OH)}\end{matrix}>\mathrm{CO},$$

is formed when truxone is melted with potash (12—15 parts). When the resulting deep-blue mass is treated with a little water, a small quantity of a purple-red dye passes into solution. On boiling the residue with a large quantity of water, a deep-blue solution is obtained, and on acidifying, the hydroxy-quinone is precipitated. It crystallises from glacial acetic acid or acetic anhydride in slender, dirty-yellow needles, melts at 266°, and is only sparingly soluble in ether, alcohol, and benzene. It dissolves slowly in cold alkalis with a violet-blue coloration, and in concentrated sulphuric acid forming a greenish-yellow solution, from which it is precipitated unchanged on adding water. The *acetyl*-derivative, $C_{28}H_{18}O_4$, prepared by boiling the hydroxyquinone with acetic anhydride and sodium acetate, crystallises from benzene in needles, melts at 180°, and is moderately easily soluble in alcohol, benzene, and glacial acetic acid.

F. S. K.

Synthesis of Chrysene and Allied Hydrocarbons. By G. KRAEMER and A. SPILKER (*Ber.*, 23, 84—87).—Klotz found that when the vapours of the higher boiling fractions of coal-tar were superheated, considerable quantities of chrysene were formed, but that neither mesitylene nor pseudocumene produced it when heated alone. He was, however, unable to continue his investigations, and the authors have therefore examined the action of heat on other constituents of coal-tar. They find that although neither coumarone nor naphthalene yield chrysene when heated alone, it is produced in considerable quantity when their mixed vapours are passed through a red-hot tube, water being formed at the same time. The reaction is represented by the equation

$$\mathrm{O}<\begin{matrix}\mathrm{C_6H_4}\\ |\\ \mathrm{C_2H_2}\end{matrix} + \mathrm{C_{10}H_8} = \mathrm{C_{10}H_6}<\begin{matrix}\mathrm{C_6H_4}\\ |\\ \mathrm{C_2H_2}\end{matrix} + \mathrm{H_2O}.$$

Further experiments showed that the power of coumarone to condense with hydrocarbons is not confined to naphthalene. When the mixed vapours of benzene and coumarone are passed through a red-hot tube, phenanthrene is formed.

It is thus probable that coumarone may play an important part in the formation of many of the condensed hydrocarbons found in coal-tar.

Researches on the Constitution of β-Nitrocamphor and of α-Chloronitrocamphor. By P. CAZENEUVE (*Bull. Soc. Chim.* [3], 2, 705—710).—The reduction of α-chloronitrocamphor by the zinc-copper couple yields α-nitrocamphor as the principal product, whereas reduction by sodium determines the formation of the β-derivative (compare Abstr., 1887, 842—970).

α-Chloronitrocamphor (100 grams) dissolved in boiling toluene (400 grams) is reduced with the theoretical amount of sodium, the precipitate formed is exhausted with alcohol, and from the solution silky needles of sodium β-nitrocamphorate separate on spontaneous evaporation of the solvent; these are identical with the product obtained from β-nitrocamphor, but differ from that yielded by α-nitrocamphor in producing an ochreous-red precipitate with ferric chloride, the α-derivative giving a blood-red coloration. An acetyl-derivative of this sodium salt exists. β-Nitrocamphor is formed by the action of hydrochloric acid on its sodium compound, and crystallises from light petroleum in white, badly-defined crystals, which melt at 83—84° (the melting point, 97°, previously given, being incorrect); it is perhaps identical with the nitrocamphor prepared by Schiff (Abstr., 1880, 891) from bromonitrocamphor.

β-Nitrocamphor differs from the α-derivative in giving Liebermann's reaction, and when it is treated with concentrated potash, potassium nitrite is formed; hence it appears to be a nitroso-derivative,  $C_8H_{14}<\begin{array}{l}C(OH)\cdot NO\\ |\\ CO\end{array}$, and the author thinks that it is formed by an intramolecular change from the α-compound, which is a nitro-derivative,  $C_8H_{14}<\begin{array}{l}CH\cdot NO_2\\ |\\ CO\end{array}$.

α-Chloronitrocamphor is probably a chloroxynitroso-derivative, as it also gives Liebermann's reaction with phenol and sulphuric acid, and when treated with potash lye yields potassium nitrite at a lower temperature than that at which potassium nitrate is reduced; again, when boiled in strong alcohol with finely-divided zinc, copper, or iron, the chlorine-atom is removed, as in the case of hexachlorophenol, and two isomeric zinc salts are produced corresponding with the general formulæ  $C_8H_{14}<\begin{array}{l}C(OM)\cdot NO\\ |\\ CO\end{array}$ and  $C_8H_{14}<\begin{array}{l}CM\cdot NO_2\\ |\\ CO\end{array}$.

T. G. N.

New Bases derived from Camphor: Camphamines. By P. Cazeneuve (*Bull. Soc. Chim.* [3], 2, 715—717).—On heating α-chlorocamphor (5 grams) with saturated aqueous ammonia (20 grams) in sealed tubes at 180° for 24 hours, a black mass is formed; this is dissolved in acetic acid at 100°, and to the solution, after precipitation and filtration of the unaltered chlorocamphor by addition of water, an excess of potassium carbonate is added, and the precipitated base is extracted with ether.

The base is removed from its solution in ether by agitation with water acidified with hydrochloric acid, and is precipitated by aqueous ammonia, and after washing dried in a vacuum; the yield is about 2 per cent.

This camphamine, $C_{10}H_{15}O\cdot NH_2$, crystallises from light petroleum in radiating groups of needles, melts at 180°, and has the odour of old tobacco; it is insoluble in water, but is soluble in alcohol, ether, and chloroform, and also in weak acids, from which its corresponding salts crystallise; the hydrochloride forms long, colourless needles. Unlike the base obtained from camphor by Schiff (Abstr., 1880, 892), this does not reduce Fehling's solution, and is unattacked by acetic chloride.

From the chlorocamphor obtained by acting on camphor with hypochlorous acid, an isomeric base may be obtained in like manner. This is not crystalline, and is unstable.

Both these bases are precipitated by the ordinary reagents for alkaloids. T. G. N.

Camphoric Acid. By E. BAMBERGER (*Ber.*, 23, 218—219).—Camphoric acid does not unite with hydrogen bromide even when heated at 120° with a solution saturated at 0°, and is only attacked with great difficulty by potassium permanganate. It cannot, therefore, contain any carbon-atoms united in the same manner as those of ethylene, and the author, therefore, believes the usually accepted formula of camphoric acid,  $\begin{array}{l}CH_2\cdot CPr\cdot COOH\\ |\qquad\ |\\ CH_2\cdot CMe\cdot COOH\end{array}$, according to which it is a derivative of tetramethylene, to be correct. This corresponds with the formula  $\begin{array}{l}CH_2\cdot CPr\cdot CH_2\\ |\qquad\ |\qquad |\\ CH_2\cdot CMe\cdot CO\end{array}$ for camphor. H. G. C.

Action of Carbon Bisulphide on Menthol and Borneol. By E. BAMBERGER and W. LODTER (*Ber.*, 23, 213—215).—The resemblance which exists between both the camphor alcohols and the alicyclic β-tetrahydronaphthol has led the authors to examine the action of carbon bisulphide on menthol and borneol; the results obtained show that these alcohols likewise form xanthic acids.

Menthylxanthic acid, $C_{10}H_9O\cdot CSSH$. To obtain this compound, an ethereal solution of menthol is treated with fine slices of sodium until no more dissolves, the solution, which contains the sodium compound partly in suspension, is then separated from the excess of sodium, and carbon bisulphide added; after remaining for two hours, the greater part of the ether and unaltered carbon bisulphide is distilled off, and the residue shaken with water, which takes up the sodium salt of the menthylxanthic acid, unaltered menthol remaining dissolved in the ether. Copper sulphate solution precipitates a dark-brown amorphous *cupric* salt, which readily passes into the *cuprous* salt on warming. This is purified by washing with water and ether, dissolving in carbon bisulphide, evaporating off the greater part of the latter, and adding light petroleum. Thus obtained the cuprous salt forms a heavy, yellow, crystalline powder. The free acid is obtained from the sodium salt by the addition of mineral acids as an unstable oil, which readily decomposes with evolution of hydrogen sulphide.

Bornylxanthic acid, $C_{10}H_{17}O\cdot CSSH$, is obtained in a similar manner from borneol. Its cuprous salt is, like the corresponding menthyl-compound, a heavy, yellow, crystalline powder.

H. G. C.

Active and Inactive Bornyl Phenylcarbamates and Isobornyl Phenylcarbamates. By A. HALLER (*Compt. rend.*, **110**, 149—152).—Bornyl phenylcarbamates are obtained by the interaction at the ordinary temperature of phenyl isocyanate and a camphol in molecular proportion; the hard, compact, crystalline mass thus obtained is recrystallised from alcohol. All the bornyl phenylcarbamates form slender, white needles which dissolve in ether, benzene, and toluene, but are only slightly soluble in cold alcohol and in light petroleum. The melting point varies with the particular camphol from which they are derived. The rotatory powers and melting points are given in the following table:—

	Melting point.	$[\alpha]_D$.
Dextrogyrate α-bornyl phenylcarbamate..	137·75°	+34·22°
Lævogyrate α- ,, ,, ..	137·25	−34·79
Lævogyrate β- ,, ,, ..	130·05	−56·77
Racemic −α +α ,, ,, ..	140·00	—
Bornyl phenylcarbamate from inactive camphol +α −β....................	133·00	−7·50
Bornyl phenylcarbamate from inactive camphol −α +β	132·60	+7·32

The melting points and rotatory powers of analogous pairs are practically identical, but the rotatory power of the β-derivatives is higher than that of the isomeric α-derivatives, and as a consequence the phenylcarbamates from the inactive αβ-camphols are active. β-Bornyl phenylcarbamate, unlike β-borneol, has the same rotatory power in solution in benzene as in alcohol. It would seem that in the isocamphols, it is the asymmetrical group $:C\cdot CH<^{CH_3}_{OH}$ which is affected by the solvent, and that when this group enters into combination the influence of the solvent disappears. C. H. B.

Apiole. By J. GINSBERG (*Ber.*, **23**, 323—325; compare Abstr., 1888, 1206).—Aponic acid is formed when manganese dioxide (60 grams) is added, in small portions at a time, to a boiling mixture of concentrated sulphuric acid (60 grams), water (240 grams), and isoapiole (6 grams). The whole is boiled for four hours with frequent agitation, the boiling solution filtered, and the residue repeatedly extracted with boiling water; the acid is extracted from the concentrated filtrate with ether, and purified by dissolving it in ammonia and reprecipitating with an acid. It crystallises from boiling water, in which it is only sparingly soluble, in small, colourless needles, and melts at 252° with decomposition. It is almost insoluble in cold water, benzene, and light petroleum, and only sparingly in ether, but more readily in hot alcohol and carbon bisulphide; it dissolves in concentrated sulphuric acid forming a colourless solution, from which it is reprecipitated unchanged on adding water.

The composition of this acid is probably either $C_{11}H_{14}O_6$ or $C_{14}H_{10}O_6$.

Apiole does not give an oxidation-product under the conditions described above.

Aponic acid is not acted on by concentrated hydriodic acid or hydrochloric acid at 200°, and it undergoes no change when boiled for a long time with a mixture of nitric acid and concentrated sulphuric acid. Chromic acid, bromine, chlorine, phosphorous chloride, phosphoric chloride, phenylhydrazine, and hydroxylamine have no action on aponic acid. The *calcium* salt is a colourless, granular powder, sparingly soluble in cold but more readily soluble in boiling water. The *barium* salt separates from dilute alcohol in the form of a colourless, granular powder. The *silver* salt is colourless, and could not be obtained in a crystalline condition. The *ethyl* salt, prepared from the silver salt, crystallises from boiling water in long, slender needles, melts at 119—120°, and is moderately easily soluble in most ordinary solvents, but insoluble in alkalis. It dissolves in concentrated sulphuric acid, forming a colourless solution, but is reprecipitated unchanged on adding water; it is not acted on by phenylhydrazine or by hydroxylamine, but it seems to be decomposed by boiling water.

The analyses of the salts gave results which leave the composition of the acid undecided. F. S. K.

Diastase. By C. J. LINTNER and F. ECKHARDT (*J. pr. Chem.* [2], **41**, 91—96; compare Abstr., 1886, 386; 1887, 165; 1888, 497).—To settle whether malt diastase and the ferment of ungerminated grain are identical, it is necessary to compare their action on starch, both as to the most favourable temperature and the quantity of sugar produced (reducing-power). To this end, the authors arranged the temperatures as abscissæ, and the reducing-powers as ordinates, of a curve, and found that, when acting on soluble starch, diastase showed the greatest activity at 50°, and the most favourable period at 50—55°. The ferment of ungerminated grain, on the other hand, showed the greatest activity at 50°, and the most favourable period at 45—50°. Moreover, at 4° the reducing-power of the grain ferment was as high as that of diastase at 14·5°; at 35° it was the same for both; but the maximum reducing-power reached by the grain ferment was 41·2, whilst that reached by the diastase was 51·0. It is thus seen that the grain ferment is less intense in its action at 50° than diastase is, but at the ordinary temperature the reverse is the case.

The following is a comparison of the above results for diastase with those of Kjeldahl, who used starch paste.

	Reducing power of diastase at		
	50°.	55°.	62°.
With soluble starch	50·16	50·02	27·30
„ starch paste	49·83	50·23	35·24

The authors doubt the existence of Reychler's artificial diastase (Abstr., 1889, 621); it is most probably identical with the ferment of ungerminated grain, and may possibly be this ferment and not a conversion-product of the gluten. The activity of diastase is not due to bacteria. A. G. B.

Synthesis of Alcohol-acids of the Pyridine Series. By A. Einhorn (*Ber.*, **23**, 219—224),—By the further investigation of ω-trichloro-α-hydroxypropylpyridine (Abstr, 1887, 845) a number of new pyridine-derivatives containing fatty residues have been obtained, some of which have an especial interest as standing in close relation to ecgonine and cocaine.

Pyridyl-ω-trichloropropylene, $C_5NH_4{\cdot}CH{:}CH{\cdot}CCl_3$, is obtained by the action of phosphoric chloride on ω-trichloro-α-hydroxypropylpyridine. It crystallises from absolute alcohol in prismatic needles, melting at 97°.

Pyridyl-α-lactic acid, $C_5NH_4{\cdot}CH_2{\cdot}CH(OH){\cdot}COOH$, is formed when an aqueous solution of ω-trichloro-α-hydroxypropylpyridine is boiled with sodium carbonate, and is isolated in the form of a basic copper salt, $(C_8H_8NO_3)_2Cu,CuO$. The free acid crystallises in transparent prisms which melt at 124—125°, and its *platinochloride* and *aurochloride* melt at 202—204° and 173—174° respectively. Its *methyl* salt, obtained by acting on the silver salt with methyl iodide, is a light-yellow oil, the aurochloride of which melts at 119°. The methyl salt does not yield a benzoyl compound directly, but it may be obtained by boiling the free pyridyl-α-lactic acid with benzoic anhydride, and treating the silver salt of the acid thus obtained with methyl iodide. It has the formula $C_5NH_4{\cdot}CH_2{\cdot}CH(OBz){\cdot}COOMe$, and forms a light-coloured oil. Its *platinochloride* crystallises in light-yellow needles, which melt at 193° with decomposition.

Pyridylacrylic acid, $C_5NH_4{\cdot}CH{:}CH{\cdot}COOH$, is prepared by boiling ω-trichloro-α-hydroxypropylpyridine with alcoholic potash, pyridyl-α-lactic acid being formed at the same time. It is likewise formed when the latter is heated at 130—140° in a vacuum. It crystallises from hot water in stellate groups of white needles, which melt at 202—203°, and gives crystalline salts with the haloïd acids. The *aurochloride* forms pale yellow needles, melting at 194—195°, and the *platinochloride* reddish-yellow prisms, melting at 209—210°. Its salts with the alkali metals are gelatinous, but the calcium and silver salts are crystalline, and its methyl and ethyl salts likewise crystallise at low temperatures. It unites with methyl iodide, forming a methiodide, which crystallises from alcohol in needle-shaped crystals melting at 219—220°. Pyridylacrylic acid unites with bromine in acetic acid solution, forming a *perbromide*, but yields the *dibromide* at 100°; this crystallises from water in yellowish prisms melting at 127°.

Pyridyl-β-lactic acid, $C_5NH_4{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$. When pyridylacrylic acid is heated at 100° with an acetic acid solution of hydrogen bromide in a sealed tube, it forms pyridyl-β-bromopropionic acid, $C_5NH_4{\cdot}CHBr{\cdot}CH_2{\cdot}COOH$, which crystallises in white needles, melting at 163—164°. If this be neutralised with a solution of sodium carbonate, and the liquid warmed, pyridylethylene or vinylpyridine, $C_5NH_4{\cdot}CH{:}CH_2$, is evolved, whilst pyridyl-β-lactic acid and regenerated pyridylacrylic acid remain in solution. The former is extremely soluble in water, and crystallises from it in slender, white needles. Its most characteristic salt is the *basic copper salt*, which forms well-developed sapphire-blue crystals. Its *hydrochloride* forms compact prisms, melting at 145—146°, whilst the *platinochloride* melts at 191°. The *methyl* salt, prepared by passing hydrogen chloride into an alcoholic solution of the acid, is a pale yellow oil. The benzoyl compound of the methyl salt could not be obtained directly, but was prepared in the following manner. Ethyl pyridyl-β-lactate (or its hydrochloride) was boiled with benzoic chloride on the water-bath, poured into water, made alkaline with sodium carbonate, and extracted with ether. The oil remaining after the evaporation of the ether was dissolved in hydrochloric acid, and allowed to remain for a few days. The product is the hydrochloride of *benzoylpyridyl-β-lactic acid*, which decomposes on the addition of water, yielding the free acid. This crystallises from water in brilliant prisms, melting at 135·5°, and is converted into the *methyl* salt by heating its silver salt with methyl iodide in a sealed tube; this crystallises from ether in transparent prisms melting at 79°.

Pyridylglyceric acid, $C_5NH_4·CH(OH)·CH(OH)·COOH$, is obtained by the careful oxidation of pyridylacrylic acid with dilute potassium permanganate. Its *hydrochloride* crystallises with 1 mol. of water, and melts at 189—190°. Its *ethyl* salt forms transparent tablets melting at 95—96°, and yields with benzoic chloride a crystalline compound which melts at 121—122°. H. G. C.

2′-Bromoquinoline. By A. CLAUS and G. POLLITZ (*J. pr. Chem.* [2], **41**, 41—48).—*2′-Bromoquinoline* is obtained by heating carbostyril (1 part) with phosphorus pentabromide (3 parts) in a stream of dry carbonic anhydride at 120—130°, and distilling the product with steam; it crystallises from alcohol in lustrous, colourless needles, melting at 48—49° (uncorr.), and soluble except in water, which decomposes them on boiling. The *platinochloride* (with 2 mols. H_2O), the *methiodide*, and the *methochloride* and its *platinochloride* are described.

Three *nitro-1′-bromoquinolines* were obtained by nitrating 1′-bromoquinoline in the cold, (1) small, white needles melting at 244° (uncorr.); (2) lustrous prisms or tables melting at 146° (uncorr.), and distilling without decomposition at 225—228°; (3) yellow leaflets and needles melting at 111° (uncorr.). When these nitro-derivatives are boiled with water, they are converted into corresponding *nitrocarbostyrils* (compare Friedländer and Lazarus, Abstr., 1885, 1139), whose properties are as follows, taking the same order as above: (1) snow-white needles melting at 283° (uncorr.), and subliming; its *potassium salt* forms yellow needles; (2) yellow, strongly refractive, four-sided prisms melting at 163° (uncorr.), and sparingly soluble; its *potassium* and *sodium salts*, its *hydrochloride* (m. p. 159—160°) and its *platinochloride* are described; (3) small, yellow needles which melt at 302° (uncorr.), with decomposition and blackening; its *potassium salt* is described.

Only one sulphonic acid has as yet been obtained by sulphonating 1′-bromoquinoline (1 part) with 40 per cent. anhydrosulphuric acid (10 parts) at 120—130°. *1′-bromoquinolinesulphonic acid* crystallises in small, colourless needles which melt with decomposition at 288—290°, but begin to darken in a capillary tube at 190°. The *potassium salt* (with 2 mols. H_2O), the *barium salt* (with $2\frac{1}{2}$ mols. H_2O), the *copper salt*, the *silver salt* (with 1 mol. H_2O), the *methyl salt* (m. p. 190°), and the *ethyl salt* (m. p. 135° uncorr.) are described.

A *tribromoquinoline* is obtained by brominating the above sulphonic acid; it crystallises in long, lustrous, colourless, efflorescent needles, with 1 mol. H_2O, melting at 247—248° (uncorr., compare this vol., p. 267) to a brown oil, which solidifies again, and sublimes in slender, felted needles.

A. G. B.

1 : 4-Hydroxyquinolinesulphonic Acid. By A. CLAUS and M. POSSELT (*J. pr. Chem.* [2], 41, 32—41; compare this vol., pp. 265, 268).

1 : 4-*Hydroxyquinolinesulphonic acid*, prepared by the action of cold fuming sulphuric acid (6—8 parts) on 1-hydroxyquinoline (1 part), crystallises in long, colourless needles, containing 1 mol. H_2O, which is lost at 120°; it decomposes at about 270° without melting, and is soluble in alcohol, glacial acetic acid, and dilute hydrochloric acid; with diazo-compounds it gives red dyes, with ferric chloride a green colour, and with ferrous sulphate a dark-brown precipitate. The *normal sodium salt*, $OH{\cdot}C_9NH_5{\cdot}SO_3Na + H_2O$, the *basic sodium salt*, $ONa{\cdot}C_9NH_5{\cdot}SO_3Na + 2H_2O$, the *normal potassium salt* (with 1 mol. H_2O), the *basic potassium salt* (with 3 mols. H_2O), the *normal barium salt* (with 1 mol. H_2O), the *normal calcium salt* (with 1 mol. H_2O), and the *silver salt* are described. When this sulphonic acid is heated with methyl iodide in hydrochloric acid at 110°, *methylhydroxysulphonebetaine* [$SO_3 : OH : Me = 1 : 4 : 1'$] is obtained as slender needles which decompose without melting at 250°.

Bromo-1 : 4-*hydroxyquinolinesulphonic acid* results from the action of bromine on the sulphonic acid (equal mols.), when they are gradually mixed; it crystallises in small prisms or needles which contain 1 mol. H_2O (lost at 120°), decomposes without melting at 280°, and is freely soluble in alcohol.

When bromine (2 mols.) is added (all at once) to the aqueous solution of the sulphonic acid (1 mol.), *dibromo-1-hydroxyquinoline* is obtained; it crystallises in lustrous, colourless needles, melting at 196° (uncorr.), and soluble in most solvents, except water and light petroleum.

The action of phosphorus pentabromide (2 mols.) on 1 : 4-hydroxyquinolinesulphonic acid at 130—140° produces *bromoquinolinesulphonic bromide*, $C_9NH_5Br{\cdot}SO_2Br$, which decomposes when heated with water, yielding 1 : 4-bromoquinolinesulphonic acid (Lellmann and Lange, Abstr., 1888, 296); this settles the constitution of 1 : 4-hydroxyquinolinesulphonic acid. If the hydroxyquinolinesulphonic acid (1 mol.) is heated with phosphorus pentabromide ($4\frac{1}{2}$ mols.) at 160—170°, a tribromoquinoline is produced, as well as the bromide; it melts at 168° (uncorr.; compare this vol., p. 173).

1 : 4-*Chloroquinolinesulphonic chloride*, obtained by the action of phosphorus pentachloride on 1 : 4-hydroxyquinolinesulphonic acid, forms small, colourless needles which decompose without melting.

1 : 4-*Chloroquinolinesulphonamide* crystallises in small, colourless needles, which have no melting point, and are insoluble in water, but soluble in other solvents.

1 : 4-*Chloroquinolinesulphonic acid* forms colourless needles with 1 mol. H_2O, decomposes without melting at about 280°, is sparingly soluble in water, and gives red dyes with diazo-compounds.

Trichloroquinoline forms slender, colourless needles, melting at 68°, (uncorr.).

1 : 4-*Dihydroxyquinoline*, obtained by fusing 1 : 4-hydroxyquinolinesulphonic acid with potash, crystallises in slender needles which are insoluble in water, and decompose without melting above 270°.

1-*Hydroxyquinolinedisulphonic acid*, obtained by heating 1-hydroxyquinoline with fuming sulphuric acid, forms large, colourless, prisms with 1 mol. H_2O, which is lost at 120°; it decomposes without melting about 280°.

A *dinitrohydroxyquinoline* has been obtained; it forms yellow needles which have no melting point.

The investigation of the above compounds is not yet complete.

A. G. B.

3-Hydroxyquinolinesulphonic Acid. By A. Claus and M. Posselt (*J. pr. Chem.* [2], **41**, 158—160; compare Lippmann and Fleissner, this vol., p. 268).—3-*Hydroxyquinolinesulphonic acid*, obtained by sulphonating 3-hydroxyquinoline with fuming sulphuric acid, crystallises in yellow needles with ½ mol. H_2O; it decomposes at 270°, and dissolves sparingly in water, more freely in alcohol, but not in ether, chloroform, or benzene; it does not form dyes with diazo-compounds. The *neutral sodium* and *potassium salts* (each with 1 mol. H_2O) are described. With 1 mol. of bromine, the acid yields a *bromo-3-hydroxyquinolinesulphonic acid*, whilst with 2 mols. of bromine a *dibromo-3-hydroxyquinoline* crystallising in slender, yellow needles, soluble in alcohol and insoluble in water, is obtained. A. G. B.

The First Synthetically prepared Base Isomeric with Quinine. By C. A. Kohn (*J. Soc. Chem. Ind.*, 8, 959—960).—With regard to Wallach and Otto's claim that pinolenitrol-β-naphthylamine (this vol., p. 170) is the first base isomeric with quinine that has been produced synthetically, the author points out that this is not the case, as three years back he synthesised hydroxyhydroethylenequinoline, an isomeride of quinine (Trans., 1886, 508).

Phen-α-phenylparazoxime. By E. Lellmann and A. Donner (*Ber.*, **23**, 172—174).—*Metanitrophenol phenacyl ether*,

$$NO_2\cdot C_6H_4\cdot O\cdot CH_2\cdot COPh,$$

is best prepared by heating an intimate mixture of potassium orthonitrophenoxide and phenacyl bromide at 68° for 4 hours, the warm mass being triturated from time to time in order to ensure complete decomposition. The product is washed with water, then with dilute soda, and recrystallised from alcohol. It forms well-defined needles, melts at 118°, and is soluble in benzene, chloroform, and glacial acetic acid, but more sparingly in ether and alcohol, and almost insoluble in water and concentrated hydrochloric acid; it is decomposed by boiling soda, yielding orthonitrophenol.

Phen-α-phenylparazoxine,  $C_6H_4\left<\begin{array}{l}O\cdot CH_2\\ \ \ |\\ N:CPh\end{array}\right.$, is obtained when the preceding compound is reduced with stannous chloride and concentrated hydrochloric acid; the intermediate product (amidophenol phenacyl ether) cannot be isolated. The acid solution is gradually poured into yellow ammonium sulphide, the precipitate washed first with ammonium sulphide and then with water, and recrystallised from warm alcohol. It forms colourless needles, melts at 102—103°, and is readily soluble in benzene, ether, chloroform, and mineral acids, but only sparingly in warm water, from which it separates in plates. When heated in small quantities, it distils with partial decomposition giving off a pleasant odour recalling that of oranges. It dissolves in concentrated hydrochloric acid and in sulphuric acid with a red coloration, which changes to yellow on adding water. The *platinochloride*, $(C_{14}H_{11}ON)_2,H_2PtCl_6$, and the *aurochloride* crystallise in microscopic plates and are unstable. Potassium dichromate and stannous chloride produce precipitates in solutions of the hydrochloride. F. S. K.

Preparation of Anhydro-bases from Amidomercaptans of the Fatty Series. By S. GABRIEL and P. HEYMANN (*Ber.*, 23, 157—160). *Phenylthiazoline*,  $CPh\left<\begin{array}{l}S\cdot CH_2\\ \ \ |\\ N\cdot CH_2\end{array}\right.$, is obtained when thiobenzamide (20 grams) is boiled for about $1\frac{1}{2}$ hours with ethylene bromide (200 grams); after separating the unchanged bromide by distilling with steam, the solution is filtered, saturated with alkali, again distilled with steam, and the product (about 7 grams) extracted by shaking the distillate with ether. It is a yellowish oil with an odour of quinoline, and boils at 275—277° without decomposition. It dissolves freely in acids. The *picrate* crystallises from boiling water in long, yellow needles. The *platinochloride*, $(C_9H_9NS)_2,H_2PtCl_6$, is a yellow, crystalline compound. When a solution of the base in hydrochloric acid is treated with bromine, it is converted into a thick, brownish syrup (benzoyltaurine) which is readily soluble in water. This syrup gives benzoic acid and taurine when heated at 150—160° with concentrated hydrochloric acid; it also forms a crystalline silver salt of the composition $C_9H_{10}NSO_4Ag$. F. S. K.

Constitution of the Quinoxalines obtained from Toluylenediamine and Bromacetophenone. By E. LELLMANN and A. DONNER (*Ber.*, 23, 166—171).—*Phenacylparatoluidine*, $C_6H_4Me\cdot NH\cdot CH_2\cdot COPh$, is easily obtained by treating paratoluidine (2 mols.) with bromacetophenone (1 mol.) in cold alcoholic solution, and dissolving the product in hot concentrated hydrochloric acid, or recrystallising it from alcohol in order to separate the diphenacyl-derivative which is also produced. The *hydrochloride* and the *nitrate* crystallise in colourless needles. The free *base* crystallises from alcohol in large, yellow plates, melts at 134°, and decomposes when heated. It is readily soluble in benzene, more sparingly in alcohol, glacial acetic acid, and warm, concentrated hydrochloric acid, and it dissolves in concentrated sulphuric acid forming a colourless solution.

Diphenacylparatoluidine, $C_6H_4Me·N(CH_2·COPh)_2$, crystallises from xylene in colourless needles, melts at 255°, and is very sparingly soluble in alcohol, benzene, and concentrated hydrochloric acid; it is not decomposed by warm soda.

Phenacylmetanitroparatoluidine, $NO_2·C_6H_3Me·NH·CH_2·COPh$, is prepared by triturating phenacylparatoluidine with nitric acid of sp. gr. 1·138 (30 parts), and keeping the mixture for 48 hours. It crystallises from alcohol in golden needles, melts at 163—165° with decomposition, and is readily soluble in benzene and chloroform, but more sparingly in alcohol. This compound can also be obtained, but only in small quantities, by dissolving bromacetophenone and metanitroparatoluidine in alcohol, and keeping the solution for some time over anhydrous magnesia. The *dinitro*-compound, $C_{15}H_{13}O_5N_3$, obtained by dissolving phenacylparatoluidine in nitric acid of sp. gr. 1·4, crystallises in golden needles, melts at 156° with decomposition, and is readily soluble in benzene and chloroform, but only sparingly in alcohol; it is decomposed by warm soda.

When phenacylmetanitroparatoluidine is treated with stannous chloride and cold concentrated hydrochloric acid, it is converted into the corresponding amido-derivative; the latter is, however, unstable, and immediately decomposes into water and dihydrophenyltoluquinoxaline. This compound cannot be isolated, as it quickly undergoes oxidation on exposure to the air, being converted into phenyltoluquinoxaline (m. p. 79°), identical with one of the compounds obtained from toluylenediamine (compare Hinsberg, Abstr., 1887, 817). The constitution of this quinoxaline is, therefore,

$C_6H_4Me<\begin{matrix}N:CPh\\ |\\ N:CH\end{matrix}$

[N : N : Me = 1 : 3 : 5], and that of the isomeride (m. p. 136°)

$$C_6H_4Me<\begin{matrix}N:CPh\\ |\\ N·CH\end{matrix}$$

[N : N : Me = 1 : 3 : 4].

F. S. K.

Paradiazine-derivatives. By P. W. ABENIUS (*J. pr. Chem.* [2], **41**, 79—86; compare this vol., p. 268).—*Dioxanilide*,

$$NPh<\begin{matrix}CO·CO\\ CO·CO\end{matrix}>NPh,$$

is obtained by shaking together hot, glacial acetic acid solutions of diphenyldiketodihydroparadiazine (this vol., p. 268) and chromic acid; the anilide crystallises out after a time. It forms small, lustrous, thin, six-sided crystals (m. p. not given) sparingly soluble in the usual solvents; when heated with aniline it is converted into oxanilide. If a large excess of chromic acid is used, and the mixture heated for 15—20 minutes and then evaporated on the water bath, a residue of diphenylparabanic acid (Abstr., 1885, 1196) is left.

Dioxalparatoluidide, $C_6H_4Me·N:(CO·CO)_2:N·C_6H_4Me$ [N : Me = 4 : 1], obtained in like manner to dioxanilide, crystallises in small, sparingly soluble, lustrous, six-sided leaflets melting above 300°. From the mother liquor, diparatolylparabanic acid (Abstr., 1878, 216) was obtained.

When diorthotolyldiketodihydroparadiazine is oxidised with chromic acid, only diorthotolylparabanic acid (Abstr., 1880, 244) is formed.

Diphenyldichlorodiketoparadiazine, $\begin{matrix}CO-CCl\cdot NPh\\ | \quad\quad | \quad\quad |\\ NPh\cdot CCl\cdot CO\end{matrix}$, produced by acting on diphenyldiketodihydroparadiazine with phosphorus pentachloride and oxychloride, decomposing with water, and dissolving the product in alcohol, crystallises in white needles or prisms (with 1 mol. alcohol), melting at 247°; by reduction it yields *diphenyldiketoparadiazine*, which is still under investigation.

Phenylorthotolyldichlorodiketoparadiazine,

$$\begin{matrix}CO-CCl\cdot N\cdot C_6H_4Me\\ | \quad\quad | \quad\quad |\\ NPh\cdot CCl\cdot CO\end{matrix} \quad [Me:N = 1:2],$$

obtained in the same way, crystallises in white needles melting at 174—175° and is soluble in alcohol, ether, and benzene.

Orthotolylparatolyldichlorodiketoparadiazine,

$$C_4N_2Cl_2O_2(C_6H_4Me)_2 \; [Me : N = 1 : 2 \text{ and } 1 : 4 \text{ respectively}],$$

crystallises in white, slender needles (with 1 mol. alcohol) melting at 146°.

A. G. B.

Derivatives of Aromatic Thiocarbamides. By D. S. Hector (*Ber.*, **23**, 357—370).—In a previous paper (Abstr., 1889, 872) the author has shown that phenylthiocarbamide is oxidised by hydrogen dioxide to *dianilido-orthodiazothiole*, $S<\begin{matrix}C(NHPh):N\\ \quad\quad\quad\quad |\\ C(NHPh):N\end{matrix}$. This name it is proposed to change to *diphenyldiamido-orthodiazothiole*, in accordance with Widman's nomenclature (*Journ. Prakt. Chem.*, **38**, 185). Further study has shown that this reaction is a general one for the aromatic mono- and di-substituted thiocarbamides. Only one of the latter has been prepared, namely, *tetraphenyldiimidotetrahydro-orthodiazothiole*, $S<\begin{matrix}C(NPh)\cdot NPh\\ \quad\quad\quad\quad |\\ C(NPh)\cdot NPh\end{matrix}$. This melts at 131°, and forms a hydrochloride and sulphate which are sparingly soluble in water, but readily in alcohol.

Di-α-naphthyldiamido-orthodiazothiole, $S<\begin{matrix}C(NH\cdot C_{10}H_7):N\\ \quad\quad\quad\quad\quad |\\ C(NH\cdot C_{10}H_7):N\end{matrix}$. To prepare this compound, 2—3 grams of α-naphthylthiocarbamide are suspended in a litre of boiling water, and hydrochloric acid, and a solution of hydrogen peroxide are then added. After boiling for a short time, the separated sulphur is filtered off, ammonia added, and the precipitated di-α-naphthyldiamido-orthodiazothiole recrystallised from alcohol. It forms white needles which contain 1 mol. of alcohol; these readily assume a reddish tinge, and melt at 104°. When crystallised from acetone, it melts at 136°. It forms a light-brown double salt with mercuric chloride melting below 100°, and a similarly coloured *platinochloride*, $(C_{22}H_{16}N_4S)_2,H_2PtCl_6$, which melts with decomposition at 224—225°. The *silver nitrate*-derivative, $C_{22}H_{16}N_4S,AgNO_3$, is a white precipitate, insoluble in alcohol, which blackens in sunlight, whilst the *picrate*, $C_{22}H_{16}N_4S,C_6H_2(NO_2)_3\cdot OH$, crystallises with ½ mol. of alcohol in yellow grains which melt under 100°. The *monacetyl*- and *monobenzoyl*-derivatives melt at 263° and 270° respectively.

Di-α-naphthyldiamido-orthodiazothiole cyanide, 
$$\begin{matrix}N-C-N(C_{10}H_7)\cdot C:NH\\ |\quad\ \ S\qquad\qquad\qquad\ \ |\\ N-C-N(C_{10}H_7)\cdot C:NH\end{matrix},$$

separates in a crystalline form when cyanogen is passed through a warm alcoholic solution of the base; it melts at 203°.

Di-β-naphthyldiamido-orthodiazothiole, 
$$S<\begin{matrix}C(NH\cdot C_{10}H_7):N\\ \qquad\qquad\quad |\\ C(NH\cdot C_{10}H_7):N\end{matrix},$$

is prepared by adding hydrogen dioxide to an alcoholic solution of β-naphthylthiocarbamide containing a little hydrochloric acid, filtering, and adding ammonia. It is thus obtained as a thick, white mass, which is very soluble in the ordinary solvents, but has not been obtained crystalline. It commences to melt at 100°, but is not completely melted below 110—117°. Its *hydrochloride* and *sulphate* are less soluble in water than the salts of the α-base, but dissolve more readily in alcohol. It also gives compounds with platinic chloride, mercuric chloride, silver nitrate, and picric acid, and yields *acetyl*- and *benzoyl*-derivatives melting at 203° and 247° respectively. *Di-β-naphthyldiamido-orthodiazothiole cyanide*, $C_{24}H_{16}N_6S$, crystallises from alcohol in indistinct prisms melting at 200°.

Diparatolyldiamido-orthodiazothiole, 
$$S<\begin{matrix}C(NH\cdot C_7H_7):N\\ \qquad\qquad |\\ C(NH\cdot C_7H_7):N\end{matrix},$$

is prepared from paratolylthiocarbamide and hydrogen dioxide. It crystallises from alcohol in thick, yellowish prisms which melt at 127°. Its hydrochloride crystallises from water in white needles which melt with decomposition at 233°. The salts and double salts are similar to those of the foregoing compounds; the *acetyl*-derivative melts at 166°, and the *benzoyl*-derivative at 186°. The *cyanide*, $C_{18}H_{16}N_6S$, crystallises from alcohol in thin plates, seemingly aggregates of slender needles, which melt at 190°.

Nitrosodiparatolyldiamido-orthodiazothiole, 
$$S<\begin{matrix}C[N(NO)\cdot C_7H_7]\cdot C:N\\ \qquad\qquad\qquad\quad |\\ C[NH—C_7H_7]\cdot C:N\end{matrix},$$

is formed by the addition of potassium nitrite to a hydrochloric acid solution of the base. It forms a yellow precipitate with a greenish tinge, and melts at 247° with decomposition.

Diorthotolyldiamido-orthodiazothiole, 
$$S<\begin{matrix}C(NH\cdot C_7H_7)\cdot C:N\\ \qquad\qquad\qquad |\\ C(NH\cdot C_7H_7)\cdot C:N\end{matrix},$$

is obtained in a manner similar to the para-compound. It is very difficult to obtain crystalline, as it is very soluble in the ordinary solvents. It is thrown down from its solution in hydrochloric acid by ammonia as a white precipitate which melts at 135°. The same salts of this base have been prepared as of the foregoing, and also the *acetyl*- and *benzoyl*-derivatives, the first melting at 221°, and the second at 214°. The *cyanide*, $C_{18}H_{16}N_6S$, is not readily obtained crystalline, as it is also very soluble; it separates from its solution in alcohol and water in indistinct crystals which begin to melt at 89°. The *nitroso*-compound, $C_{16}H_5(NO)N_4S$, obtained in a manner similar to the corresponding paratolyl-compound, separates from alcohol in brown crystals which melt at 135°.

Dimetaxylyldiamido-orthodiazothiole, $S<\begin{matrix}C(NH\cdot C_8H_9)\cdot C{:}N\\ \vert \\ C(NH\cdot C_8H_9)\cdot C{:}N\end{matrix}$, is obtained in the same manner from metaxylylthiocarbamide; the latter compound is prepared from metaxylidine hydrochloride and ammonium thiocyanate, and forms a crystalline compound which is soluble in boiling water, more readily in alcohol, and melts at 176°. Dimetaxylyldiamido-orthodiazothiole is, like the foregoing tolyl base, difficult to obtain crystalline; it separates from its solution as an oil which after solidification melts at 79°. The *cyanide*, $C_{20}H_{20}N_6S$, melts at 103°, and the *nitroso*-derivative, $C_{18}H_{19}(NO)N_4S$, forms brown crystals which melt at 146°. H. G. C.

Narcotine. By W. Roser (*Annalen*, **254**, 334—358, 359—368; compare Abstr., 1888, 1115 and 1316, Abstr., 1889, 417).—In this paper, the author gives an account of experiments which have been made to ascertain the constitution of cotarnine.

Benzoylcotarnine, $C_{12}H_{14}NO_4Bz + \frac{1}{2}H_2O$, can be easily prepared by treating cotarnine with benzoic chloride and soda in the cold, according to Baumann's method. It crystallises from hot alcohol, in which it is very readily soluble, in long, colourless needles, melts at 122—123°, and is insoluble in water. The *oxime*,

$$NOH{:}CH\cdot C_8H_6O_3\cdot CH_2\cdot CH_2\cdot NMeBz,$$

separates from alcohol in small, colourless crystals, melts at 165—166°, and is readily soluble in alcohol and soda, but insoluble in water and ether. Benzoylcotarnine combines readily with phenylhydrazine, yielding a crystalline, unstable hydrazone.

Cotarnine oxime hydrochloride, $C_{12}H_{16}N_2O_4,HCl$, separates on cooling in small, yellowish needles when cotarnine is boiled for some hours with an alcoholic solution of hydroxylamine hydrochloride; it is readily soluble in water, but only moderately easily in alcohol. The crystalline *platinochloride*, $(C_{12}H_{16}N_2O_4)_2,H_2PtCl_6 + 2H_2O$, is sparingly soluble in cold, and is decomposed by boiling water. The *mercurochloride* crystallises from hot water in long, colourless needles. The free *oxime*, $C_{12}H_{15}NO_3{:}NOH$, prepared by decomposing an aqueous solution of the salt with sodium carbonate, crystallises from alcohol in short prisms, turns yellow at 150°, and melts at 165—168° with decomposition; it is insoluble in water, but moderately easily soluble in alcohol and alkalis.

Cotarnmethine methochloride, $C_{11}H_{11}O_4NMe_3Cl$, combines with hydroxylamine hydrochloride when warmed therewith for several hours in alcoholic solution, and on cooling, the hydrochloride of the nitrile, $C_{14}H_{19}N_2O_3Cl + 2\frac{1}{2}H_2O$, separates from the solution; the oxime could not be obtained. The *platinochloride* of the nitrile is crystalline and insoluble in water. The *mercurochloride* crystallises from hot water in needles. When the hydrochloride is warmed with soda, trimethylamine is evolved, and cotarnonenitrile separates from the solution in colourless needles.

Cotarnonenitrile, $CN\cdot C_8H_6O_3\cdot CH{:}CH_2$, crystallises from hot alcohol in long, colourless needles, melts at 160°, and is insoluble in water.

The *dibromide*, $CN\cdot C_8H_6O_3\cdot CHBr\cdot CH_2Br$, prepared by treating the nitrile with bromine in chloroform solution, crystallises from alcohol in yellowish prisms, melts at 140°, and is very readily soluble in chloroform.

Cotarnelactone,  $\begin{matrix}CO-O\\ |\\ C_8H_6O_3\end{matrix}\!>CH\cdot CH_2\cdot OH$, the intermediate product in the oxidation of cotarnone to cotarnic acid, is best prepared as follows: finely divided cotarnone (10 grams) is shaken with cold water (about 1 litre) and a 4 per cent. solution of potassium permanganate (10 grams) gradually added in small portions at a time, with constant shaking; if the process is carefully carried out, the cotarnone will have almost completely disappeared by the time the permanganate has been added, but if the addition takes place too quickly, the lactone in solution will be further oxidised, and some of the cotarnone will remain unchanged. The solution, which remains quite clear, is kept for some time to allow the manganese oxide to separate, then filtered, slightly acidified, and evaporated; on cooling, the lactone separates from the solution in small, shining crystals. The yield is about 9 grams. Cotarnelactone separates from alcohol in prismatic crystals, melts at 154°, and is only sparingly soluble in cold alcohol and water, but readily in the hot liquids. It separates unchanged from ammonia and from sodium carbonate solution, but it is decomposed by alkalis or alkaline earths, yielding a salt of cotarnelactonic acid.

Cotarnelactonic acid, $COOH\cdot C_8H_6O_3\cdot CH(OH)\cdot CH_2\cdot OH$, separates as an oil when hydrochloric acid is added to a concentrated solution of the lactone in soda, but on warming it is reconverted into the crystalline lactone. It is obtained in crystals when the lactone is boiled with water and the solution allowed to cool; it melts at about 90—100°, being reconverted into the lactone. The *barium* salt, $(C_{11}H_{11}O_7)_2Ba + 5H_2O$, prepared by boiling the lactone with baryta, crystallises in needles, and is partially decomposed by hot water.

Acetylcotarnelactone,  $\begin{matrix}CO-O\\ |\\ C_8H_6O_3\end{matrix}\!>CH\cdot CH_2\cdot OAc$, separates from glacial acetic acid in crystals, and melts at 174°; the *benzoyl*-derivative, $C_{18}H_{14}O_7$, crystallises from glacial acetic acid in plates, and melts at 184°.

Cotarnic acid is best prepared by dissolving cotarnelactone (1 part) and an alkali (2 parts) in water (50 parts), and gradually adding a 4 per cent. solution of potassium permanganate (= 2 mols. of oxygen) to the cold solution. The filtered solution is then acidified with acetic acid and concentrated; on cooling, or on rubbing, the potassium salt separates from the solution. 10 grams of the lactone yield 5 grams of the potassium salt.

Cotarnic acid does not yield methyl chloride when it is heated with hydrochloric acid, but the presence of one methoxy-group in the acid can be proved by Zeisel's method. When cotarnic acid is heated with hydriodic acid and amorphous phosphorus at 150—160°, it yields gallic acid. These decompositions, and the fact that cotarnic acid yields an anhydride, prove that it is a methylmethylenegallocarboxylic acid (methylmethylenetrihydroxyphthalic acid),

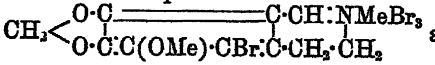
$$\mathrm{OMe{\cdot}C_6H(COOH).}<^{\mathrm{O}}_{\mathrm{O}}>\mathrm{CH_2}.$$

When cotarnic acid is warmed on the water-bath with hydrochloric acid, in sealed tubes, until the solution becomes greenish-yellow, it is decomposed into carbonic anhydride and methylmethylenegallic acid.

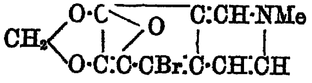
Methylmethylenegallic acid, $\mathrm{OMe{\cdot}C_6H_2(COOH)}<^{\mathrm{O}}_{\mathrm{O}}>\mathrm{CH_2}$, crystallises from water and alcohol in needles, melts at 210° with previous softening, and is readily soluble in alcohol, but only sparingly in water. It dissolves in concentrated sulphuric acid with a yellow coloration, which on warming passes through green and becomes blue; the addition of water then causes the precipitation of a brown, flocculent substance. The *barium* salt, $\mathrm{(C_9H_7O_5)_2Ba}$, crystallises in slender needles, and is readily soluble in hot, but only sparingly in cold water, and insoluble in alcohol. The *calcium* salt, $\mathrm{(C_9H_7O_5)_2Ca}$, resembles the barium salt in crystalline form and in its behaviour with solvents.

Methylmethylenetribromopyrogallol, $\mathrm{OMe{\cdot}C_6Br_3}<^{\mathrm{O}}_{\mathrm{O}}>\mathrm{CH_2}$, is formed when cotarnic acid is treated with a slight excess of bromine in cold glacial acetic acid solution; on adding water, carbonic anhydride is evolved, and the bromo-derivative is precipitated. It crystallises from dilute alcohol in slender needles, melts at 160°, and is readily soluble in alcohol and ether, but insoluble in water and alkalis.

Constitution of Cotarnine.—It has previously been shown that cotarnine combines with acids with elimination of 1 mol. $\mathrm{H_2O}$, yielding derivatives of isoquinoline. The compound previously described as bromocotarnine dibromide hydrobromide is readily converted into bromocotarnine hydrobromide by hydrogen sulphide, so that it is probably a perbromide; this perbromide, when heated, gives bromotarconine with elimination of methyl bromide (1 mol.) and hydrogen bromide (2 mols.). This reaction can be explained by assuming that bromocotarnine perbromide and bromotarconine have the constitution



and



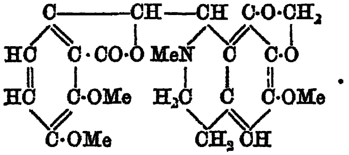
respectively. The above constitutional formula is in complete accordance with the properties of bromotarconine; a compound having this constitution would be a tertiary base, should give apophyllenic acid on oxidation, would be easily reduced, and its intense colour would be explained by the presence of the chromophore which characterises rosolic acid.

From these considerations, and from the experiments described above, it follows that cotarnine has the constitution

$$CH_2<\begin{matrix}O\\O\end{matrix}>C_6H(OMe)(CHO)\cdot CH_2\cdot CH_2\cdot NHMe$$

[CHO : $CH_2\cdot CH_2\cdot NHMe$: H : OMe = 2 : 3 : 4 : 5].

Constitution of Narcotine.—In the narcotine molecule, $C_{22}H_{23}NO_7$, the hydrocotarnine- and opianic acid-groups are not combined together by any one of the seven oxygen-atoms, because of these five are combined with alkyls (three with methyl and two with methylene), and the other two are members of the lactone-group. Since, further, the five valency units of the nitrogen-atom are fully combined with carbon-atoms of the pyridine nucleus, the two groups cannot be united through nitrogen. It follows, therefore, that the hydrocotarnine- and opianic acid-groups are combined together by a carbon-atom of each and, without doubt, by those two carbon atoms which, on oxidation, are converted into the aldehyde-groups in opianic acid and cotarnine. Narcotine has, therefore, the constitution



It is a meconine-hydrocotarnine, and, like hydrastine, is nearly related to papaverine; both these opium alkaloïds are derivatives of a benzylisoquinoline. Hydroxynarcotine (this Journal, 1876, i, 461) is most probably an opianyl-hydrocotarnine, but narceine, as has been shown by Claus and Meixner, is a naphthalene-derivative.

Methoxyhydrocotarnine methiodide, $C_{14}H_{20}NO_4I + \frac{1}{2}H_2O$, is formed when cotarnine, in cold methyl alcoholic solution, is treated with methyl iodide (1 mol.), and the solution kept for about three days; the methyl alcohol takes part in the formation of this compound, although cotarnine is not acted on by methyl alcohol alone. On evaporating, the product separates in yellow needles melting at 173° with decomposition. It loses its water at 120—130°, is readily soluble in hot water and alcohol, and dissolves unchanged in alkalis; it is therefore a quaternary ammonium iodide, but it differs from the isomeric compound (cotarnemethine methiodide) previously obtained (Abstr., 1889, 417) from cotarnine and methyl iodide. When treated with silver oxide, it gives a strongly alkaline base which is slowly decomposed by boiling water with liberation of dimethylamine. The *methochloride*, prepared by decomposing the methiodide with silver chloride, is hygroscopic, and gives an orange, crystalline, sparingly soluble *platinochloride* of the composition $(C_{14}H_{20}NO_4Cl)_2PtCl_4$. The base has the constitution

$C_8H_6O_3<\begin{matrix}CH(OMe)\\CH_2\cdot CH_2\end{matrix}>NMe_2I$.

Ethoxyhydrocotarnine methiodide, $C_{15}H_{22}NO_4I + \frac{1}{2}H_2O$, prepared by treating cotarnine with methyl iodide in ethyl alcoholic solution, as described above, crystallises in small plates, melts at 168° with decomposition, and is more readily soluble in water and alcohol than the corresponding methoxy-derivative.

Isobutoxyhydrocotarnine methiodide, $C_{17}H_{26}NO_4I + H_2O$, separates in crystals when cotarnine is treated with methyl iodide in cold isobutyl alcoholic solution. It crystallises from hot water in needles or plates, and melts at about 120°.

Methyltarconic acid, $C_{11}H_{11}NO_3$, is obtained when steam is passed for a long time into a hot solution of tarconinemethyl hydroxide (1 part) in baryta (4 parts). After saturating with carbonic anhydride, the precipitate is warmed with dilute sulphuric acid, the filtered solution neutralised with sodium carbonate, concentrated, and the crystals obtained recrystallised from hot water. It crystallises in slender, yellow needles with 2 mols. H_2O, loses its water at 100°, melts at 244°, and is soluble in water, alkalis, and acids. It is isomeric with the compound (methyltarconic acid) previously obtained (Abstr., 1888, 1115) by boiling an aqueous solution of tarconinemethyl hydroxide; as the new compound is the true methyltarconic acid, the substance previously described must be called *pseudomethyltarconic acid*. The *hydrochloride*, $C_{11}H_{11}NO_3,HCl + H_2O$, crystallises in colourless needles or prisms, loses its water and turns yellow at 100°, and is moderately easily soluble in water and alcohol. The *sulphate* crystallises in small, colourless prisms, is readily soluble in water, and seems to contain water of crystallisation. The *platinochloride* is amorphous. F. S. K.

Hydrastine. By M. FREUND and A. ROSENBERG (*Ber.* 23, 404—415).—Hydrastine unites with methyl iodide at 100°, forming *hydrastine methiodide*, $C_{21}H_{21}NO_6,MeI$, which crystallises in needles melting at 208° (compare Freund and Will, Abstr., 1887, 1057). By the action of silver chloride in aqueous solution it yields the corresponding *hydrastine methochloride*, $C_{21}H_{21}NO_6,MeCl$. When this compound is treated with a solution of potassium hydroxide, a yellow plastic mass separates; this will be described later. From the evaporated filtrate, white, lustrous prisms separate, which consist of *hydrastine methyl hydroxide*, $C_{21}H_{21}NO_6,MeOH + H_2O$; after recrystallisation from water or alcohol this compound melts at 242°. It was previously obtained by Freund and Will (*loc. cit.*) by acting on the methyl iodide with silver oxide. It may readily be reconverted into the chloride and iodide.

Methylhydrastine, $C_{22}H_{23}NO_6$, the above-mentioned yellow compound, is the chief product of the reaction, and crystallises from dilute alcohol in small, deep-yellow, needles melting at 156°. It is also formed when an alkali is carefully added to a hot aqueous solution of hydrastine methiodide. From its formation and analysis it must be regarded as methylhydrastine. It is almost insoluble in water, but dissolves in chloroform, benzene, and alcohol. With Frohde's reagent, it gives a violet coloration, which speedily becomes blue, and on standing changes to green, and finally becomes discoloured. Its salts, for the most part sparingly soluble, are even decomposed by ammonia and sodium carbonate; the *hydrochloride* melts at 241° with decomposition, the *sulphate* at 250°, and the former yields double salts with stannous, zinc, and mercuric chlorides.

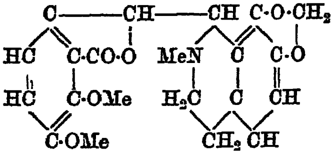
Methylhydrastine unites with methyl iodide very readily, forming *methylhydrastine methiodide*, $C_{22}H_{23}NO_6,MeI$, which crystallises in yellow needles, more soluble in hot water than in alcohol, and decomposing at 250°. It is readily decomposed by alkalis with evolution of trimethylamine and formation of a compound free from nitrogen which has the formula $C_{20}H_{20}O_8$.

Methylhydrasteïne, $C_{22}H_{27}NO_6 + H_2O$. When an aqueous solution of hydrastine methochloride is warmed with an excess of potassium hydroxide, the precipitate first formed redissolves, and on neutralising the partially evaporated solution with acetic acid, colourless crystals of a substance having the above composition are obtained. It may also be more conveniently prepared by dissolving methylhydrastine in strong alkali, warming, and evaporating the solution until the oily mass becomes thick. The product is then dissolved in water, neutralised with acetic acid, and the substance recrystallised from water. It melts at 150—151°, is sparingly soluble in cold, more readily in hot water or alcohol, and loses its water of crystallisation at 100°. It shows both acid and basic properties, but is precipitated by carbonic anhydride from its alkaline solution. It forms salts with the strong acids, but not with acetic acid, and gives with Fröhde's reagent a colour reaction similar to that of methylhydrastine. It resembles in many respects the pseudonarceïne obtained by Roser (Abstr., 1888, 1316), which in the anhydrous state has the formula $C_{23}H_{27}NO_8$. An attempt to eliminate a second molecule of water from methylhydrasteïne, and obtain an anhydrous substance whose formula corresponded with that of pseudonarceïne, resulted only in the decomposition of the substance. Methylhydrasteïne is also a tertiary base, and readily unites with methyl iodide and is reconverted into methylhydrastine by warming with concentrated hydrobromic acid. Its salts are colourless, the *hydrochloride* forming spherical aggregates of crystals, melting at 290°.

Compounds similar to the above, containing the ethyl-group instead of methyl, have also been obtained. Hydrastine ethiodide and hydroxide, and ethylhydrastine have been previously obtained (Schmidt and Wilhelm, Abstr., 1888, 1212; Eykman, 1887, 505), and the authors have been able to confirm their results, with the exception of the melting points. This was found for hydrastine ethiodide to be 225° instead of 205—206°, and for ethylhydrastine 126—127° instead of 124°. The latter forms salts resembling those of methylhydrastine, and unites with ethyl iodide, forming *ethylhydrastine ethiodide*, $C_{25}H_{25}NO_6,EtI$, a beautifully crystalline substance which decomposes at 241°.

Ethylhydrasteïne is obtained in the same manner as the methyl-derivative, and crystallises from water in needles melting at 130°.

The above results make it evident that hydrastine is a tertiary base, and the formula given in the previous paper (Abstr., 1889, 1222), therefore requires modification. In a recent publication, Roser (preceding Abstr.) has proposed a formula for the closely allied alkaloïd narcotine, which shows at once its relation to papaverine and its lactone-like nature. The modified formula now proposed by the authors for hydrastine, viz.:—



,

corresponds well with Roser's narcotine formula. The formation of methylhydrastine, and the conversion of its methiodide into trimethylamine and a substance free from nitrogen can be readily explained, like the corresponding reactions of coneïne, by assuming that the piperidine ring is split (compare Ladenburg, *Ber.*, **14**, 2057). For methylhydrasteïne the following formula is regarded as the most probable:—

$$NMe_2\cdot C_2H_4\cdot C_6H_2(<^{O}_{O}>CH_2)\cdot CH(OH)\cdot CH(OH)\cdot C_6H_2(OMe)_2\cdot COOH.$$

H. G. C.

Hydrastine. By M. Freund (*Ber.*, **23**, 416—417).—A personal discussion with E. Schmidt as to the priority of claim for the investigation of hydrastine. H. G. C.

Adenine and Hypoxanthine. By G. Bruhns (*Ber.*, **23**, 225—229).—Adenine sometimes crystallises from slightly impure solutions in plates having a nacreous lustre, and differing entirely in appearance from the needles usually obtained. They have, however, the same composition and melting point.

When a solution of adenine hydrochloride is mixed with one of sodium picrate, adenine picrate is formed. This is very sparingly soluble in cold water (1 : 3500), more readily in alcohol and hot water, and crystallises from the latter in voluminous fascicular groups of yellow needles. It has the formula $C_5H_5N_5,C_6H_2(NO_2)_3\cdot OH + H_2O$, loses its water of crystallisation at 100°, and then remains unaltered at 220°. The author proposes to make use of this compound for the quantitative estimation of adenine, proceeding as follows:—Adenine and hypoxanthine are separated from xanthine and guanine in the usual manner by the addition of silver nitrate to the nitric acid solution. The mixture of adenine silver nitrate and hypoxanthine silver nitrate is then decomposed (the author obtains good results by employing for this purpose dilute hydrochloric acid in place of hydrogen sulphide), the resulting solution nearly neutralised with sodium carbonate, and a solution of sodium picrate added; after remaining 15 minutes, the precipitate is collected and washed. A correction of +2·2 milligrams must be made for each 100 c.c. of filtrate and wash water. The filtrate is then neutralised with ammonia, and the hypoxanthine precipitated with ammoniacal silver nitrate. No correction need be made for the solubility of hypoxanthine silver nitrate if there is no excess of ammonia in either solution.

Adenine and hypoxanthine combine, in aqueous solution, forming a compound having the formula $C_5H_4N_4O,C_5H_5N_5 + 3H_2O$; this crystallises from water in aggregates of slender needles, which readily effloresce, and quickly lose water at 100°. It forms a homogeneous hydrochloride, but may be separated into its constituents by dissolving it in dilute sulphuric acid and submitting it to fractional crystallisation.

Adenine unites with dry bromine, forming a dark-red substance which appears to contain six atoms of bromine. It decomposes in the air, and more quickly at 100—120°, forming *bromadenine*, $C_5H_4N_5Br$, which crystallises in white stellate groups of needles insoluble in water, but readily soluble in ammonia, and is only attacked with difficulty by alcoholic potash. It is a strong base, and forms an insoluble picrate, which is more voluminous than that of adenine. A similar bromohypoxanthine could not be obtained.

H. G. C.

Ricin. By H. STILLMARK (*Chem. Centr.*, 1889, ii, 978—979; from *Pharm. Centralhalle*, **30**, 650—651).—The poisonous principle of the castor-oil bean is *ricin*, an albuminous substance which belongs to the group of unorganised ferments. It loses its poisonous properties at once if boiled, although it is not so severely affected by a dry heat. It is best separated by extracting the fresh castor-oil beans with a 10 per cent. sodium chloride solution, which extract, after filtration, is saturated with magnesium and sodium sulphates at the ordinary temperature. If this solution is cooled, the salts crystallise out, and with them a white precipitate which is readily separated by dialysis; this must be conducted at a low temperature or fermentation will ensue.

It would appear as though several members of the Euphorbiaceæ contain a poisonous albuminous substance, which may indeed be identical with that present in the castor-oil bean. The author draws attention to the fact that large quantities of the refuse of the castor-oil factories are allowed to remain in the open at the disposal of the public, and that since this substance is tasteless and more poisonous than arsenic, a considerable danger arises therefrom. J. W. L.

Action of Hot Water on different Albuminoïds. By S. GABRIEL (*Chem. Centr.*, 1889, ii, 988; from *J. Landw.*, **37**, 335—345).—Instigated by the results of his experiments on the action of superheated steam on the albuminoids of lupins and rye, the author has conducted a series of determinations of the effect of water at comparatively high temperatures on albumin, fibrin, casein, conglutin, and wheat-gluten. The first result at which the author arrived is that if the same substance be heated with water under the same conditions, the same products in the same quantities are always obtained. The temperature would appear to exert a greater influence on the result than the time. Albumin, fibrin, and casein, for instance, when heated with water at 152° for six hours, were decomposed to the same extent as when heated at the same temperature for one hour; whereas when heated at 135° for three hours, the decomposition appeared not to proceed so far. Conglutin and wheat-gluten are more readily decomcomposed than the three first-named albuminoïds.

The following table gives the results of the action of water at 152° for six hours on the several albuminoids :—

	Protein nitrogen.	Peptone nitrogen.	Amide nitrogen.
Albumin	37·04	25·90	37·87
Fibrin	36·97	29·88	33·15
Casein	35·09	27·86	37·05
Conglutin........	22·47	39·93	37·60
Wheat-gluten	26·45	59·28	14·28

Physiological Chemistry.

Temperature in Nerves. By H. D. Rolleston (*J. Physiol.*, **11**, 208—225).—The observations were made by the help of an electrical resistance thermometer, invented by H. L. Callender, which is fully described. The conclusions arrived at are :—

(1.) During the passage of a nervous impulse there is no evidence of (even $\frac{1}{5000}$°) any heat being evolved from the nerve trunk.

(2.) In dying, a nerve does, however, evolve heat. In many cases sufficient heat is developed to raise the temperature of the thermometer in contact with it $\frac{1}{7}$°.

(3.) The development of heat roughly corresponds with the intensity of the natural nerve current; this, however, is not absolutely constant.

(4.) There is some evidence to show that nerves die at different rates.

W. D. H.

Artificial and Natural Digestions. By A. S. Lea (*J. Physiol.*, **11**, 226—263).—The following factors, present in normal digestion, are absent in artificial digestion experiments as usually performed in flasks and beakers :—(1) Constant movement of the contents; (2) constant removal of digestive products, (3) continuous additions of fresh portions of digestive fluid. In the present experiments, an apparatus was employed which tends to obviate these disadvantages. The artificial digestion is carried out not in a flask but in a tube of parchment paper, kept in constant up and down movement by connecting it to a motor; this tube is suspended in a cylindrical glass vessel, filled with the same mixture as that contained in the tube, but minus any ferment; an outer cylindrical glass vessel is filled with water kept at the necessary constant temperature. By this means, two of the more important conditions under which natural digestion takes place may be imitated, namely, continuous movement, and removal by dialysis of digestive products.

The first question investigated was the digestion of starch by saliva; the great contrast between natural and artificial digestion of starch is the appearance of large quantities of dextrin in the latter case (opinions, however, differ as to the relative amounts of sugar and dextrin formed), whilst in the stomach and intestines mere traces of the dextrins are discoverable. Notwithstanding imperfections in the present method of experimentation, which are freely admitted, the contrast between a digestion carried on in the moving dialyser and in a flask is very marked; the iodine reaction of starch or dextrin disappears first in the contents of the dialyser; in prolonged digestions the contents of the dialyser remain clear and more free from putrefactive organisms than those of the flask, and the proportion of dextrin present is less in the dialyser than in the flask. This last point may be illustrated by the following table:—

	Duration of experiment in hours.	Strength of starch in solution per cent.	Dextrin per cent. in dialyser.	Maltose per cent. in dialyser.	Maltose per cent. in dialysate.	Dextrin per cent. in flask.	Maltose per cent. in flask.
1	6	0·4	7·67	—	—	15·23	—
2	22	2·4	8·58	—	—	14 16	84·23
3	21	4·23	16·78	—	—	36·62	61·81
4	68	4·23	8·48	—	—	35·70	62·33
5	18	0·43	10·31	12·42	76·67	—	—
6	48	4·18	12·61	14 20	71·15	—	—
7	90	3·35	4·29	3·06	91·18	—	—

The conclusions drawn from these and similar experiments are as follows:—

When the digestion of starch by saliva is carried out under conditions which ensure a very considerable removal of the products (maltose) as they are formed, then:—

1. The *rate* at which the digestion takes place is increased.
2. The total *amount* of starch converted into sugar is much greater, and the residue of dextrin is much less, than under conditions, otherwise similar, when the products are not removed.
3. The influence of the removal of digestion products on the relative amounts of dextrin and maltose formed is least marked when the starch solution is dilute.
4. These results justify the assumption that in the alimentary canal starch is completely converted into sugar before absorption.
5. The experiments afford no evidence that any sugar other than maltose is formed by the action of saliva on starch.

The next series of experiments dealt with the pancreatic digestion of proteïds; here the occurrence of an insoluble bye-product (antialbumid) is believed to be due to the imperfection of the method of artificial digestion, and probably does not occur in natural digestion; the question, however, which was specially investigated was the occurrence of leucine and tyrosine. Kühne has already stated that these amido-acids are formed in natural as well as in artificial pancreatic digestion, but careful quantitative experiments do not seem to have been made, although it may be roughly stated that less of these materials are found in the intestine than in a flask. This may be due to one of two causes; either they are normally formed in large amount and then rapidly absorbed, or else they are formed in only small amount. By the help of the digesting dialyser, combined with the examination of the intestinal contents of animals, it was hoped in the present research to elucidate this question. A few typical experiments are described in detail and the following conclusions drawn:—(1) The undigested residue in a flask digestion is always greater than that of a dialyser digestion, other conditions being the same; (2) the amount of leucine and tyrosine formed in a flask digestion is always greater than in a dialyser digestion, other conditions being the same. The amount formed in a dialyser digestion is, however, always considerable, and it is possible that the amount formed is less than in a flask digestion, because the peptones from which they originate are continually dialysing out. Leucine and tyrosine were also found in not inconsiderable quantities in the intestines of the animals examined, not merely in microscopic amounts, as some previous observers seem to imply.

The paper concludes with remarks of a theoretical nature on the function of the amido-acids formed in plants and in animals. It is regarded as inconceivable that the animal, like the vegetable organism, should construct its proteïds from the nitrogen contained in the amido-acids, and their importance is likened to that of the inorganic salts and extractives contained in beef-tea, or other meat extract. We do not know what part these play exactly in the total processes of tissue-metabolism, but we do know that the salts are in some way essential, and that the extractives are an extremely important accessory to that metabolism.

Experiments on the pancreatic digestion of starch are in progress.

The term zymolysis is suggested as a convenient one to denote generally the changes produced by enzymes or unorganised ferments.

W. D. H.

The saving effect on Albumin of Organic Acids in Vegetable Foods. By H. WEISKE and E. FLECHSIG (*Bied. Centr.*, **19**, 31—39; from *Journ. f. Landw.*, **37**, 199—234).—The object of the experiments described in the paper was to determine whether the considerable quantities of organic acids which occur in sour fodder, and other foods in which fermentation occurs, have a physiological value similar to that of starch and some of the other non-nitrogenous food constituents. A rabbit was fed for some days on a mixture of meat meal (15 grams), fat (1·8 grams), starch (30 grams), sugar (10 grams), crude nut-shell fibre (5 grams), hay ash (0·5 gram), and salt (0·2 gram). The nutritive ratio was kept close, being as 1 : 3·7, in order that the action, if any, of the non-nitrogenous substances given might be more distinct. After eight days, the urine was collected for 10 days and the nitrogen determined. The average daily amount of nitrogen in the urine was 1·46 grams. The weight of the animal remained nearly constant (2390 grams). During the next period, a portion of the starch (10 grams) in the food was replaced by an equal amount of acetic acid, first as calcium and afterwards as sodium acetate; but as after three days a considerable amount of food was left, lactic acid (10 grams), in the form of calcium lactate, was substituted for the acetate. But this also had to be discontinued after three days. The live weight sank from 2345 to 2132 grams, and the average daily amount of nitrogen in the urine was 1·92 grams. So that, notwithstanding the less amount of nitrogen taken in the food, there was an increase in the amount eliminated. An amount of acetic or lactic acid as high as 4·3 grams per 1000 grams of live weight, therefore, not only does not save albumin, but it increases the albumin consumption. In the third period, in which the food used in the first period was again employed, the live weight attained nearly its original amount and the nitrogen of the urine again sank to 1·46 grams per day. In the fourth period, the same food-mixture was again used, but minus 10 grams of starch. In four days the live weight sank to 2225 grams, whilst the daily separation of nitrogen rose to 1·71 grams. Inasmuch as the amount of nitrogen separated during period II was still higher than this, it would seem that the presence of acetic or lactic acid in the food is actually prejudicial. In another experiment, in which only 2·2 grams of lactic acid per 1000 grams of live weight was used, there was no increased separation of nitrogen; but there was also no preservation of albumin.

The next experiments were made with a wether, fed for seven days with a mixture of meadow hay, starch, cane-sugar, earth-nut cake, and salt. The nutritive ratio was as 1 : 3·4. During the next period, lactic acid (60 grams) as calcium lactate was mixed with the food. It is shown that rather less proteïn, fat, and crude fibre were digested in the second period, and that the rise observed in the digested non-nitrogenous extract-substance was less than the lactic acid added. But there was more (1·73 grams) nitrogen deposited in the second period than in the first. There was thus a not inconsiderable deposition of albumin, caused by the presence of calcium lactate. With twice the amount of lactic acid, there was, however, an increased amount of nitrogen eliminated, whilst with still more acid the nitrogen of the urine was not raised, but there was a gradual rise in the amount of proteïn in the fæces.

Further experiments with a wether showed that the action of acetic acid (as sodium acetate) is quite different from that of lactic acid; the urine production was very much increased, and the urine was also somewhat richer in nitrogen. The undigested nitrogen of the fæces remained practically the same.

The results of the experiments do not support v. Wolff's view, that the volatile fatty acids (especially acetic acid) have a nutritive value but little less than that of the carbohydrates. N. H. M.

Amount of Substances yielding Oil of Mustard in various Foods, and their Action on the Animal Body. By ULBRICHT

(*Bied. Centr.*, 18, 53—56).—The seeds of black mustard contain two substances, potassium myronate and myrosin, which in presence of water react on each other, forming allylthiocarbimide and other compounds. The same or similar compounds are also obtained from the different organs of various species of *Allium*, and in small quantities from rape-seed. The author has determined the amount of mustard oil which various seeds used in the oil factories of different countries will produce, as well as that of the seeds of weeds which accompany them. It has long been known that so-called rape cake, when treated with water, often develops a more or less powerful odour of mustard oil, owing to the adulteration of the cake with black or Indian mustard. Experiments, in which sheep had considerable amounts of black mustard mixed with their food, showed that a daily amount of 284 grams was not injurious, whilst a bull-calf consumed 148—444 grams with the same result. Cows took 343 to 820 grams of mustard a day, about a week before calving, without injury. Cake containing much potassium myronate may safely be given to quite young calves.

Although quite uninjurious to sheep and bullocks, it is doubtful whether, if given to cows, a cake containing potassium myronate may not have some influence on the taste and quality of the milk and butter; and it is suggested that, until more is known, cows should not be fed with oil cake which yields more than 0·5 per cent. of mustard oil. N. H. M.

Methyl Mercaptan as a Constituent of Human Intestinal Gases. By L. Nencki (*Monatsh.*, 10, 862—863).—Planer and Ruge have shown that intestinal gas consists of carbonic anhydride, hydrogen, hydrogen sulphide, and marsh gas. Bearing in mind that methyl mercaptan is one of the products of putrifying albumin (compare Nencki and Sieber, this vol., p. 78), the author has endeavoured to show its presence as a degradation-product in human fæces, and that it is probably formed in the large intestine. To this end he reduced fresh excrement (3 kilos.) to a thin paste with water, added oxalic acid (90 grams), and distilled the mixture. The gases evolved, consisting in the main of carbonic anhydride, were first passed into a flask to condense the water, and then into a 3 per cent. solution of mercuric cyanide, which at first became yellow, and ultimately contained a small quantity of a black precipitate. This was collected, well washed, and treated with hydrochloric acid, the resulting gases being passed into a neutral solution of lead acetate, which assumed the characteristic odour of mercaptan, and ultimately contained a quantity of microscopic yellow plates or prisms insufficient for analysis. This unmistakable proof of the presence of mercaptan leads the author to suppose that alkaline compounds of mercaptan are decomposed in the large intestine by acids formed during the decomposition of albumins and carbohydrates; the liberated thio-alcohol being evolved in the gaseous form. G. T. M.

Uric Acid. By W. Roberts (*Proc. Med. Chir. Soc.*, 1890, 85—87).—The presence of uric acid in human urine is somewhat anomalous. As a vehicle for the elimination of nitrogen it is not needed; its place being taken by urea, which by its easy solubility is better adapted to the liquid urine of mammals. Perhaps uric acid is a vestigial remnant in mammalian descent; but although physiologically insignificant, uric acid is pathologically the most prominent component of the urine, this being chiefly due to its tendency to form concretions.

All acid urines tend inevitably to deposit their uric acid sooner or later. The time of onset of precipitation various from a few hours to five or six days, or even longer. The inference is drawn that pathological gravel is due to an exaggeration of conditions which exist in a less pronounced degree in health. To get at an explanation of this spontaneous precipitation, it is necessary to examine the states of combination of uric acid in urine.

Uric acid ($C_5H_4N_4O_3 = H_2\bar{U}$) is a bibasic acid, and forms two regular series of salts—namely, *normal urates* ($M_2\bar{U}$) and *acid* or *hydrogen urates* or *biurates* ($MH\bar{U}$). But in addition to these it forms a series of hyperacid combinations, first discovered by Bence Jones, and termed by him *quadrurates* ($MH\bar{U},H_2\bar{U}$). The normal urates are never found in the animal body, and are only known as laboratory products. The biurates are only encountered pathologically as gouty concretions. The quadrurates, on the other hand, are specially the physiological salts of uric acid. They constitute exclusively the combination in which uric acid exists in solution in normal urine, and they become visible sometimes as the amorphous urate sediment. The urinary excretion of birds and serpents is composed exclusively of quadrurates. The quadrurates can, moreover, be formed artificially under conditions which prevail in the animal body. The special and characteristic reaction of the quadrurates is that they are immediately decomposed by water into free uric acid and biurates.

They exist in acid urine in the presence of water and of superphosphates. These conditions necessarily involve the ultimate liberation and precipitation of uric acid. The first step is the breaking up of the quadrurate by the water of the urine into free uric acid and biurate according to the following equation:

$$\underset{\text{Quadrurate.}}{(MH\bar{U},H_2\bar{U})} + H_2O = \underset{\text{Free uric acid.}}{(H_2\bar{U})} + \underset{\text{Biurate.}}{(MH\bar{U})}.$$

This explains the liberation of half the uric acid. But the biurate thus formed is forthwith changed in the presence of superphosphates into quadrurate. Thus:

$$\underset{\text{Biurate.}}{2(MH\bar{U})} + \underset{\text{Superphosphate.}}{(MH_2PO_4)} = \underset{\text{Quadrurate.}}{(MH\bar{U},H_2\bar{U})} + \underset{\text{Dimetallic phosphate.}}{(M_2HPO_4)}.$$

By these alternating reactions all the uric acid is at length set free.

Seeing that uric acid exists in acid urine (that is, for some 16 hours out of the 24) amid conditions which, if the quadrurate stood alone and uncontrolled, would lead to its immediate precipitation, and yet that in the normal course no such early precipitation occurs, it is obvious that the urine must contain certain ingredients which inhibit or greatly retard the action of the water in breaking up the quadrurates. These inhibitory ingredients consist, chiefly, of (1) the mineral salts, (2) the pigments of the urine.

The conditions of the urine which tend to accelerate the precipitation of uric acid as in the formation of concretions and deposits, are —(1) high acidity, (2) poverty in mineral salts, (3) low pigmentation, (4) high percentage of uric acid. The converse conditions tend to retard precipitation. On the interaction of these factors the occurrence or non-occurrence of uric acid gravel appears to depend, and probably the most important of these factors is the grade of acidity. W. D. H.

Physiological Action of Selenious Acid. By C. CHABRIÉ and L. LAPICQUE (*Compt. rend.*, **110**, 152—153).—0·2 per cent. of selenious acid prevents the putrefaction of infusions of beef by the ordinary microbes of the air. With a smaller quantity, putrefaction takes place and the selenious acid is reduced.

Sodium selenite introduced into the blood of a dog, killed it when the dose reached 3 milligrams per kilo. of body weight. The most pronounced symptoms are intense congestion of all the viscera, and an abundant bronchial secretion of a rose-coloured liquid which contains no selenium.

Sodium selenite therefore acts essentially as an irritant, as Rabuteau observed, but the authors were unable to discover any of the crystals which he described as being present in all the organs. C. H. B.

Physiological Action of Sulphonal. By J. GORDON (*Brit. Med. J.*, i, 1890, 710—714).—From observations and experiments on the lower animals and on human beings, the following conclusions are drawn:—Sulphonal reduces the excitability of the reflex function of the spinal cord, and diminishes peripheral sensation. In men, large doses slow the respiration, but do not affect the pulse. It destroys slowly the conductivity of motor nerves, and the irritability of muscles, which subsequent washing with salt solution tends to revive. Urea is excreted in increased quantity after small doses (5—10 grains), in diminished quantity after larger doses; the volume of the urine is, however, not affected. It produces no effect on the skin, or on the body temperature; it, however, occasionally causes vomiting and diarrhœa. Although incoordination of the extremities, giddiness, and a feeling of depression or confusion sometimes follow its administration, as a rule these effects do not supervene, and the sleep which follows its use is tranquil and refreshing. The hypnotic action of the drug is marked even in healthy people, and in cases of insomnia it is found most trustworthy. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Decomposition of Albumin by the Bacillus of Malignant Œdema. By R. KERRY (*Monatsh.*, **10**, 864—873; compare Nencki, this vol., p. 78).—The author has investigated the decomposition of serum albumin by a pure culture of the bacillus of malignant œdema. On distillation, after saturation with oxalic acid, the fermented liquid gave gaseous products, and an oily liquid which when pure boils at 165—171°, has the formula $C_8H_{16}O_4$, and is of a ketonic or of an aldehydic nature. It is optically active [α] = +5·63, and may, therefore, be assumed to contain an asymmetric carbon-atom: it gives a violet coloration with magenta decolorised with sulphurous acid, and a violet-red coloration with diazobenzenesulphonic acid, soda, and sodium amalgam. It reduces an ammoniacal solution of silver nitrate without the formation of a mirror, gives a crystalline compound with phenylhydrazine and sodium acetate; but does not react with sodium hydrogen sulphite or reduce Fehling's solution. On oxidation it is converted almost entirely into valeric acid. On evaporating the distillation residue and exhausting it with ether, leucine, hydroparacoumaric acid, and a small quantity of fatty acids, but no indole or scatole (compare Nencki, *loc. cit*), were obtained. The gases produced in the fermentation consisted of carbonic anhydride, hydrogen sulphide, marsh-gas, and hydrogen in varying proportions. G. T. M.

Decomposition of Gelatin by Anaërobic Ferments. By L. SELITRENNY (*Monatsh.*, **10**, 908—917).—The author has used the method adopted by Nencki (this vol., p. 78) to investigate the decomposition of a solution of gelatin by *Bacillus liquefaciens magnus* and the *Rauschbrand bacillus*. With the former ferment, a considerable quantity of methyl mercaptan is formed during the progress of growth of the organism, the other products being volatile fatty acids, phenylpropionic acid, glycocine, leucine, and a considerable quantity of the so-called "*gelatin-peptone*," but no indole, scatole, or phenol is formed. When the fermentation is induced by the *Rauschbrand bacillus*, the same products together with phenylacetic acid are obtained, and in this case also the fermented liquid gives no indication of its containing indole, scatole, or phenol. On oxidising the gelatin-peptone with fuming nitric acid or with permanganate, succinic and benzoic acids are obtained.

From these results, the author infers that the benzoic acid, obtained by earlier observers on oxidation of gelatin, was derived from phenylpropionic acid, and that albumin and gelatin differ in that the latter on fermentation gives rise to a large quantity of glycocine, but to neither parahydroxyphenolpropionic acid, scatol acetic acid, nor to any of their derivatives. G. T. M.

Formation of Nitrates in Plants. By BERTHELOT (*Compt. rend.*, **110**, 109).—The facts observed by Heckel (next abstract) and by Lundström, combined with the results of André and those obtained by the author concerning the formation of nitrates by various species of *Amaranthus*, prove that there is a close connection between the life processes of the microbes in the soil and those which inhabit and develop in plants, whether they are microbes which fix nitrogen in vegetable soils and in legumes, or those which form nitrates in *Amaranthus*, *Sterculia*, the coffee plant, or vegetable soils.

C. H. B.

Utilisation and Transformations of Alkaloïds during the Germination of Seeds. By E. HECKEL (*Compt. rend.*, **110**, 88—90).—The seeds of *Sterculia acuminata* contained 2·37 per cent of caffeine.

After the first year, the cotyledons, which remain attached to the stalk, contained only 1·072, after the second year 0·70, and after the third year 0·21. As the caffeine disappears, chlorophyll and potassium nitrate are formed in the cotyledon, and hence its disappearance is due to a kind of nitrification.

In order to investigate the behaviour of pyridic alkaloïds, seeds of *Strychnos nux vomica* and *Datura stramonium* were used. After two to three months, according to the size of the seeds, all the alkaloïds had disappeared and been converted into more assimilable products, the change taking place under the influence of the embryon, for if the germs are removed from the seeds, the latter remain unaltered in moist earth for a long time.

In *Physostigma venenosa* the eserine undergoes transformation in the cotyledons themselves during the germinative movements, for whether the seeds are sown with or without their gemmule the eserine disappears, and it follows that the cotyledons contain substances which produce this change.

Whether the seeds have an endosperm or not, the disappearance of the alkaloïds becomes complete, and they pass into the young plant. The exact changes which they undergo are not yet known, but they are undoubtedly true reserves of food for the young plants, which, however, must undergo complete alteration before they can be assimilated. Reveil's observations that plants watered with solutions of their own alkaloïds always died, show that they cannot be absorbed directly with impunity. C. H. B.

Sugar-yielding Insoluble Carbohydrates in Seeds. By W. MAXWELL (*Amer. Chem. J.*, **12**, 51—60).—The finely-ground seeds were extracted with ether, to remove fats, and with dilute aqueous potash, to remove proteids, and the residue was washed with water until neutral, and treated with a solution of diastase to separate the amyloïds. The insoluble residue, consisting of cellulose, remnants of less soluble albuminous matters, and "nitrogen-free extractive matter," was boiled for one hour with a 3·5 per cent. solution of sulphuric acid; the filtered extract was boiled for two hours in a reflux apparatus, and then neutralised with barium carbonate. The neutral solution was evaporated to a syrupy consistence, and extracted with alcohol. The alcoholic extract was evaporated, and the action of the residue on Fehling's solution and on polarised light was studied, as well as the products which it yielded when oxidised with nitric acid. It is found that the insoluble non-nitrogenous matters, exclusive of cellulose, are carbohydrate substances which, when treated with a dilute mineral acid, are convertible into sugars. This sugar is generally galactose; hence the carbohydrate is in most cases paragalactin; occasionally some levulose appears to be also obtained. The seeds of *Pisum sativum* and *Phaseolus vulgaris* contain respectively about 20 and 10 per cent. of insoluble carbohydrates, and this is all convertible into galactose. *Faba vulgaris* and *Vicia sativa* contain respectively 14 and 15 per cent. of insoluble carbohydrates, and not more than half of these can be converted into sugars by the action of a dilute mineral acid.

These insoluble carbohydrates are secreted in the cells of the endosperm. It is found that the thick membranes of the cells of the cotyledons are insensible to colour reagents, and do not dissolve in a cuprammonic solution, but after they have been boiled with dilute acid, and the carbohydrates thereby removed, the residue gives all the cellulose reactions. C. F. B.

Constituents of Urtica urens, Urtica dioïca, and Urtica pilulifera. By L. Reuter (*Chem. Centr*, 1889, ii, 991—992, from *Pharm. Centralhalle*, **30**, 609—610).—From the leaves of these plants no alkaloïd could be separated, but by treatment with slaked lime, a glucoside is obtained; this reduces Fehling's solution very slightly; but after boiling with acids it reduces it readily. The product of boiling with acids is a brown, tarry substance. The glucoside contains no nitrogen. Tannin and salt do not precipitate it. Iodine in potassium iodide solution and potassiomercuric iodide form precipitates; potassium ferricyanide and potassium chromate in sulphuric acid are reduced by it. Its aqueous solution has a neutral reaction.

From the seeds of *Urtica pilulifera*, a green, fatty oil, containing chlorophyll, is obtained by treating them with magnesia and water, drying, and extracting with chloroform; the extract contained neither glucoside nor alkaloïd. The seeds, after treatment with chloroform, yielded a glucoside soluble in absolute alcohol. J. W. L.

Influence of Gypsum and of Clay on the Conservation of Soil Nitrogen, on Fixation of Atmospheric Nitrogen, and on Nitrification. By Pichard (*Ann. Agronom.*, **15**, 505—521).—The author has made a number of experiments on the nitrification of the nitrogen of arachida cake when mixed with artificial soils composed of pure silicious sand of different degrees of fineness, mixed with varying proportions of gypsum, clay, and common salt. The mixtures were seeded with the washings of arable soil, and the initial and final nitrogen in the forms of ammonia, nitrates, and total nitrogen were estimated; the following conclusions were arrived at. In mixtures containing 1 per 1,000 of cake with the nearly pure sands, kept very slightly moist, and without vegetation for 18 months, the loss of nitrogen (greatest in the coarse sand) was as much as 70 per cent., and less than 15 per cent. was found as nitrate or ammonia at the end of that time. The addition of 5 per 1,000 of gypsum reduced the loss of nitrogen to 58 per cent. at most, the difference being due to more nitrogen nitrified. Salt in the proportion of 1 per 1,000 does not at all interfere with this beneficial action of gypsum. The addition of 10 per cent. of pure clay to the sand reduces the loss of nitrogen, and more is found as ammonia. One part per 1,000 of gypsum, in mixtures containing from 10 to 40 per cent. of clay, reduced still more, and progressively, the loss of nitrogen. One of these mixtures (that with 40 per cent. clay), containing 0·1023 per cent. initial nitrogen, showed a gain over the 18 months of 0·0293 per cent., equal to 28·53 per cent. of the initial nitrogen; the author regards the greater part of this gain as consisting of free nitrogen fixed from the air. J. M. H. M.

Preparation of Silage. By O. KELLNER and J. SOWANO (*Landw. Versuchs-Stat.*, 1890, 16—22).—In continuation of his former researches made with the object of determining the form in which nitrogen is lost during the preparation of silage, the author ensiled some *Lespedeza cyrtobotyra, Miq.*; and after a certain time had elapsed, a portion was extracted with cold water, and the solution distilled; in the distillate were found ammonia, and a small quantity of what appeared to be a substituted ammonia. It was also noted that the upper layers in the silo contained less nitrogen than the lower. The loss of nitrogen as ammonia in silage made from green maize was small. The author criticises the work of other workers on the same subject. E. W. P.

Digestibility of Rice-Straw. By O. KELLNER (*Landw. Versuchs-Stat.*, **37**, 23—26).—Sheep were fed for a time on irrigated rice-straw and for another period on upland rice-straw (rice cultivated on dry lands); in both cases the live weight remained practically constant. The following table shows the composition of the straws, and their mean coefficients of digestion:—

	Paddy straw.	Coefficient of digestibility.	Upland rice.	Coefficient of digestibility.
Moisture on the dry ...	20·79	—	10·33	—
Albumin..............	6·80	46·54	6·75	43·84
Fat	2·17	41·45	2·16	51·90
Fibre...............	48·68	58·10	40·35	55·24
Non-nitrogenous extract.	24·80	35·41	32·14	28·86
Ash	17·55	—	18·60	—
Dry matter...........	—	43·86	—	39·18
Organic matter	—	49·88	—	41·03

Both of these straws surpass all other straws as fodder.

Analytical Chemistry.

New Form of Air-Bath. By M. A. ADAMS (*Analyst*, 1889, 222—228).—The apparatus consists of an outer jacket, within which is a copper vessel containing an annular thermostat. This is composed of two concentric cylinders of sheet copper, joined at the top and bottom, and enclosing an air space 5 mm. thick. This thermostat forms the wall of the drying chamber. It is connected with a U-tube, containing mercury for the control of the gas as usual. Air admitted at the bottom, between the jacket and the copper vessel, rises to the top, and there enters the space between the walls of the vessel and the thermostat, by which it is deflected downwards to enter the drying chamber through a perforated shelf at the bottom. Access to the drying chamber is obtained by removing a dome-shaped glass chimney. The drying chamber is about 9 inches high and 12 in diameter, and the whole space above 4 inches from the shelf has a uniform temperature, whilst 7 cubic feet of air pass through it per minute. M. J. S.

Detection of Free Chlorine in Hydrochloric Acid. By G. A. Le Roy (*Bull. Soc. Chim.* [3], 2, 729; compare this vol., p. 289).—When a few crystals of diphenylamine are added to hydrochloric acid containing traces of chlorine, a blue coloration is produced the intensity of which varies with the amount of free chlorine present.
T. G. N.

Detection of Sodium in Lithium Carbonate. By W. H. Symons (*Chemist and Druggist*, 36, 153, 291).—Since lithium chloride is readily soluble, whilst sodium chloride is only sparingly soluble (1 in 450—500) in concentrated hydrochloric acid, the treatment of a mixture of the two carbonates with about 10 parts of strong acid will reveal the presence of 2 or 3 per cent. of the sodium salt by the formation of a crystalline precipitate. For a quantitative separation, the acid should be previously saturated with sodium chloride, and a filter toughened by nitric acid (Francis) should be used. One part of lithium carbonate requires for solution 68·9 parts of water at 15°; the sodium carbonate can therefore be washed out, and tested for by hydrochloric acid in the residue of the evaporated washings.
M. J. S.

Estimation of Copper by Titration with Potassium Cyanide. By G. E. R. Ellis (*J. Soc. Chem. Ind.*, 8, 686—687).—Referring to the interference caused by the presence of zinc and iron in estimating the percentage of copper by titration with potassium cyanide, the author finds that the presence of 4 to 5 per cent. of zinc does not practically affect the correctness of the indications afforded by the potassium cyanide solution, but that when the zinc exceeds that amount, the indications are perfectly untrustworthy, necessitating the removal of the zinc before titration is effected. With regard to iron, the author's investigations are not yet complete. The present results show that the percentage of copper found is always low when a considerable amount of iron is present, owing probably to the retention by the precipitated hydroxide of a portion of the blue ammoniacal compound. D. B.

Precipitation of Copper as Thiocyanate in Assaying. By F. Johnson (*J. Soc. Chem. Ind.*, 8, 603—604).—The ore is dissolved in any suitable acid, the excess being in great part boiled off. The moist residue is now diluted with about 20 times its volume of water, and ammonium thiocyanate added to the extent of at least three times the weight of copper possibly present. Stannous chloride solution is then added until bleaching of the deep-red coloured liquid ensues and a solution more or less turbid from precipitated cuprous thiocyanate and the insoluble portion of the ore is obtained; this is passed through a filter and washed once with water containing about 1 per cent. of hydrochloric acid. The filter-paper, with its contents, is then transferred to the dissolving flask, treated with 50 c.c. of a dilute acid mixture of 1 part of nitric acid, 1 of hydrochloric acid, and 4 of water, and boiled gently for about a quarter of an hour. Ammonia is now added and the solution titrated with standard potassium cyanide. D. B.

Estimation of Minute Quantities of Aluminium in Iron and Steel. By J. E. STEAD (*J. Soc. Chem. Ind.*, 8, 965—966).—Dissolve 11 grams of the iron in 44 c.c. of strong hydrochloric acid (or 22 grams in 88 c.c. if less than 0·01 per cent. of aluminium is expected) on the sand-bath in a 600 c.c. beaker. Evaporate to dryness, redissolve in hydrochloric acid and water, filter into a 500 c.c. beaker, and wash. The total bulk should not exceed 200 c.c. Add 3 c.c. of a saturated solution of sodium phosphate, then dilute ammonia until the free acid is neutralised. Now add hydrochloric acid, drop by drop, until the solution is clear, heat to boiling, add a large excess of a saturated solution of pure sodium thiosulphate (50 c.c. is sufficient), and continue to boil for about one hour. The precipitate is then collected on a filter, washed, treated with 5 c.c. of hydrochloric acid and 5 c.c. of boiling water, and the filtrate evaporated to dryness in a platinum dish. The residue from the evaporation is now fused with 2 grams of pure sodium hydroxide (dissolved in 1 c c. of water), after which it is cooled and dissolved in boiling water, the solution being made up to 110 c.c. The insoluble oxides are then filtered off, 100 c.c. of the filtrate (= 10 grams of iron) is neutralised with hydrochloric acid, and treated with 3 c.c. of sodium phosphate and a large excess of sodium thiosulphate. The mixture after boiling is treated with 2 c.c. of ammonium acetate and boiled for five minutes longer. The precipitate is collected, washed with hot water, ignited, and weighed. It consists of $AlPO_4$, and therefore contains 22·36 per cent. of aluminium. D. B.

Convenient Solution for Use in Titrating Weldon Muds for Manganese Peroxide. By W. G. M'KELLAR (*J. Soc. Chem. Ind.*, 8, 968—969).—The author recommends the use of standard solutions of potassium dichromate and ferrous sulphate containing 11·862 grams and 69·4 grams per litre respectively. 1 c.c. = 0·04 pound of MnO_2 per cubic foot when using 1 cubic inch of the mud.

D. B.

Assay of Emetine in Ipecacuanha Wine. By T. P. BLUNT (*Pharm. J. Trans.* [3], **20**, 380).—The method recently described (this vol., p. 310) having been adversely criticised, the author has made further investigations, and finds the process is useless.

General and Physical Chemistry.

Production of Monochromatic Light. By E. Fleischl v. Markow (*Ann. Phys. Chem.* [2], 38, 675—676).—The author recommends the use of sodium bromide in place of the chloride for the production of monochromatic light, as the former melts without decrepitation, and gives a much brighter light than the latter.

H. C.

Refractive Indices of Normal Salt Solutions. By C. Bender (*Ann. Phys. Chem.* [2], 39, 89—96).—The author showed (Abstr., 1884, 144) that Valson's law of moduli could be extended so as to represent the specific gravity of aqueous salt solutions as an arbitrary standard plus the product of the molecular concentration into the sum of two constants, one determined by the metal of the salt, and the other by the salt-radicle. From an investigation of aqueous solutions of the chlorides, bromides, and iodides of sodium, potassium, and cadmium, he now finds that the same mode of expression holds good for the refractive index (compare Walter, this vol., p. 202).

J. W.

Molecular Refraction of the Halogen Salts of Lithium, Sodium, and Potassium. By R. Wegner (*Chem. Centr.*, 1890, i, 78—79).—The author has determined the molecular refraction of the chlorides, bromides, and iodides of potassium, sodium, and lithium, the index of refraction of the pure salts being first of all determined, and the molecular refraction being then calculated by means of Landolt's formulæ $M = P\frac{n-1}{d}$ and $M = P\frac{n^2-1}{(n^2+2)d}$, in which $P =$ the molecular weight, $n =$ index of refraction, $d =$ specific gravity. Difficulties were encountered first of all with the determination of the index of refraction of the pure salts from that of their solutions, the index increasing slightly as the concentration decreased, so that only an approximate result could be arrived at. The molecular refraction of the several salts calculated from the aqueous solutions varies slightly, therefore, with the concentration. If it be accepted that the atomic refraction of the several halogens does not vary in their different salts, then that of the alkali metals increases considerably with the atomic weight of the halogen with which it may be combined. The author regards it, however, as probable that the atomic refractions of the elements are not constant in compounds, but that they influence each other.

J. W. L.

Electrical Resistance of Iron and its Alloys at High Temperatures. By H. Le Chatelier (*Compt. rend.*, 110, 283—286).—The resistance is expressed in ohms per mm. of wire 1 mm. in diameter.

Pure soft iron—carbon 0·05 per cent.—

t. ...	15°	290°.	460°.	7[illegible]0°.	800°.	860°.	910°.	1060°.
R ...	0·14	0·38	0·59	1·10	1·21	1·31	1·34	1·40

Cast steel, medium hardness—carbon 0·6, manganese 0·4 per cent.—

t. ...	15°.	300°.	420°.	600°.	700°.	820°.	960°.	1100°.
R ...	0·16	0·43	0·55	0·80	0·97	1·28	1·32	1·34

Hard steel—

t. ...	15°.	280°.	410°.	680°.	730°.	830°.	870°.	940°.	1050°.
R ...	0·24	0·46	0·60	1·06	1·13	1·39	1·43	1·46	1·48

The angular points in the curves representing the variations in the electrical resistance of iron and steel, show clearly the two alterations of state described by Osmond (see this vol., pp. 566, 567), and also that the temperature at which the changes take place is independent of the proportion of foreign matter present.

An alloy of iron with manganese, containing 13 per cent. of the latter, shows only one indefinite angular point at about 700°. Nickeliferous iron shows a very distinct angular point at 340°.

The variation in the electrical resistance of platinum and of a platinum-rhodium alloy is proportional to the temperature.

When an alloy of iron with 25 per cent. of nickel is heated in an atmosphere of pure and dry hydrogen, the variation in the electrical resistance is regular, and the curve shows no angular points, but if the alloy is heated in moist hydrogen, it undergoes a very remarkable change. The colour becomes steel-grey or yellowish-grey, the tenacity increases from 65 kilos. to 80 kilos. (A. Le Chatelier), the elongation falls from 65 per cent. to practically *nil*, and the limit of elasticity becomes almost twice as great. The resistance becomes one-third less, and the curve shows a decided angular point at 550°, but above this temperature coincides with the normal nickel-iron curve. During cooling, there is a retardation of transformation from one modification to another similar to that produced by tempering, but this retardation may be avoided by very slow cooling. The alteration in the properties of the alloy is due to the oxidation of the silicon. C. H. B.

A Silver-Mercury Cell and its Relation to Temperature. By F. STREINTZ (*Ann. Phys. Chem.* [2], 38, 514—534).—According to Helmholtz, the difference between the electrical and chemical energy of a cell is equivalent to the product of the absolute temperature with the change in potential difference with change of temperature, or, in other words, with the temperature coefficient of the cell. If the chemical is greater than the electrical energy, the temperature coefficient is negative, in the reverse case it is positive. Hence, from the nature of the temperature coefficient it may be at once seen whether the chemical energy is only partially converted into electrical energy, or if the electrical is in excess of the chemical energy (compare Jahn, Abstr., 1886, 840).

The author formerly observed that the cell Ag | Ag_2SO_4 | Hg_2SO_4 | Hg has an E.M.F. of zero at the ordinary temperature. This he now finds is due to the fact that a change in the temperature coefficient here takes place from positive to negative, this change taking place at a certain temperature, T_0, at which the potential difference $p_0 = 0$. Hence, if the cell be plunged into ice-cold water, the silver forms the positive pole, whereas in hot water the positive pole is formed by the mercury.

The author employs this cell in testing the above theory of Helmholtz, and finds a perfect agreement between the theoretical deductions and the results of his own experiments. H. C.

Batteries with Fused Electrolytes, and the Thermoelectric Forces at the Surface of Contact of a Metal and a Fused Salt. By L. Poincaré (*Compt. rend.*, **110**, 339—342).—The thermoelectric forces at the surface of contact of a metal with a fused salt are of the same order and sign as those observed by Bouty with saturated solutions. Employing the method of compensation, with the same metal and salt in two tubes at different temperatures, the thermoelectric force is practically independent of the absolute temperature, and proportional to the difference of temperature. With silver in silver nitrate, the hot metal is negative outside the cell; with zinc in zinc chloride, the warm metal is positive outside. If one of the salts solidifies, no change in the thermoelectric force is observed, and if the temperature is raised so high that the metal fuses, no electric change is observed at the moment of fusion. With a battery consisting of zinc in zinc chloride and tin in stannous chloride, the observed difference of potential is almost identical with that calculated from thermochemical data, and between 250° and 350° the E.M.F. of the battery is almost completely independent of the temperature, hence it may be concluded that, in accordance with Lippmann's theorem, the specific heat of the system is not altered by the passage of the electricity. In a similar battery in which one of the electrolytes remains solid whilst the other is fused, the E.M.F. varies notably with the temperature, a result also in agreement with Lippmann's theorem, the specific heat of the element varying with the changes of state which the current produces in the system.

Helmholtz's theory and its consequences hold good in case of batteries in which the electrolytes are made conducting, not by solution, but by igneous fusion. C. H. B.

Polarisation of Platinum Electrodes in Dilute Sulphuric Acid. By F. Richarz (*Ann. Phys. Chem.* [2], **39**, 67—88).—The polarisation of platinum electrodes in dilute sulphuric acid amounts to 2·5 dan. when the current-density is small, but with great current-density, values rising to 4·3 dan. have been found (Fromme, Abstr., 1888, 390). Such high results were doubted by the author, who subjected the methods by which they were obtained to a critical examination. He found that one or other of the assumptions on which Ohm's method is based (namely, that both the resistance of the electrolytic cell and the polarisation remain constant, although the intensity of the current varies) must be incorrect. The same criticism applies to Buff's method, which assumes that the change of resistance in the cell with varying intensity is negligible with respect to the total resistance. On the assumption that the polarisation remains constant at 2·5 dan., the resistance for a current of 0·01 amp. is some eight times as large as the resistance for an intensity of 0·75 amp. This diminution of the resistance with increase of current may be partially accounted for by the heating of the electrolyte round the small electrode (a thin platinum wire) owing to the great current density. The heating may proceed so far as to surround a part of the electrode with a sheath of steam. Another cause of the change of resistance is the increasing difficulty of formation of gas bubbles on the electrode when the current is weak. Finally, there is the diminution of "transfer" resistance as the current increases (compare Sankey, this vol., p. 317). J. W.

Surface-tension of Polarised Mercury in Different Electrolytes. By F. Paschen (*Ann. Phys. Chem.* [2], **39**, 43—66).—Lippmann's capillary electrometer, whilst yielding excellent results for electromotive forces of less than 0·9 volt, is found by the author to be untrustworthy for values above this limit, on account of the polarisation caused by the liberation of hydrogen at the meniscus. In its stead he employs an open U-tube, one limb of which is about 24 mm. in diameter, the other about 3 mm. and shorter The tube should be so far filled with mercury that the meniscus nearly reaches the top of the narrow limb. The whole is immersed upright in a beaker containing dilute sulphuric acid and a layer of mercury, so that the meniscus in the shorter limb alone is below the surface of the liquid. Connection is made with the meniscus through the wide limb. This instrument, although not so delicate as Lippmann's, can be used for large electromotive forces. By its means the author investigated the change of surface-tension of mercury occasioned by polarisation in solutions of sulphuric acid, hydrochloric acid, sodium hydroxide, and various salts. He finds that all changes of surface-tension take place between the limits of +0·1 and −2 dan., and gives curves which show that up to the maximum it is the anion that exerts the decisive influence, whilst beyond the maximum it is the cathion. The position of the two characteristic points of the curves, the maximum and the point where electrolysis becomes evident, would appear to depend greatly on the concentration. The polarisation in Lippmann's electrometer, as well as in the instrument above described, seems to be entirely at the meniscus, and not at the large (anodic) mercury surface. When the polarisation attains a constant value, the surface-tension also becomes constant.

Temperature influences the results slightly, but not to such an extent as to interfere with the accurate working of the instruments under ordinary laboratory conditions. J. W.

Electrolysis of Fused Aluminium Oxide and Fluoride. By A. Minet (*Compt. rend.*, **110**, 342—343).—Electrolysis of aluminium oxide and fluoride by igneous fusion yields a quantity of metal dependent on the time and the quantity of electricity acting. The yield varied in the experiments quoted from 50 to 70 per cent. of the theoretical quantity, and in one instance, with iron electrodes, was as high as 82 per cent. C. H. B.

Formation of Salts in Alcoholic Solution. By C. M. van Deventer and L. T. Rlicher (*Zeit. physikal. Chem.*, 5, 177—180).—Since, according to the dissociation theory, the heat of neutralisation of an acid by a base in aqueous solution is not due to the combination of the negative and positive radicles, but is only that caused by the union of the hydrogen of the acid with the hydroxyl of the base, the authors propose to measure the heats of neutralisation of acids by bases in cases where dissociation cannot possibly take place. In this paper the results of the determination of the heat of neutralisation of acetic acid by potassium ethoxide in alcoholic solution are given, the number obtained being 7280 cals. The authors show that this number is in agreement with that which may be calculated from Berthelot's determination of the heat of neutralisation of acetic acid by potassium hydroxide in aqueous solution. H. C.

Thermochemical Properties of Silk. By L. Vignon (*Compt. rend.*, 110, 286—289).—Raw silk and silk freed from gum by treatment with soap were immersed in quantities of 9 to 12 grams in 500 c.c. of normal solutions of various compounds at 12°. The silk contained the average proportion of water, 10 per cent. The numbers represent the heat developed per 100 grams of silk:—

	H_2O.	KOH.	NaOH.	NH_3.	H_2SO_4.	HCl.	HNO_3.	KCl.
Raw....	0·10	1·35	1·55	0·65	0·95	0·95	0·90	0·20
Washed.	0·15	1·30	1·30	0·50	0·90	0·90	0·85	0·10

The heat developed is the sum of the chemical and physical changes which take place. The total heat developed by the raw silk in all the experiments is 13·15 Cals., and by the washed silk 11·95 Cals. It follows that the chemical energy of the silk-glue (grès) is greater than that of the fibroin, the ratio being 1·451 : 1. More heat is developed by the action of acids and bases than by the action of neutral salts, and hence it would seem that silk-glue and fibroin have decided basic and acidic functions. C. H. B.

Compounds which have a Tension of Dissociation equal to the Vapour-pressure of their Saturated Solution. By H. Lescœur (*Compt. rend.*, 110, 275—276).—The behaviour of sodammonium and potassammonium as described by Joannis (this vol., pp. 209 and 560) is closely analogous to the behaviour of hydrated salts as observed by the author. All saline hydrates during a longer or shorter period of their definite existence afford examples of compounds the dissociation tension of which is equal to the vapour-pressure of their saturated solutions. The facts observed by Joannis are therefore not anomalous, and Roozeboom's hypothesis (this vol., p. 450) has no sufficient foundation. C. H. B.

Composition of the Vapour of Mixed Liquids. By A. WINKELMANN (*Ann. Phys. Chem.* [2], **39**, 1—5).—This research was undertaken to test the validity of the theoretical formulæ deduced by Planck (Abstr., 1888, 1146) to express the difference between the concentration of a solution of one liquid in another, and the concentration of the vapour given off by the solution. Concentration with respect to a certain substance is here taken to mean the ratio which the number of its molecules bears to the total number of molecules in the mixture, whether liquid or gaseous. The substances chosen by the author were water and propyl alcohol, and the method of experiment was either (1) to pass a slow current of dry air through the solution, kept at constant temperature, and collect the vapours in a vessel immersed in a mixture of solid carbonic anhydride and ether; or (2) to exhaust the flask containing the solution to such an extent that gentle ebullition took place, the vapours being condensed as before. Since the composition of the solution changes as the vaporisation proceeds, only relatively small quantities of the distillate could be collected, so that the composition of the latter had to be determined by a process of physical analysis, namely, by ascertaining the index of refraction. The results obtained with mixtures containing respectively 6·2 per cent. and 88·8 per cent. of propyl alcohol are considered by the author to be in satisfactory accordance with the formulæ, which, strictly speaking, hold good only for very dilute solutions.

J. W.

Vapour-pressures of Solutions in Acetic Acid. By F. M. RAOULT and A. RECOURA (*Compt. rend.*, **110**, 402—405).—The vapour-tensions of acetic acid at various temperatures are as follows:—

t.	115°.	116°.	117°.	118°.	119°.	120°.	121°.	122°.	123°.	124°.
V. T.	700·6	722·5	745·2	768·4	792·8	818·5	844·2	871·0	898·2	925·6

The vapour-tensions of solutions of various substances in acetic acid were determined by the dynamical method, that is, by observing the boiling point under known pressures. This method can only be applied in somewhat concentrated solutions, but by means of other observations on solutions of various strengths, it is possible to calculate the reduction of vapour-tension in a very dilute solution (Abstr., 1888, 1145).

It has been shown that if f is the vapour-pressure of the solvent at a given temperature, f' its vapour-pressure at the same temperature when it holds a solid substance in solution, P the weight of the solid substance in 100 grams of the solvent, M the molecular weight of the solid, and M′ the molecular weight of the solvent, then, in very dilute solutions—

$$k = \frac{100(f - f')}{fP}\frac{M}{M'},$$

k being a constant for each solvent. The value of k varies between 0·96 and 1·09, the mean being 1·05, and it is, therefore, practically unity for every solvent. Taking $M' = 60$, or, in other words, assuming that the physical molecule of boiling liquid acetic acid is identical with the chemical molecule, the following values of k were obtained with various solids:—Nitronaphthalene 1·63, monobromcamphor 1·63, benzophenone 1·68, picric acid 1·60, salicylic acid 1·60, benzoic acid 1·59, diphenylamine acetate 1·57, potassium acetate 1·57, the mean being 1·61.

Acetic acid, therefore, presents an apparent anomaly. All analogy indicates, however, that at a given temperature the constitution of the physical molecule of a substance is the same in both the liquid state and the state of saturated vapour. If this be so, the molecular weight of boiling acetic acid will be 97, since the vapour-density of its saturated vapour at 118° is 3·35. If this value 97 is substituted for 60 in the calculation of the value of k, the mean result is practically 1·0, as in the case of all other solvents. The exception is, therefore, only apparent, and is correlated to the anomalous vapour-density of the acetic acid. C. H. B.

Influence of Capillarity and Diffusion on the Solvent Action of Liquids. By N. v. Klobukoff (*Zeit. physikal. Chem.*, 5, 181—190).—The author describes a number of experiments on the solvent action of liquids similar to those made by Spring (this vol., p. 328). He comes to conclusions with respect to the explanation of the phenomena observed which are in agreement with those of Bechhold (*loc. cit.*). H. C.

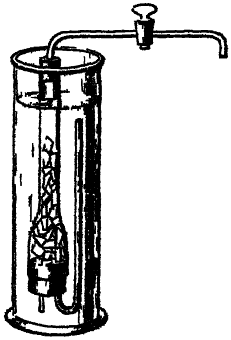
Nature of Osmotic Pressure. By J. H. van't Hoff (*Zeit. physikal. Chem.*, 5, 174—176).—A reply to the paper on the same subject by L. Meyer (this vol. p. 441). The author defends his view that the osmotic pressure is caused by the dissolved substance and not by the solvent, and supports it by the following argument. If we imagine nitrogen contained in a vessel of a material which it cannot permeate, but which is permeable by other gases, and this vessel be immersed in an atmosphere of hydrogen, the pressure of the hydrogen within and without the vessel will be the same, and any excess of pressure within the vessel will be due to the nitrogen which cannot permeate its walls. This will be true whatever the initial pressure and density of the hydrogen gas may be, and any change in this will in no way affect the excess of pressure within the vessel in magnitude, this latter being due solely to the nitrogen. Hence, if we imagine the pressure on the hydrogen increased until the gas is liquefied, the excess of pressure within the vessel will still remain the same, and will be that due to the nitrogen. But in this last case we must regard the hydrogen as the solvent and the nitrogen as the disolved substance, and the excess of pressure, which is what the author has called the osmotic pressure, is evidently due solely to the nitrogen, that is, to the dissolved substance. H. C.

Stereochemical and Mechanical Views with reference to Single and Multiple Union of Atoms, and the Changes of One into the Other. By A. Naumann (*Ber.*, 23, 477—484).—The carbon-atom is regarded as occupying the centre of a regular tetrahedron, its attractions being exercised in the directions of the four solid angles. The line joining the centres of two such carbon-atoms with one another is assumed in each case to represent in magnitude and direction the resultant of the attractions by which the two atoms are held together. If in the case of a single bond the length of this line be taken as unity, then it follows geometrically that for a double bond the length will be 0·5774, and for a treble bond 0·3333; that is, the magnitude of the attraction in the first case being unity, in the second it will be 2 × 0·5774, and in the third 3 × 0·3333. Similar reasoning to the above may be employed in ascertaining the attractions of atoms other than carbon for one another. H. C.

Molecular Theory of a Substance formed from two different Components. By J. D. VAN DER WAALS (*Zeit. physikal. Chem.*, 5, 133—173).—A mathematical paper not suitable for abstraction. H. C.

Apparatus for Fractional Distillation under Reduced Pressure. By E. VALENTA (*Zeit. anal. Chem.*, 28, 673—676).—This apparatus was designed for the fractional distillation of substances which solidify at ordinary temperatures. The only novel portion is the receiver. This is a cylindrical vessel having at the top a tubulure to receive the end of the condenser tube, and a stopcock for connection with the pump. At the lower end the cylinder is narrowed to a tube which can be fitted into the necks of the flasks which are to receive the various fractions. This tube has a three-way tap, by which either the cylinder or the flask, or both, can be put in communication with the external air, so that the vacuum in the cylinder can be maintained while the flask is being changed. The cylinder is surrounded by a water-jacket, by which it can be kept at any convenient temperature. M. J. S.

Apparatus for Preparing Gases. By A. BURGEMEISTER (*Zeit. anal. Chem.*, 28, 676).—A lamp-chimney is fitted with tubes as shown in the figure. The short straight one ending inside level with the lower cork is about 10 mm. in diameter, and projects 10—20 mm.



The bent tube is narrower, and projects inside 20—30 mm. above the cork. When the stopcock is opened, the acid enters by the narrow tube, and the heavier liquid produced by the reaction flows away by the short tube, and remains at the bottom of the outer vessel.

M. J. S.

Removal of Exhausted Solutions from Gas Apparatus. By A. C. HERZOG (*Zeit. anal. Chem.*, 28, 678).—Instead of a separate syphon tube, the author uses a thistle-headed funnel which has a side tube branched in at a spot where the funnel tube is expanded into a bulb. The funnel can be shut off by a stopcock, and the gas pressure in the flask (when the gas outlet is closed) drives up the nearly exhausted liquid to the side tube, where it flows away.

M. J. S.

Inorganic Chemistry.

Action of Fluorine on Different Forms of Carbon. By H. MOISSAN (*Compt. rend.*, 110, 276—279).—Chlorine does not combine directly with carbon even at very high temperatures, but fluorine and carbon combine with great energy even at the ordinary temperature. Lamp-black, purified and dried, immediately becomes incandescent; wood charcoal takes fire spontaneously, with projection of brilliant sparks. Denser forms of carbon must be heated to 50° or 100° before they will become incandescent. Ferruginous graphite from cast iron unites with fluorine below a dull red heat; Ceylon graphite, purified by fusion with potash, requires to be heated to a somewhat higher temperature; gas carbon burns in fluorine only at a red heat; the diamond is not affected when heated to redness in a current of fluorine. The products are gaseous, and are usually mixtures of different carbon fluorides.

The action of fluorine on an excess of one of the lighter forms of carbon, care being taken that the temperature does not rise very high, yields carbon tetrafluoride, CF_4, a colourless gas which liquefies under a pressure of 5 atmos. at 10°. Its sp. gr. agrees closely with the calculated number. Carbon tetrafluoride in contact with alcoholic potash yields potassium fluoride and carbonate. It is not decomposed by an electric spark, and is soluble in carbon tetrachloride, alcohol, benzene, and to a slight extent in carbon bisulphide. The gas can also be obtained by passing carbon tetrachloride vapour over silver fluoride heated at 300° in a glass or metal tube (compare Abstr., 1888, 1262).

The action of fluorine on carbon at a red heat yields a gaseous carbon fluoride which is not decomposed by electric sparks, is not absorbed by aqueous or alcoholic potash, is almost insoluble in water, but dissolves in alcohol. A small quantity of a solid product is obtained at the same time.

Both gaseous carbon fluorides yield a complex spectrum of lines and bands, amongst which the lines of fluorine are very distinct.

Guntz commenced the investigation of carbon fluorides, which he obtained by the action of carbon tetrachloride on metallic fluorides, but, at Berthelot's suggestion, relinquished the research in favour of Moissan. C. H. B.

General Method for the Preparation of Carbon Fluorides. By C. Chabrié (*Compt. rend.*, 110, 279—282; compare Moissan, preceding abstract).—Silver fluoride and carbon tetrachloride are heated together at 220° for two hours in sealed tubes of Bohemian glass. The glass is only slightly attacked. The product is carbon tetrafluoride, a gas which is only slightly soluble in water, but dissolves in benzene, and is absorbed by potassium hydroxide with formation of potassium carbonate and fluoride. Dicarbon tetrachloride yields dicarbon tetrafluoride, C_2F_4; sp. gr. = 3·43 (calc. = 3·46). C. H. B.

Vapour-densities of Selenium Chlorides. By C. Chabrié (*Bull. Soc. Chim.* [3], 2, 803).—When selenium tetrachloride is heated with chlorine in sealed tubes at 190—200° for 10—15 hours, it sublimes, and is deposited in well-defined crystals at the cooler end of the tube. The vapour-density, as determined by Meyer's method in an atmosphere of nitrogen at 360°, was found in two experiments to be 3·85 and 3·78 respectively, which corresponds with a dissociation occurring at that temperature, according to the equation—

$$2SeCl_4 = Se_2Cl_2 + 3Cl_2.$$

The vapour-density of selenium dichloride was found to be normal, the obtained values 7·69 and 8·123 agreeing closely with the calculated value 7·95. T. G. N.

Hydroxylamine Hydrochloride. By Eichkoff (*J. Pharm.* [5], 21, 245—246; from *Arch. Pharm.* [3], 27, 713).—According to Raschig, the salt is obtained as follows:—A saturated solution of sodium nitrite (1 mol.) is added to a solution of hydrogen sodium sulphite (2 mols.) in a cooled vessel, and then a cold saturated solution of potassium chloride is added. In 24 hours hydroxylamine potassium disulphonate separates. This salt is boiled in water during several hours, and, on cooling, potassium sulphate is first deposited, and subsequently hydroxylamine sulphate. A solution of this salt, treated with the necessary amount of barium chloride, yields the hydrochloride, which can be obtained in colourless crystals, very hygroscopic, easily soluble in water and in alcohol. It melts at 151°, and decomposes at a higher temperature, yielding nitrogen, hydrogen chloride, ammonium chloride, and water. J. T.

Compounds of Hydroxylamine with Metallic Chlorides. By L. Crismer (*Bull. Soc. Chim.* [3], 3, 114—121).—Dihydroxylamine zinc chloride, $ZnCl_2,2NH_2·OH$, is formed when zinc reacts with hydroxylamine hydrochloride at 100°, or when an aqueous solution of the latter is treated with zinc sulphate and barium carbonate, or with zinc oxide or carbonate, as also when zinc chloride is added to an alcoholic solution of hydroxylamine hydrochloride. It is best prepared by dissolving hydroxylamine hydrochloride (10 parts) in strong alcohol (300 c.c.) contained in a reflux apparatus, and adding zinc oxide (5 parts) to the boiling solution; after a few minutes' ebullition, the clear liquor is decanted, and deposits, on cooling, dihydroxylamine zinc chloride as a white, crystalline powder. This substance is soluble in solutions of hydroxylamine hydrochloride, and is but slightly soluble in water and alcohol; it is alkaline to litmus, and its solutions decompose on evaporation, hydroxylamine being liberated. At 120°, it decomposes into zinc chloride, nitrous acid, ammonia, and hydroxylamine.

Dihydroxylamine cadmium chloride, $CdCl_2,2NH_2\cdot OH$, may be prepared by any of the above methods, and forms brilliant crystals which are much more stable than those of the zinc compound.

Dihydroxylyamine barium chloride, $BaCl_2,2NH_2\cdot OH$, is formed when barium carbonate reacts with a concentrated aqueous solution of hydroxylamine hydrochloride. It separates from its aqueous solution in large, tabular crystals.

Regarding dihydroxylamine zinc chloride as a combination of a dehydrating agent with anhydrous hydroxylamine, the author suggests its use for the preparation of aldoximes and of hydroxamic acids, and has already prepared acetoxime, camphoroxime, and acetohydroxamic acid by a simple reaction of the substance with acetone, camphor, and acetic acid respectively. T. G. N.

Combination of Ammonia and Hydrogen Phosphide with Silicon Chloride and Silicon Bromide. By A. BESSON (*Compt. rend.*, **110**, 240—242).—Ammonia is rapidly absorbed by silicon chloride with formation of the compound $SiCl_4,6NH_3$ described by Persoz in 1830. Silicon bromide acts less energetically, and must be left in an atmosphere of ammonia for 48 hours. The product $SiBr_4,7NH_3$ is an amorphous, white solid, similar in appearance to the chlorine compound. It is decomposed by water with formation of an alkaline solution smelling strongly of ammonia.

Hydrogen phosphide is not absorbed by silicon chloride at the ordinary temperature, but at −23°, the chloride absorbs about 20 vols. of the gas, which are given off unchanged if the temperature is raised to 20°. At −50°, 40 vols. of hydrogen phosphide are absorbed, with formation of a compound $SiCl_4,2PH_3$, which remains liquid even at −60°. Under a pressure of 20 atmos. at 16°, hydrogen phosphide and silicon chloride yield small, highly refractive crystals, which disappear when the pressure falls to 15 atmos. At 0°, the crystals appear under 15 atmos., and disappear when the pressure falls to 10 atmos.; at −23°, they appear under 5 atmos., and remain after the pressure is removed; at −35°, the crystals form under the ordinary pressure. The composition of this compound could not be determined; it is formed from the vapour of the chloride, and is never formed in the liquid.

Silicon bromide is without action on hydrogen phosphide under the ordinary pressure, even at a temperature at which it solidifies. After repeated compression and maintenance of the pressure for several hours, a colourless liquid forms, which becomes white and opaque and changes into an amorphous, white solid. C. H. B.

Compounds of the Alkali Metals and Ammonia. By JOANNIS (*Compt. rend.*, **110**, 238—240).—The author has previously found (this vol., p. 209) that the vapour-pressure of a solution of sodium in liquid ammonia varies until the composition Na + 5·3NH$_3$ is reached, then remains constant until solid sodammonium separates, the complete removal of ammonia being followed by the dissociation of the sodammonium.

The method adopted enabled a difference of pressure of 0·2 mm. to be recognised. At 0° the tension remained constant; at —10° it remained constant, whilst the composition varied from NaNH$_3$ + 0·46NH$_3$ to 0·19NaNH$_3$ + 0·81Na; at 22·4° the tension was constant, although the composition varied from NaNH$_3$ + 2·42NH$_3$ to 0·67NaNH$_3$ + 0·33NH$_3$. At the different temperatures the volatilisation of the ammonia left a crystalline residue of sodammonium, and not of sodium alone. Similar results were obtained with potassammonium between 0° and +8·44°.

Roozeboom's hypothesis (this vol., p. 450) requires unequal pressure below 0°, and the decomposition of the saturated solution into sodium and ammonia above 0°, without the appearance of any solid sodammonium. C. H. B.

Blue Flame produced by Common Salt in a Coal Fire. By G. SALET (*Compt. rend.*, **110**, 282—283).—The well-known blue flame which is produced when common salt is thrown into a coal or coke fire, and which A. P. Smith attributed to hydrogen chloride (Abstr., 1879, 497) is due to cupric chloride, and its spectrum (*loc. cit.*) corresponds with the second spectrum of the chloride as described by de Boisbaudran. Copper was readily detected in the ash of the coke used by a delicate method which is generally applicable. The copper in the solution is deposited on the point of a needle, and if the latter is held in a bunsen flame, no coloration is produced, but when hydrochloric acid is volatilised in the flame, the green colour of the copper chloride becomes visible. The reaction is very delicate. The volatilisation of hydrochloric acid in a flame for this and similar purposes is readily effected by introducing into the flame a bundle of very fine platinum wire which has been dipped in the acid. It is easy to arrange this bundle so that the acid is supplied to the flame continuously. C. H. B.

Ammonium Borofluoride. By F. STOLBA (*Chem. Centr.*, 1890, i, 211—212, from *Chem. tech. Centralanzeig.*, **7**, 459—460).—Ammonium borofluoride is prepared by saturating commercial hydrogen fluoride with boric acid, and then adding ammonia to alkaline reaction. The silicic acid contained in the commercial hydrofluoric acid is precipitated and is filtered off, and the filtrate allowed to cool, when ammonium borofluoride crystallises out. It may be purified by recrystallisation from water. When heated in a platinum dish, it completely volatilises; the freshly prepared solution has a slightly acid reaction to litmus. The aqueous-alcoholic solution burns without any green flame. It has only slightly antiseptic properties, and is not nearly so poisonous as the silicofluoride. Its density = 1·851 at 17·5°. It is soluble in 4 parts of water at 16°, and in 1·02—1·05 parts of boiling water. J. W. L.

Silver. By J. S. Stas (*Chem. Centr.*, 1890, i, 87; from *Bull. Acad. roy. Belg.* [3], 18, 23).—At the request of Dumas, the author has repeated all his experiments on silver. He finds that the metal is slightly volatile at a low red heat in a vacuum, but not at this temperature under the ordinary atmospheric pressure, nor in a vacuum at 440—450°. Finally, he finds that the silver which he used in his atomic weight determinations contained gases, but that their quantity was altogether insignificant ($\frac{1}{35600}$ by weight), and the error caused thereby could not affect the results to any greater extent than those errors which are unavoidable in such experiments. J. W. L.

Barium, Strontium, and Calcium Plumbates. By G. Kassner (*Arch. Pharm.* [3], 28, 109—115).—Equal weights of barium hydroxide and lead oxide, when heated together while exposed to air, give a new black compound, barium plumbate, Ba_2PbO_4; a mixture of lead oxide (1 mol.) and barium carbonate (2 mols.), heated to bright redness, gives the same compound, but the temperature required is much higher than with the hydroxide, where it can be produced in the bunsen flame. Similarly, strontium carbonate gives a salt of a chocolate-brown colour, whilst calcium plumbate is formed from the carbonate at a comparatively low temperature, that of a bunsen flame sufficing. The calcium mixture remains pulverulent to the end, and the plumbate forms a heavy, yellowish-red powder, scarcely distinguishable in appearance from powdered lead oxide. The three new compounds are entirely insoluble in water; but on long standing the water becomes alkaline, and a skin of alkaline carbonate forms on the surface. They are all decomposed by acids: in the case of hydrochloric acid, with evolution of chlorine; other acids cause the precipitation of lead peroxide, which may be looked on as the anhydride of orthoplumbic acid, H_4PbO_4. To obtain a clear solution of the three compounds in acid, a reducing agent is necessary, such as oxalic acid, sugar, &c. Nitric acid and hot acetic acid are most suitable for this purpose. Carbonic anhydride in the presence of moisture decomposes the plumbates. The alkaline hydrogen carbonates decompose them with considerable increase of temperature and formation of alkaline hydroxide, which is free from lead when excess of lead oxide has been avoided in preparing the plumbate. Finally, water alone under high pressure and increased temperature produces considerable decomposition. If ammonium salts are added to the water, ammonia is set free, a salt of the earth is produced and lead peroxide; if the salt be soluble, lead peroxide can thus be obtained in a pure form.

J. T.

Sodium Beryllium Silicates. By P. HAUTEFEUILLE and A. PERREY (*Compt. rend.*, **110**, 344—346; compare Abstr., 1889, 104).—A mixture of beryllia, silica, and sodium oxide, in the same proportions as in beryllium nepheline, when heated with excess of normal sodium vanadate at about 800°, yields crystals which, when purified by treatment with hot water and levigation, have the composition

$$3SiO_2,Be_2O_3,Na_2O.$$

The crystals are hexagonal prisms terminated by well-developed hexagonal prisms, are birefractive, uniaxial, and negative, and have a conchoidal fracture. They have a blue or green coloration, due to minute quantities of vanadium, melt easily before the blowpipe, and are slowly attacked by concentrated acid in the cold.

If the three oxides are mixed in proportions corresponding with the preceding product and treated in the same way, they yield a new compound which has the composition of an albite, $6SiO_2,Be_2O_3,Na_2O$, crystallises in monoclinic prisms with modified angles, and is not attacked by acids.

Silica in the proportion of $4{\cdot}5SiO_2$ to Be_2O_3, yields rhombic prisms of the composition $20{\cdot}67$ to $22{\cdot}41SiO_2,3Be_2O_3,2Na_2O$.

A mixture in the proportion $2SiO_2 + Be_2O_3 + 1{\cdot}5Na_2O$ yields a mixture of the two compounds $3SiO_2,Be_2O_3,Na_2O$ and

$$15SiO_2,2Be_2O_3,3Na_2O.$$

They crystallise together, and can be separated by treating the crystals with hydrochloric acid and then levigating with a solution of cadmium tungstoborate.

A mixture of $7SiO_2$, Be_2O_3, $1{\cdot}5Na_2O$ yields rhombic prisms of the compound $18SiO_2,2Be_2O_3,3Na_2O$, which has the same form as the compound containing $15SiO_2$.

With sodium tungstate instead of vanadate, the compounds $14SiO_2,2Be_2O_3.3Na_2O$ and $18SiO_2,2Be_2O_3,3Na_2O$ are obtained.

C. H. B.

Action of Potassium and Sodium Arsenates on Oxides of the Magnesium Series at High Temperatures. By C. LEFÈVRE (*Compt. rend.*, **110**, 405—408).—Magnesium carbonate or oxide dissolved at a low temperature in excess of fused potassium metarsenate yields a pyroarsenate, $4MgO,2K_2O,3As_2O_5$, crystallising in transparent prisms with angles of extinction at 45° from the axis. If the metarsenate is saturated with the oxide at a higher temperature, the orthoarsenate, $2MgO,K_2O,As_2O_5$, is obtained; it is analogous to the phosphate formed under similar conditions. In presence of potassium chloride, the same product is obtained if the proportion of chloride does not exceed 85 per cent., but with a higher proportion, chlorine compounds are formed. Potassium pyroarsenate and orthoarsenate in presence of potassium chloride yield the same compound; it crystallises in foliated lamellæ with longitudinal extinction.

At low temperatures, without excess of oxide, sodium metarsenate yields the pyroarsenate, $4MgO,2Na_2O,3As_2O_5$, in the form of large, transparent lamellæ, which act only slightly on polarised light. At higher temperatures, and with a greater proportion of oxide, the product is the orthoarsenate, $2MgO,Na_2O,As_2O_5$. Sodium pyroarsenate and orthoarsenate yield the same product, and it is also formed in presence of sodium chloride; it crystallises in large, transparent prisms which show longitudinal extinction and dissolve slowly in dilute acids.

Zinc oxide in excess of potassium metarsenate yields the compound $2ZnO,As_2O_5$ in small lamellæ which act on polarised light and are slowly altered by water. With excess of zinc oxide, the product is $2ZnO,K_2O,As_2O_5$, which is also formed in presence of potassium chloride in any proportion. Potassium orthoarsenate and pyroarsenate yield the same product; it crystallises in small, slightly opaque prisms, with longitudinal extinction. Sodium metarsenate at low temperatures yields the compound ZnO,Na_2O,As_2O_5, which acts energetically on polarised light. With excess of zinc oxide at a higher temperature, the product is $2ZnO,Na_2O,As_2O_5$, which is also formed in presence of sodium chloride; it crystallises in elongated, transparent prisms with longitudinal extinction.

Manganese carbonate, or one of the oxides, dissolved in excess of potassium metarsenate, yields the compound $2MnO,As_2O_5$, isomorphous with the corresponding product from zinc. With excess of manganese, the product is $2MnO,K_2O,As_2O_5$, which is also formed in presence of potassium chloride in proportion not exceeding 88 per cent. With a higher proportion of the chloride, chlorine compounds are obtained. Potassium pyro- and ortho-arsenate yield the same compound; it crystallises in rose-coloured prisms, and is isomorphous with the corresponding magnesium compound. Sodium metarsenate yields the compound $2MnO,4Na_2O,3As_2O_5$ in small, colourless crystals with oblique extinction. In presence of sodium chloride, the same product is obtained, together with the compound $MnO,2Na_2O,As_2O_5$, which is the sole product when the orthoarsenate or pyroarsenate is employed, and crystallises in small, transparent, rose-coloured crystals without action on polarised light.

Cadmium oxide, or carbonate, and potassium metarsenate yield the product $2CdO,As_2O_5$, or if the oxide is in excess, $2CdO,K_2O,As_2O_5$, isomorphous with the corresponding zinc compound. No chlorine-products are formed even in presence of large quantities of potassium chloride. Sodium arsenates yield the products $2CdO,4Na_2O,As_2O_5$ and $CdO,2Na_2O,As_2O_5$, isomorphous with the corresponding manganese compounds.

Nickel oxide dissolved in potassium metarsenate to the extent of 8 per cent. yields the compound $12NiO,3K_2O,5As_2O_5$ in prisms, which are probably rhombic. With a higher proportion of nickel, the product $2NiO,K_2O,As_2O_5$ is obtained at the same time, and in presence of potassium chloride it is the only product; it crystallises in large, pale-yellow, micaceous lamellæ which depolarise light feebly. Sodium metarsenate yields green, transparent, monoclinic prisms of the pyroarsenate, $4NiO,2Na_2O,3As_2O_5$. In presence of sodium chloride, the compound $2NiO,Na_2O,As_2O_5$ is also obtained; the latter is the sole product when sodium pyroarsenate or orthoarsenate is used; it crystallises in green lamellæ derived from a hexagonal prism.

Cobalt oxide in small quantity in potassium metarsenate is converted into violet mamillary crystals of the compound $2CoO,As_2O_5$, which act on polarised light. With more cobalt oxide, the product $2CoO,K_2O,As_2O_5$ is obtained in slightly opaque, blue prisms with longitudinal extinction. This compound is the sole product in presence of potassium chloride. Sodium metarsenate yields the compound $4CoO,2Na_2O,3As_2O_5$ in violet, strongly macled lamellæ, isomorphous with the corresponding compound of nickel. In presence of sodium chloride, the compound $CoO,2Na_2O,As_2O_5$ is also formed, and it is the only product when sodium orthoarsenate or pyroarsenate is used; it forms blue, transparent crystals, isomorphous with those of the corresponding manganese and cadmium compounds.

With the potassium arsenates, all the oxides yield as the ultimate product a compound with the formula $2MO,K_2O,As_2O_5$. With the sodium arsenates, magnesium, zinc, and nickel yield a similar product, but cobalt, cadmium, and manganese yield a compound $MO,2Na_2O,As_2O_5$. C. H. B.

Thiosulphates. By A. Fock and K. Klüss (*Ber.*, 23, 534—541; compare this vol., p. 330).—The solid manganese thiosulphate described by Vortmann and Padberg (this vol., p. 12) could not be obtained by the authors; the reddish oil which is precipitated on adding alcoholic ether to its solutions decomposes, into sulphur and manganese sulphite.

Cadmium thiosulphate, $CdS_2O_3 + 2H_2O$, is obtained in crystals when a solution of strontium thiosulphate is treated with cadmium sulphate, the filtrate mixed with alcoholic ether and kept for some time. It does not lose its water over sulphuric acid, but it gradually decomposes into cadmium sulphide and sulphate on keeping, with liberation of sulphurous anhydride.

The salt $NH_4S{\cdot}SO_2{\cdot}OK$ crystallises in small, colourless, monosymmetric plates, $a : b : c = 1·3547 : 1 : 0·8521$; when boiled with water and ethyl bromide, it yields potassium ethyl thiosulphate, $SEt{\cdot}SO_2{\cdot}OK$. The salt $SK{\cdot}SO_2{\cdot}ONH_4$ could not be obtained.

Potassium magnesium thiosulphate, $K_2S_2O_3,MgS_2O_3 + 6H_2O$, forms large, transparent, monosymmetric crystals, $a:b:c = 2·0001 : 1 : 0·4744$; it is not deliquescent, and does not lose weight when kept over sulphuric acid.

The ammonium magnesium salt, $(NH_4)_2S_2O_3,Mg_2S_2O_3 + 6H_2O$, crystallises in monosymmetric prisms, $a : b : c = 0·6422 : 1 : 0·9238$, is stable in the air and does not lose water over sulphuric acid.

F. S. K.

Saturated Solutions of Compounds of Cupric and Potassium Chlorides. By W. Meyerhoffer (*Zeit. physikal. Chem.*, 5, 97—132).—In a former paper (Abstr., 1889, 819), the author has shown that two compounds of cupric and potassium chlorides, $CuCl_2,2KCl + 2H_2O$ and $CuCl_2,KCl$, are capable of existing in the solid form. A determination of the solubility of the compounds of cupric and potassium chlorides at temperatures from 0° to 100°, and an examination of the curves obtained, show that between the three substances $CuCl_2$, KCl, and H_2O the following conditions of equilibrium may exist.

First Group: Two substances and three phases—

1. KCl + solution + vapour.
2. $CuCl_2,2H_2O$ + " + "
3. $CuCl_2,KCl$ + " + "
4. $CuCl_2,2KCl,2H_2O$ + " + "

Second Group: Three substances and four phases—

5. $CuCl_2,2KCl,2H_2O$ + KCl + solution + vapour.
6. $CuCl_2,KCl$ + KCl + " + "
7. $CuCl_2,2KCl,2H_2O$ + $CuCl_2,2H_2O$ + " + "
8. $CuCl_2,KCl$ + $CuCl_2,2H_2O$ + " + "
9. $CuCl_2,KCl$ + $CuCl_2,2KCl,2H_2O$ + solution + vapour.

H. C.

Crystalline Mercury Oxychloride and Estimation of Mercury. By J. VOLHARD (*Annalen*, **255**, 252—256).—Mercury oxychloride, $Hg_3O_2Cl_2$, can be easily prepared by treating a cold saturated solution of mercuric chloride with sodium acetate. After keeping for some days, crystals are deposited together with a colourless, flocculent compound which can be easily separated; when no further separation of the oxychloride occurs, a solution of potassium hydrogen carbonate is added, in small quantities at a time, whereon a further crop of crystals is obtained. The crystals are monoclinic, $a : b : c = 0·9178 : 1 : 0·9978$, $\beta = 65° 30'$; they are anhydrous, and when crushed form a reddish-brown powder. Mercury oxychloride is insoluble in water, but readily soluble in acids; it is converted into the red oxide when treated with alkalis. When heated carefully, mercury chloride sublimes, leaving almost pure oxide.

Mercury sulphide is completely precipitated from its solution in alkalis on the addition of ammonium salts; this reaction can be employed for the estimation of mercury as follows:—The solution of mercury, which must be in the mercuric condition, is partially neutralised with sodium carbonate, treated with a slight excess of a concentrated, freshly prepared solution of ammonium sulphide, and pure sodium hydrate added, with constant shaking, until the solution commences to become transparent. The whole is then boiled, the addition of soda continued until the sulphide has completely dissolved, and then a solution of ammonium nitrate added to the boiling solution until the sulphide is completely reprecipitated. After boiling until the ammonia is almost completely expelled, the precipitate is allowed to settle, washed by decantation with boiling water until the washings give no reaction with silver solution, then transferred to a weighed filter, dried, and weighed. If the boiling has been continued so long that the precipitate may be contaminated with sulphur, a little sodium sulphite is added, and the solution boiled again.

By this method mercury can be estimated as sulphide much more conveniently, accurately, and quickly than by precipitation with hydrogen sulphide.

F. S. K.

History of the Rare Earths. By L. DE BOISBAUDRAN (*Bull. Soc. Chim.* [3], **3**, 53—67).—A lengthy controversial paper, in which the author criticises some of the statements made by Mr. Crookes in his presidential address (Trans., 1889, 269). The author considers the substances denoted as Z_α and Z_β to be quite distinct from "yttria," both as regards their atomic weights and their chemical properties, and that they are actively fluorescent, and do not give the yttria spark spectrum. Further, he replies to Crookes in reference to reversion spectra, the gadolinium question, and the fluorescence of alumina.

T. G. N.

Constitution of Manganese Peroxide. By W. SPRING and M. LUCION (*Bull. Soc. Chim.* [3], 3, 4—8).—From the fact that when barium peroxide is triturated with a slight excess of crystalline manganous chloride, oxygen is evolved and manganic sesquioxide is formed, it would seem that the molecular structure of manganese peroxide differs from that of barium peroxide.

When barium manganate is heated with a solution of manganous sulphate at 100° for a week, manganese peroxide is obtained, and from this method of formation it may be regarded as a manganous manganate, $MnMnO_4$.

At a high temperature, sodium manganate and manganous carbonate react without evolution of oxygen to form manganese sesquioxide. Manganese peroxide, when heated with sodium hydroxide in an atmosphere of nitrogen, leaves a residue of manganese sesquioxide, and not of manganese peroxide, and from this fact the authors conclude that manganous oxide is formed in the reaction and unites with manganese peroxide, thus—$MnO + MnO_2 = Mn_2O_3$, and they consider this relationship is substantiated, since manganese sesquioxide reacts with dilute nitric acid to produce manganous nitrate and manganese peroxide—$Mn_2O_3 + 2HNO_3 = Mn(NO_3)_2 + MnO_2 + H_2O$.

The authors conclude that the formula for manganese peroxide should be doubled, and Mn_2O_4 would then represent a manganous manganate, $MnMnO_4$.

T. G. N.

Influence of certain Foreign Metals on the Properties of Steel. By F. OSMOND (*Compt. rend.*, **110**, 242—245).—It is known that while iron cools from a high temperature, two distinct developments of heat take place, one, a_3, which causes the temperature to remain at 855° for a long time, and is due to the conversion of the allotropic modification $Fe\beta$ into the modification $Fe\alpha$; the other, a_3, at about 730°, much less strongly marked and possibly due to another allotropic change, possibly merely the final stage of a_3 which has been retarded by the presence of carbon. In addition to these, there is the change a_1, or recalescence, due to the conversion of tempered carbon into annealed carbon.

Boron.—Iron containing boron was prepared by Roberts-Austen by fusing the metal with crystallised boron in a vacuum. The boron behaves in the same manner as carbon; a_3 is lowered and takes place at 815—805°, and partly at 735—725°, or becomes partially coincident with a_2.

Nickel, in quantity varying from traces to 5·97 per cent., the proportion of carbon being 0·34 per cent. In similar steel free from nickel a_3

and a_2 are coincident, but remain quite distinct from a_1. When the steel contains nickel, a_3, a_2, and a_1 coincide at 660—640°, a point distinctly below the normal temperature of recalescence. Hopkinson has observed that with a steel containing 25 per cent. of nickel, the critical point remained below 0° during the whole period of cooling. The effect of nickel is similar to that of manganese.

Copper.—Samples prepared by Ball and Wingham had the following composition—

	1.	2.	3.
Copper	0·847	4·10	4·44
Carbon	0·102	0·183	0·10

As the proportion of copper rises, a_3 and a_2 are lowered, and with the quantity present in samples 2 and 3, a_3 and a_2 coincide at 730—720°, whilst a_1 takes place at 625—600°. Copper has the same effect as carbon, but in a lower degree; its influence on recalescence is similar to that of manganese and nickel.

Silicon.—With specimens prepared by Hadfield, as the proportion of silicon increases the quantity of heat liberated during a_3 decreases, and with 2 per cent of silicon is practically *nil*. Moreover, the evolution of heat does not take place at a lower temperature as with carbon, manganese, nickel or copper, and it follows that silicon prevents the conversion of Feα into Feβ; the other elements enumerated tend to keep the iron in the form of Feβ during cooling. a_2 is as well marked as usual, but takes place at 730—720° or 710—700°. a_1 is also distinct, but takes place at a higher temperature, 660° to 650° or 710° to 700°.

Arsenic, varying in quantity from traces to 0·55 per cent. in specimens prepared by Harbord and Tucker, raises the temperature at which a_3 occurs, and makes the phenomenon less distinct. It has no effect on a_2 and a_1, and hence resembles silicon in its action.

Tungsten, in proportion varying from traces to 1·5 per cent., has no effect on a_3, but if the metal has been sufficiently strongly heated it lowers a_1 very considerably, recalescence taking place at 540—530° in the most marked instance. C. H. B.

Influence of Foreign Substances on Iron and Steel: Relation between their Atomic Volume and the Allotropic Modifications of Iron. By F. OSMOND (*Compt. rend.*, **110**, 346—348; compare preceding abstract).—The elements present in the irons and steels which the author has used in his researches on the allotropic modifications of iron may be classed in two groups, according to their atomic volumes.

Element.	Carbon.	Boron.	Nickel.	Manganese.	Copper.
At. vol. . .	3·6	4·1	6·7	6·9	7·1

Element.	Chromium.	Tungsten.	Silicon.	Arsenic.	Phosphorus.	Sulphur.
At. vol. . .	7·7	9·6	11·2	13·2	13·5	15·7

Other conditions being the same, the elements in the first group, which have an atomic volume less than that of iron, 7·2, retard the conversion of Feβ into Feα, and that of "tempered carbon" into "annealed carbon," and hence, if the rate of cooling is equal, they increase the proportion of Feβ in the cooled metal and consequently its hardness. They are, therefore, equivalent in their effect to a higher or lower degree of tempering.

Metals with a higher atomic volume than iron, on the other hand, tend to raise, or to keep at its normal temperature, the conversion of Feβ into Feα, and hence they render the reverse change more or less incomplete during heating, and hasten, as a rule, the conversion of tempered carbon into annealed carbon. They therefore keep the iron in the α condition at high temperatures and also at low temperatures, and their presence in the iron would be one cause of softness and malleability, resembling in this respect the operation of annealing, if it were not that their own properties and those of their compounds produce strongly marked secondary effects.

The connection between the atomic volume of a metal and its effect on iron is similar to that found by Roberts-Austen to exist between the atomic volumes of elements and their effect on gold (*Phil. Trans.*, **179**, 339—349).

C. H. B.

Action of Sodium Carbonate and Bromine on Solutions of Cobalt and Nickel Salts. By J. GIBSON (*Proc. Roy. Soc. Edin.*, **17**, 56—58).—When sodium carbonate is added in large excess to a solution of a cobaltous salt, and the mixture shaken with a sufficient quantity of bromine, the whole of the precipitated cobaltous carbonate dissolves to a dark-green solution, stable at ordinary temperatures, cobaltic oxide being precipitated on the addition of aqueous alkalis. If this green liquid is acidified with sulphurous anhydride, and the decolorised solution then rendered alkaline, a red-coloured solution is produced, which absorbs oxygen from the air, and again becomes green.

If excess of sodium carbonate is added to a solution of nickel, the resulting mixture behaves differently on addition of bromine, according to the quantity of bromine added. If a large excess of bromine is added, part of the nickel goes into solution, part remains undissolved as pale-green carbonate; if a smaller proportion of bromine is added, so as to have excess of sodium carbonate, the nickel is completely converted into peroxide.

The author hopes, by making use of these peculiarities, to devise a rapid and effectual method of separating the two metals.

E. W. P.

Chrome Iron. By S. MEUNIER (*Compt. rend.*, **110**, 424—426).—When a mixture of ferrous chloride and chromic chloride in suitable proportions is heated to redness in a porcelain tube in an atmosphere of hydrogen, a silvery-white, distinctly magnetic metal is obtained, which is not attacked by boiling concentrated nitric or hydrochloric acid, and only very slightly by aqua regia. It has the composition Fe 35·01, Cr 64·80 = 99·81. This alloy is found in the porcelain boat (used to contain the chlorides) in the form of irregular, highly crystalline tubercles, and the interior of the tube is coated with the alloy, which, when in very thin layers, takes dendritic forms.

If this alloy is heated to redness in a current of steam, it is completely oxidised and yields chromite of sp. gr. 4·48, identical in all its properties with the natural mineral.

The alloy can be obtained in concretions round particles of minerals contained in the porcelain tube, and these concretions can be converted into chromite by the action of steam. The author concludes that chromite and analogous minerals have been produced in a similar way from metallic alloys formed in the depths of the earth and brought up into the water-bearing layers of the earth's crust by mechanical forces. C. H. B.

Mineralogical Chemistry.

Native Gold in Calcite. By J. S. DILLER (*Amer. J. Sci.* [3], 39, 160).—At a mine on Digger Creek, Minersville, Trinity Co., California, excellent specimens have been obtained of gold associated with calcite. The calcite occurs in irregularly distributed, small, lenticular masses in a dark, carbonaceous shale. It is not always auriferous, but is occasionally very rich in gold. Quartz has also been found in the mine, but it is less abundant than the calcite, and is rarely auriferous. In the bed containing the calcite, as well as in the metamorphosed beds of the auriferous slate series below it, considerable quantities of iron pyrites occur. This may, perhaps, have been the source of the gold. B. H. B.

Lussatite, a new form of Silica. By E. MALLARD (*Compt. rend.*, 110, 245—247).—Transparent crystals of quartz associated with bitumen at Pont-du-Château are frequently covered with a translucent envelope, which does not hide the form of the crystals, but rounds off their edges and solid angles. It consists of very small nodules with a fibro-lamellar structure, the fibres being perpendicular to the face of the enclosed crystal. These fibres are less birefractive than quartz, extinguish almost exactly along their length, and the sign of their optical elongation is positive; their sp. gr. is 2·04. The optical elongation of chalcedony is always negative; it is more strongly birefractive, and its sp. gr. is 2·59. The sp. gr. of tridymite is 2·22, of opal 1·93 to 2·09. The refractive index of the new mineral for D is 1·446, being almost identical with that of opal and distinctly lower than that of tridymite. It is practically pure silica, but loses 8·1 per cent. of water above 600°. After ignition, its sp. gr. is reduced to 1·94, and the grains have become white and almost opaque, but the fibres retain their birefractive power and the sign of optical elongation remains positive.

This new form of silica, which the author proposes to call *lussatite*, from one of its localities, is never quite pure, but is usually intimately associated with opal, to the presence of which the loss on ignition is probably due. It occurs in concretions consisting mainly of opal; in yellowish stalactitic chalcedony; with opal in the yellowish silica from the Faroe Islands; and probably in many other localities. C. H. B.

Minium from Leadville. By J. D. Hawkins (*Amer. J. Sci.* [3], **39**, 42—43).—Minium from the Rock Mine, Leadville, gave on analysis—

Insol.	Pb_3O_4.	Fe_2O_3.	V_2O_3.	Total.
7·51	91 39	0·80	0·52	100·22

The portion insoluble in hydrochloric acid contained—

SiO_2.	Al_2O_3,Fe_2O_3.	CaO.	PbS.	Total.
2·00	0·41	0·28	5·08	7·77

The mineral has a sp. gr. of 4·55. Its hardness is 2·5, fusibility 1, lustre dull, colour bright-red, streak orange-red, and fracture cubical. The cubical fracture and the occurrence in the minium of galena suggest that the mineral is a pseudomorph after galena.

B. H. B.

Corundum in Patrick Co., Virginia. By F. A. Genth (*Amer. J. Sci.* [3], **39**, 47—50).—On a hill near Stuart, Patrick Co., Virginia, corundum and associated minerals were found on the surface. The rocks of the district are mica schists, chloritic schists, and slates, intersected by several granite dykes. Neither serpentine nor olivine rock has been observed in connection with the corundum. This occurrence of corundum is thus entirely different from any previously described. Only a small quantity of the mineral has been found. Sometimes only microscopic grains of the corundum are left disseminated in the materials resulting from its alteration, namely, andalusite, cyanite, mica, and chloritoid. The alteration of corundum into andalusite has never been observed before. B. H. B.

Manganese Oxides: Psilomelanes and Wads. By A. Gorgeu (*Compt. rend.*, **110**, 247—249).—Three samples of psilomelane, from Romanèche, Thuringia, and Lorca, in Spain, were examined with a view to determine their constitution. That from Romanèche was the richest in barium, but the composition of the different layers of the mineral differed considerably. In psilomelanes generally, the higher oxides of manganese are not present in the form of dioxide, but in the form of manganous manganites, such as $MnO,6MnO_2$ and $MnO,8MnO_2$. The basic oxides are variable; manganous and barium oxides in the mineral from Romanèche; manganous, barium, calcium, and potassium oxides in that from Thuringia; manganous, barium, and sodium oxides in that from Lorca. All the psilomelanes are hydrated, and the most basic have the composition $RO,3MnO_2$.

Wads from Romanèche, Giessen, and another locality were examined. Two of them were found to be crystalline, a fact which has not been observed before. The crystals were so small that their form could not be determined, but it was proved that they act distinctly on polarised light. Like the psilomelanes, they are manganites with variable bases, their composition oscillating between $MnO,7MnO_2$ and $MnO,10MnO_2$. One of the crystalline specimens, from Romanèche, had almost exactly the composition $RO,3MnO_2 + H_2O$, and the other. locality unknown, the composition $RO,3MnO_2 + 3H_2O$, and they are therefore closely analogous to the more basic psilomelanes.

The energy of the acidic function of the manganic peroxide is shown by the fact that when finely-powdered psilomelanes or wads are boiled with nitric acid diluted with 4 vols. of water, only a very small proportion of the basic oxides is dissolved even in the case of the specimens richest in barium. C. H. B.

Composition of Saline Sublimates at Vesuvius. By G. FREDA (*Gazzetta*, 19, 16—21).—The analyses here given confirm Scacchi's view that these sublimates often contain a larger percentage of potassium than of sodium chloride. The author ascribes the origin of the potassium chloride to the substitution underground of soda for potash in the molten silicates of potassium by the action of infiltrated sea-water and to the greater volatility of potassium chloride. This substitution may also account for the variations in the composition of leucite from different lavas. S. B. A. A.

Lansfordite and Nesquehonite. By F. A. GENTH and S. L. PENFIELD (*Amer. J. Sci.* [3], 39, 121—137).—Under the name of lansfordite, Genth (Abstr., 1888, 793) described a new mineral discovered in one of the anthracite mines near Lansford, Pennsylvania. Analysis gave results corresponding with the formula $3MgCO_3,Mg(OH)_2 + 21H_2O$. Where the crystals were attached to the carbonaceous shales, groups of transparent, white, radiating prismatic crystals were found. On examination these crystals proved to be a new mineral, having the composition $MgCO_3 + 3H_2O$. To this mineral, the authors have assigned the name of *nesquehonite*, after the locality where it was found, the Nesquehoning mine being one of the best known in Pennsylvania. The crystallisation of this mineral is orthorhombic. The authors also describe a crystallised artificial salt of the same composition as nesquehonite, obtained by dissolving magnesium carbonate in water containing carbonic anhydride, and allowing the solution to remain until crystals are deposited. Altered stalactites from the Nesquehoning mine were found to be pseudomorphs of nesquehonite after lansfordite, and from the crystal faces on the stalactites the authors have been able by very careful study to make out the crystallisation of the original lansfordite, a mineral at present only known as pseudomorphs. The crystals are triclinic, and the measurements given by the authors were obtained from 13 crystals. B H. B.

Monazite from Ural. By C. W. BLOMSTRAND (*J. pr. Chem.* [2], 41, 266—277).—The author has made fresh analyses of this mineral with a view of deciding whether the thorium which has been generally found therein is an essential constituent of the mineral, or is present merely as an accidental admixture of thorite. Three samples were analysed :—

I. Colour, light brown. Cleavage, easy. Powder, pale yellow. Sp. gr., 5·01. General formula, $100(3RO,P_2O_5) + 13(2RO,SiO_2) + 12H_2O$. Special formula, $20(Ce,La)_2(PO_4)_2 + 2ThSiO_4 + 0{\cdot}6R_2SiO_4 + 2{\cdot}4H_2O$.

II. Colour, dark yellowish-brown. Brittle. Fracture, splintering. Powder, pale yellow. Sp. gr., 5·266. Crystals, $2\frac{1}{2}$ cm. long, greatest thickness 1 cm., irregular. General formula, $100(3RO,P_2O_5) + 29(2RO,SiO_2) + 18H_2O$. Special formula, $20(Ce,La)_2(PO_4)_2 + Th_3(PO_4)_4 + 5\ 4ThSiO_4 + R_2SiO_4 + 4H_2O$.

III. Small, indistinct crystals and crystalline fragments. Colour, faint greyish-brown. Cleavage not distinct. Sp. gr., 4·87. General formula, $100(3RO,P_2O_5) + 120(2RO,SiO_2) + 30H_2O$. Special formula, $20(Ce,La)_2(PO_4)_2 + 1{\cdot}2Th_3(PO_4)_4 + 7ThSiO_4 + 19R_2SiO_4 + 6H_2O$.

	P_2O_5.	SnO_2.	SiO_2.	ThO_2.	Ce_2O_3.	La_2O_3.	Y_2O_3.	Fe_2O_3.	FeO.
*I.	27 32	0·95	1·37	5·55	31·31	31·86	0·52	0·26	—
II.	25·09	0·43	2·90	17·82	34·90	17·60	0·43	0 43	—
III.	19·13	0·40	9·67	16·64	22·88	14·69	1·71	—	3·56

	Al_2O_3.	MnO.	CaO.	MgO.	H_2O.	Total.
*I.	0·13	—	0·55	—	0·41	100·23
II.	—	—	0·36	—	0·56	100·52
III.	2·90	4·89	1·25	0·40	0·71	98·83

A. G. B.

Minerals from Arizona. By W. P. BLAKE (*Amer. J. Sci.* [3], **39**, 43—45).—The sodium sulphate deposits of the Verde Valley, Arizona, have long been quarried as a substitute for salt for cattle. The occurrence of thenardite was made known by Silliman in 1881 (Abstr., 1881, 1109). A visit to the locality has enabled the author to describe allied species in association with the thenardite. The minerals described are mirabilite, halite, glauberite, and pseudomorphs of calcium carbonate after glauberite.

In conclusion, the author makes what he believes to be the first announcement of the occurrence of bournonite in the United States. It occurs sparingly in brilliant characteristic crystals at the Boggs mine, Big Bug district, Arizona. B. H. B.

Barium Sulphate from Perkins' Mill, Quebec. By E. S. DANA (*Amer. J. Sci.* [3], **39**, 61—65).—In 1889, Lacroix described (Abstr., 1889, 838), under the name of *michel-levite*, a mineral from Quebec, having the same composition as heavy spar, but, as he believed, crystallising in the monoclinic system. The discovery of the dimorphism of barium sulphate is a point of so great chemical interest that the author has been induced to examine upwards of 50 specimens from Perkins' Mill, Templeton, Quebec, the locality described by Lacroix. Optically and crystallographically, the specimens examined conform to normal barium sulphate. The apparent easy cleavage and the accompanying pearly lustres of one of the prismatic faces appear to be secondary in origin, and to have been called out by pressure. The existence of a monoclinic form of barium sulphate at Perkins' Mill is consequently extremely doubtful. B H. B.

---

* Mean of two analyses.

Jarosite from Utah. By F. A. GENTH (*Amer. J. Sci.* [3], 39, 73). —At the Mammoth mine, Tintic district, Utah, minute crystals of jarosite occur, lining cavities of a siliceous limonite, and sometimes associated with a pulverulent yellow mineral, probably a basic ferric sulphate. The crystals are of a yellowish-brown colour, and exhibit rhombohedral forms. Analysis gave the following results:—

SiO_2.	Fe_2O_3.	Na_2O.	K_2O.	SO_3.	H_2O.	Sp. gr.
0·29	51·16	0·33	9·05	28·93	10·24	3·163

B. H. B.

Zinciferous Clays of South-west Missouri. By W. H. SEAMON (*Amer. J. Sci.* [3], 39, 38—42).—In connection with the calamine deposits of Missouri, there occur, in considerable abundance, clays of peculiar composition, the probable commercial value of which has hitherto been unsuspected. They occur in layers of from several inches up to 3 feet, or in lumps weighing from 50 to 500 lbs., above, below, and intermixed with the calamine. The author gives 22 analyses, of which the following three are selected as typical:—

	H_2O.	Loss.	ZnO.	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	Total.	Sp. gr.
I.	4·03	3·92	54·06	35·29	1·64	—	1·80	100·74	2·91
II.	6·33	8·93	35·63	38·26	6·17	4·67	trace	99·99	2·77
III.	2·48	13·64	4·30	66·22	4·91	8·44	—	99·99	—

The loss at a low red heat consists mainly of water. I is a thin streak of a pure white variety of so-called "tallow clay" found in small amounts; II, flesh-coloured tallow clay from Aurora; III, dark red "joint clay" from Aurora. The clays termed joint clays by the miners are tougher than the tallow clay, and are usually found nearer the surface. B. H. B.

Composition of Recent Vesuvian Lavas. By G. FREDA (*Gazzetta*, 19, 10—16).—*Lava of* 1884.—The surface of this lava is frequently coated with an extremely thin, hard, strongly adherent, bright, metallic film which contains iron and nitrogen, and gives off ammonia when boiled with concentrated potash solution, but differs from the ferric nitride observed by Silvestri, at Etna, by its permanence in the atmosphere.

Lava of 1886.—This is of a dark iron-grey colour, and contains crystals of augite and nodules of leucite disseminated throughout the interior. The surface, which is smooth, lustrous, and almost pitchy in appearance, is covered with a thin film which is seen to be yellow and transparent at the sharp angles. The powdered lava gelatinises when heated with dilute sulphuric acid. It fuses to a brown glass under the blowpipe.

Lava of 1887.—This lava resembles the preceding in appearance; but under the microscope it exhibits less ground-matrix. The nodules of leucite, which are of a dark-grey colour and contain numerous inclusions, are less conspicuous; but the crystals of augite are more abundant than in the 1886 lava. The composition of these three lavas is as follows:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	P_2O_5.
Lava of 1884	48·06	18·37	10·62	9·46	3·51	5·63	1·80	0·69
„ 1886	48·56	17·91	11·93	8·94	3 68	6·21	1·65	0·77
„ 1887	48·40	18·09	10·81	9·53	3·45	5·48	2·13	0·62

S. B. A. A.

New Stone Meteorite. By L. G. EAKINS (*Amer. J. Sci.* [3], **39**, 59—61).—The fragment of the meteorite described was presented by R. T. Hill to the United States National Museum. It is of irregular shape, and weighs 2½ kilos. It is hard, compact, and very tough. The stony mass is very uniform in structure, but under the microscope is seen to consist of olivine and enstatite, with a small quantity of a colourless felspar. The mass has a sp. gr. of 3·543 at 30°, and on analysis yielded—

SiO_2.	Al_2O_3.	Cr_2O_3.	FeO.	Fe.	NiO.	Ni.	Co.	CaO.	MgO.
44·75	2·72	0·52	16·04	1·83	0·52	0·22	0·01	2·23	27·93

K_2O.	Na_2O.	P_2O_5.	S.	H_2O.	Total.	Less O for S.	Total.
0 13	1·13	0·41	1·83	0·84	101·11	0·92	100·19

The metallic portion constituted 2·23 per cent. of the mass and contained—

Fe.	Ni.	Co.	Total.
88·74	10·68	0·58	100·00

The residue from which the metallic portion had been removed was digested with dilute hydrochloric acid, and the soluble and insoluble portions analysed. In the soluble portion the ratio of the RO-group to the SiO_2 is very close to that of olivine. The insoluble portion, after removing the chromium oxide and a proportional amount of ferrous oxide to form chromite, gives ratios which seem to bear no definite relations to each other. Assuming, however, that the alumina and alkalis are present in the proportion required for a felspar of the oligoclase type, and deducting this amount of felspar, there remains—

$$RO : SiO_2 = 0·789 : 0·774,$$

which corresponds closely with enstatite. The general composition of the meteorite is as follows:—

Metallic.	Troilite.	Soluble in acids.	Insoluble.	Total.
2 23	5·03	39·84	52·42	99·52

B. H. B.

Organic Chemistry.

Stereochemistry of Nitrogenous Compounds. By R. BEHREND (*Ber.*, 23, 454—458).—In the course of his researches on the alkyl-derivatives of hydroxylamine, made jointly with Leuchs and König, the author obtained results which appeared to show that whilst paranitrobenzylhydroxylamine and benzyl chloride on the one hand, and β-benzylhydroxylamine and nitrobenzyl chloride on the other, gave rise to the same β-benzylparanitrobenzylhydroxylamine, the hydrochlorides of the bases obtained by the two methods differed from one another in crystalline form and solubility. Further investigations have not confirmed this, but it has led the author to ideas concerning the nature of the nitrogen-atom which differ considerably from those of Hantzsch and Werner (this vol., p. 348).

The grounds on which the theory is based are as follows: Through the central points of the atoms, or groups of atoms combined with nitrogen in ammonia or the substituted ammonias, a plane may always be imagined to pass; whether this plane also passes through the centre of the nitrogen-atom is not discussed. Ammonia can unite simultaneously with a positive and negative element, and it is assumed that these take up their position on either side of the plane at points previously fixed; in other words, that ammonia has a positive and negative pole. This is graphically represented in Fig 1.

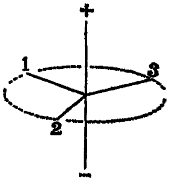


FIG. 1.

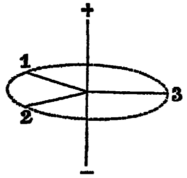

FIG. 2.

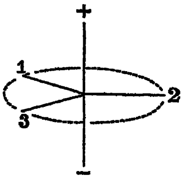

FIG. 3.

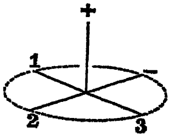

FIG. 4.

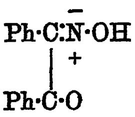
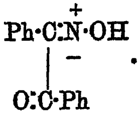
If two different radicles (represented by 1 and 3) are substituted for two hydrogen-atoms in ammonia, two configurations are possible (Figs. 2 and 3), which would scarcely be distinguishable from one another, but whose salts would have the same relation to each other as the active tartaric acids. Experiments made to obtain such isomeric salts have so far been unsuccessful. It is, however, possible that as soon as both poles of the ammonia are saturated, the two isomerides may pass into the same state of equilibrium, as shown in Fig. 4. In favour of this view is the identity of the ammonium bases obtained on the one hand from diethylamine and methyl iodide, and on the other from dimethylamine and ethyl iodide (V. Meyer and Lecco, this Journal, 1876, i, 381).

The isomerism of the benzil monoximes and dioximes is explained by the assumption that the two carbon-atoms, which in themselves can, according to Van't Hoff and Wislicenus, rotate freely, take up different positions of equilibrium under the influence of the attractions between the radicles with which they are combined. Whatever assumptions may be made as to the forces between these radicles, the monoxime can only exist in two, and the dioxime in three forms. If the phenyl-group be taken as feebly positive and the oxygen-atom as strongly negative, the following stereometric formulæ represent the compounds, the names given to each formula being only intended to indicate the one whose properties are best represented by that formula:—



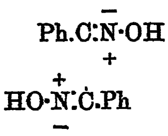
$$\begin{array}{l}\mathrm{Ph{\cdot}C{:}\overset{-}{N}{\cdot}OH}\\ \quad\;\; | +\\ \mathrm{Ph{\cdot}C{\cdot}O}\end{array}$$

α-Monoxime.



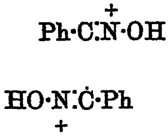
$$\begin{array}{l}\mathrm{Ph{\cdot}C{:}\overset{+}{N}{\cdot}OH}\\ \quad\;\; | -\\ \mathrm{O{:}C{\cdot}Ph}\end{array}.$$

γ-Monoxime.



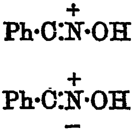
$$\begin{array}{c}\mathrm{Ph.C{:}\underset{+}{\overset{-}{N}}{\cdot}OH}\\ \mathrm{HO{\cdot}\underset{-}{\overset{+}{N}}{:}\dot{C}.Ph}\end{array}$$

α-Dioxime.



$$\begin{array}{c}\mathrm{Ph{\cdot}C{:}\overset{+}{N}{\cdot}OH}\\ \mathrm{HO{\cdot}\underset{+}{N}{:}\dot{C}{\cdot}Ph}\end{array}$$

β-Dioxime.



$$\begin{array}{c}\mathrm{Ph{\cdot}C{:}\overset{+}{N}{\cdot}OH}\\ \mathrm{Ph{\cdot}C{:}\underset{-}{\overset{+}{N}}{\cdot}OH}\end{array}$$

γ-Dioxime.

This explanation is very closely allied to that previously given by V. Meyer and Auwers (Abstr., 1888, 597), and is in full accordance with the views of Wislicenus concerning the attraction which takes place between groups not directly connected together.

The author regards the above group of oximes as the only group of stereometric isomerides containing nitrogen which has been sufficiently investigated to allow of any conclusions as to the nature of the nitrogen-atom being drawn. He further doubts the validity of the proof given by Goldschmidt (this vol., p. 253), and adopted by Hantzsch and Werner (this vol., p. 248), as to the structural identity of the two benzaldoximes. The two forms of the latter which can, according to Behrend's theory, exist would show such slight differences as probably to be indistinguishable. H. G. C.

Arrangement in Space of the Atoms in Compounds containing Nitrogen. By C. W. Willgerodt (*J. pr. Chem.* [2], **41**, 291—300).—The author complains that Hantzsch and Werner (this vol., p. 348) have ignored his work on this subject (*J. pr. Chem.* [2], **37**, 449).

In this paper he gives figures showing the probable geometrical arrangement of several typical nitrogen compounds.

The author and F. Schulz have obtained two picryl-*α*-naphthylhydrazines: one forms yellow, almost pulverulent crystals; this is very unstable and, when treated with solvents or heated to 145—150°, easily changes into the other, a red-brown, stable modification; rotation of various parts of the molecule will probably explain such cases of isomerism.

The properties of the two hydrobenzoïns (Zincke, Abstr., 1880, 118) are easily explained on the supposition that they are geometrical isomerides,  $\begin{matrix}\mathrm{OH{\cdot}CHPh}\\ |\\ \mathrm{OH{\cdot}CHPh}\end{matrix}$ being the formula for isohydrobenzoïn, and  $\begin{matrix}\mathrm{OH{\cdot}CHPh}\\ |\\ \mathrm{H{\cdot}CPh{\cdot}OH}\end{matrix}$ that for hydrobenzoïn. A. G. B.

Preparation of Iodoform. By Casthélaz and Bruère (*Chem. Centr.*, 1890, i, 19; from *Pharm. Zeit.*, **34**, 714).—By the method of Suilliot and Raynaud (Abstr., 1889, 1055), in which potassium hypoiodite reacts with acetone, the authors have obtained a very high yield of iodoform, the reaction occurring quantitatively between the hypoiodite and acetone. The iodoform thus prepared is completely soluble in alcohol, ether, chloroform, and carbon bisulphide, and has only a faint ethereal odour. J. W. L.

Preparation of Octyl Chloride. By H. Malbot (*Bull. Soc. Chim.* [3], **3**, 68—70; compare Abstr., 1889, 687).—Octyl alcohol, after saturation with hydrogen chloride and subsequent addition to the product of half its volume of concentrated hydrochloric acid, is heated in sealed vessels at 120—130°. The conversion is rapid, and the heating must not be prolonged. The yield is 87 per cent. of the theoretical. T. G. N.

Action of Sulphur on Glycerol. By C. H. Keutgen (*Arch. Pharm.* [3], **28**, 1—7).—When sulphur and glycerol were heated together, there was no reaction below 285°; at 290° to 300° much gas was evolved with violent intumescence and partial coking of the mass. The gases consisted of hydrogen sulphide, carbonic anhydride, and ethylene. During the reaction, a distillate was obtained containing undecomposed glycerol, water, and sulphur, as well as a thick, oily, tenacious liquid. The receiver was provided with a condenser to prevent loss of allyl mercaptan. The distillate was treated with ether, which separated a pungent, fuming oil, found to be allyl mercaptan boiling at 90°. After distilling all ether from the residue, there were obtained, on cooling, crystals of sulphur and reddish-brown crystals of diallyl hexasulphide. The brown crystals were extracted by means of cold alcohol of 90 per cent., the alcohol evaporated, and this repeated until no more sulphur separated on cooling. The brown crystals have the empirical formula $C_3H_5S_3$, and when treated with nascent hydrogen from tin and hydrochloric acid, yield allyl sulphide and, in smaller quantity, allyl mercaptan. *Diallyl hexasulphide* forms reddish-brown, rhombic prisms which gradually darken in the air, and has a penetrating, repulsive odour; it melts at 75·5 and begins to volatilise at 180°, but with partial decomposition. It is very easily soluble in ether, less so in alcohol, and only in traces in water. With the alcoholic and ethereal solutions, water gives a yellow precipitate. Its alcoholic solution gives with mercuric chloride solution a yellow precipitate of $(C_3H_5)_2S_6,2HgCl_2$, and with platinum chloride solution, a reddish precipitate of $(C_3H_5)_2S_6,PtCl_4$.

Oxidation of the diallyl hexasulphide with nitric acid yielded an *oxysulphide*, $SO(C_3H_5)_2$, a yellow, thick, syrupy liquid, which becomes brown in the air, and at 0° forms an amorphous solid soluble in alcohol and hot water. It is not volatile without decomposition. With nascent hydrogen, it yields allyl sulphide.

The first residue after removal of the diallyl hexasulphide formed a thick tenacious liquid which began to decompose at 110° with sudden increase of temperature and evolution of hydrogen sulphide, the mass coking even when heated in a vacuum. The residue thus obtained gave with nitric acid a mixture of oxalic and sulphuric acids.

Benzoyl-derivatives of Carbohydrates, of Glucosamine, and of certain Glucosides. By L. Kueny (*Zeit. physiol. Chem.*, **14**, 330—371).—All carbohydrates on treatment with benzoic chloride, according to Baumann's method, give benzoyl compounds. On examining these compounds, they were found to be mixtures of higher and lower benzoylised substances; it was difficult, and in some cases impossible, to separate these, because few of them are crystalline, and their melting points are not well defined. Dilute solutions of carbohydrates give a mixture of benzoates with a higher percentage of carbon than concentrated solutions. With dextrose, the substances obtained in a fairly pure condition were the penta-, tetra-, and tri-benzoates melting respectively at 179°, 141°, and 80°. The other carbohydrates examined were levulose, saccharose, lactose, maltose, dextrin, and glycogen. Dextrose and galactose are, as Skraup (*Sitzungsb. Wien. Akbd. Naturw.*, *Classe*, **98**, *iib*, 438) first found, completely benzoylised; in the case of the other carbohydrates, one or more hydroxyl-groups are left unreplaced. All these compounds are very resistant to the action of dilute mineral acids; by treatment with fuming nitric acid, they are partially decomposed. On treatment with alkali, the benzoates of the glucoses show the greatest resistance, the benzoylised saccharoses come next, whilst the benzoyldextrins are easily saponified. Nearly all these compounds are very badly characterised, and were not obtained in a state of purity. Most of them have been previously obtained, but the derivatives of amylodextrin and erythrodextrin are new; these, however, in each case were only obtained as mixtures of several benzoates.

Baumann has shown that by treating glucosamine with benzoic chloride, a glucosamine tetrabenzoate is formed, mixed with lower benzoylised compounds; it was not possible to prepare a pentabenzoate. By the action of fuming nitric acid on the tetrabenzoate, a crystallisable dibenzoate melting at 166° was obtained. The sugar obtained from glucosamine is a reducing sugar, but is not fermentable with yeast. Its benzoyl compound comes in elementary composition nearest to a dextrose tribenzoate, but differs from that compound in being easily decomposed by acids and alkalis. Tetrabenzoylglucosamine gives no reaction with hydrocyanic acid and phenylhydrazine; it is not attacked by nitrous acid, from which it follows that one benzoyl-group is attached to the NH_2 residue. By treating the benzoyl compounds of glucosamine with sodium amalgam, there is no evolution of hydrogen; they thus resemble benzamide and hippuric acid, and therefore probably contain the group NHBz.

The glucosides, like the carbohydrates, are easily benzoylised on treating them according to Baumann's method. Of the four glucosides examined, complete benzoylation, and a quite pure product (a pentabenzoate melting at 159—165°) was only obtained with one; namely, arbutin. Amygdalin, coniferin, and salicin were always incompletely benzoylised, giving mixtures of products containing a large number of benzoyl-groups, but these could not be separated by crystallisation. The benzoyl glucosides show even more resistance to the action of reagents than the similar compounds of the glucoses. Even by boiling with alkalis they were only decomposed with the greatest difficulty. W. D. H.

Influence of Temperature on the Specific Rotation of Cane-sugar. By C. W. Andrews (*Chem. Centr.*, 1890, i, 20—21; from *Mon. Sci.* [4], 3, 1366—1369).—The author has determined the specific rotation of cane-sugar, and his results coincide very closely with those of Dubrunfaut, who, in 1846, found that the rotation of cane-sugar diminishes as the temperature rises.

The author's determinations were made with a large Laurent polariscope, by means of which the angle of rotation could be read off to the nearest minute. The tubes, which were very carefully measured, were rather more than 40 cm. long. The sugar used was pure, and for a solution of the concentration $C = 26\cdot01$ showed a rotation of 66·398° at 20°, whereas, according to Landolt's formula, it should be 66·421°. Two series of determinations were made. In the first, 100 c.c. contained 23·686 grams of sugar, the readings showing a specific rotation of $[\alpha]_D = 66\cdot415°$ at 18·5° and $[\alpha]_D = 66\cdot174°$ at 41·5°. In the second series, 100 c.c. contained 15·344 grams of sugar, with which the readings were equal to $[\alpha]_D = 66\cdot642°$ at 19°, 66·405° at 39·9°, and 66·664° at 20·1°, from which results the author calculates $[\alpha]_D^t = [\alpha]_D^{20} - 0\cdot000114\ (t - 20)$ for cane-sugar.

J. W. L.

Behaviour of the Hydroxides of Calcium and the Alkalis with Sugars. By H. Leplay (*Chem. Centr.*, 1890, i, 108—110; from *Zeit. Rüb. Zuck. Ind.*, 1889, 1017—1026).—After experimenting on the inversion of saccharose by water, the author made a similar series of experiments to determine the action of sodium and calcium hydroxides. A solution of sugar, containing 100 grams in 1 litre, was boiled with sodium hydroxide solution (strength, 50 alkaline degrees in 1 litre) for 52 hours. During the first 8 hours the alkali was found to have prevented the inversion, but from this time inversion begins, the polariscope readings being 97·2° at the commencement, 95·5° at the end of 12 hours, 93·1° at the end of 16 hours, 91·5° at the end of 20 hours, 75° at the end of 42 hours, 40·5° at the end of 54 hours. When heated without alkali, the same sugar solution became levorotatory at the end of 12 hours, and at the end of 54 hours the reading was − 21·5°. Two other similar experiments were made with a sugar solution of the same strength, but with considerably less alkali, from all of which the author concludes that the sodium hydroxide on the one hand prevents the inversion of the sugar, but that it attacks a portion of the sugar, becoming thereby itself neutralised. The rotatory power of the sugar solution is reduced, but the reducing power for Fehling's solution is not altered;

no reducing substances are formed if the heating be discontinued at the moment when the alkali is entirely neutralised. The action of calcium hydroxide on a similar solution of sugar proved to be the same as that of sodium hydroxide, but was more feeble; a part of the alkali becomes neutralised, the rotatory power becomes reduced, but no reducing substance is formed. This coincides with the experiences of sugar refiners, an acid substance being formed which unites with the lime to form a thick syrupy liquid which prevents crystallisation. As the compound formed with sodium is of a much more limpid nature, the author recommends the use of sodium hydroxide.

The author draws attention to the importance of the estimation of these acid products of the decomposition of glucose, some of which reduce alkaline copper solutions, but do not rotate the ray of polarised light, and points out that whilst the quantity of glucose may remain nearly constant, the amount of these acids increases constantly, a small quantity of cane-sugar being continually converted into glucose, whilst at the same time a nearly corresponding quantity of glucose is converted into acid substances. J. W. L.

Compounds of Raffinose with Bases. By K. BEYTHIEN and B. TOLLENS (*Annalen*, **255**, 195—213; compare Abstr., 1889, 846). —The specific rotatory power of pure raffinose, $C_{18}H_{32}O_{16} + 5H_2O$, is $[\alpha]_D = 104.4°$.

Strontia raffinose, $C_{18}H_{32}O_{16},2SrO + H_2O$, is best prepared by boiling a solution of crystalline raffinose (5 grams), crystalline strontium hydrate (10 grams), and water (20 c.c.), for four to six hours in a salt-water-bath; at 100° the precipitate separates in a sticky condition, but by prolonged boiling in a salt-water-bath, or by adding a little alcohol, it is obtained as a granular, amorphous powder. It loses its water at 100°, and is soluble in alcohol and ether. Attempts to prepare a monostrontia compound were unsuccessful.

Baryta raffinose, $C_{18}H_{32}O_{16},BaO$, can be obtained by dissolving crystalline barium hydrate (2 grams) in water (60 c.c.), adding alcohol until the precipitate produced just redissolves, and then adding a solution of raffinose (2·5 grams) in water (5 c.c.). The reddish, amorphous precipitate gradually hardens, and is then washed with alcohol and ether. *Dibaryta raffinose*, $C_{18}H_{32}O_{16},2BaO$, is prepared in like manner, but employing excess (4—5 grams) of barium hydrate. Both compounds are difficult to purify.

Lime raffinose, $C_{18}H_{32}O_{16},3CaO + 2H_2O$, is easily obtained by dissolving raffinose (3 grams) in water (100 c.c.), adding calcium hydrate (0·4 gram), and, after keeping for some time, heating the filtered solution for some hours. It is a colourless powder, and loses its water at 100°.

Lead oxide raffinose, $C_{18}H_{32}O_{16},3PbO$, prepared by adding a clear ammoniacal solution of lead acetate to an aqueous solution of raffinose, is a colourless powder.

The two compounds $C_{18}H_{31}O_{16}Na$ and $C_{18}H_{31}O_{16}Na,NaOH$ were also prepared by the method previously described (Rischbieth and Tollens, (*Annalen*, **232**, 182). F. S. K.

Behaviour of Inverted Raffinose with Phenylhydrazine. By K. BEYTHIEN and B. TOLLENS (*Annalen*, **255**, 214—216).—When raffinose (10 grams) is heated for ten minutes at 68° with hydrochloric acid of sp. gr. 1·19 (6 c.c.) and water (90 c.c.), the solution then freed from hydrochloric acid with silver carbonate, and treated with phenylhydrazine and acetic acid, an osazone is obtained which has the same melting point and the same composition as the osazone of levulose and of dextrose. This experiment, together with Haedicke and Tollens' observation that the glucose formed is strongly lævorotatory, proves that levulose is produced by the partial inversion of raffinose. The fact that galactose cannot be isolated from the inverted solution, in spite of the readiness with which it crystallises, seems to show the existence of a compound of galactose with dextrose in the partially inverted solution.

Mannose phenylhydrazine could not be obtained from the inverted solution, as stated by Fischer (Abstr., 1889, 480). F. S. K.

Cellulose and its Forms. By W. HOFFMEISTER (*Chem. Centr.*, 1890, i, 112—114; from *Landw. Jahrb.*, **18**, 767—784).—The author has further experimented with the two methods already described (*Chem. Centr.*, 1888, 1211, 1426; 1889, ii, 721). Although cellulose may be purified by treatment with cold hydrochloric acid and hot ammonia, which remove the foreign substances, after which the cellulose is completely dissolved by cuprammonium hydroxide solution, it is now recommended to use glacial acetic acid, which does not effect any change in any form of soluble cellulose in the cold, sugar-formation not occurring until a few degrees below 100°. Starch is not affected by acetic acid at 88—92°, but if one drop of hydrochloric acid is added, the starch becomes completely dissolved in 2 to 3 hours. Substances are therefore digested for several hours at 86—90° with 5 parts of glacial acetic acid, to which one drop of hydrochloric acid per 20 c.c. is added, after which the residue is digested with ammonia and thoroughly washed, and may then be dissolved in cuprammonium hydroxide solution. The method is, however, too complicated for the usual determination of cellulose in feeding stuffs.

The "chlorine mixture" is useful for the approximate determination of crude woody fibre, and for the preparation of the soluble and insoluble forms of cellulose, but is not suitable for the analysis of feeding stuffs.

The author considers that Weender's method is the best for this purpose. He has also made a series of experiments with clover and barley, with the object of determining whether soluble forms of cellulose occur at every period of the life of plants, and whether the relative proportions of soluble and insoluble cellulose can be determined during the different periods of plant life, and he has arrived at the conclusion that soluble cellulose does exist at every period of the life of plants, and that the relative proportion of soluble cellulose increases with the period of vegetation. J. W. L.

The Melting Points and Preparation of Osazones. By K. BEYTHIEN and B. TOLLENS (*Annalen*, **255**, 217—221).—The observed melting point of an osazone depends, as has been previously stated by other investigators, on the rapidity of heating; the levulosazone obtained from raffinose, for example, melts at 208° when the rise in temperature from 23—208° occurs in 13 minutes, whilst by heating much more slowly the melting point falls to 185°. It is advisable, therefore, in identifying an osazone by its melting point, to do so by direct comparison.

In the preparation of osazones from phenylhydrazine acetate (or phenylhydrazine hydrochloride and sodium acetate). the solution should not be evaporated to dryness, as, under these conditions, acetylphenylhydrazine (m. p. 128·5°) is also formed.

Phenylhydrazine, under certain conditions not determined, produces troublesome sores on the skin. F. S. K.

Ethyl Orthoformate. By T. Hulleman (*Rec. Trav. Chim.*, 8, 386—390).—It is stated in text-books that ethyl orthoformate is decomposed by sodium ethoxide; alcohol, ether, sodium formate, and carbonic monoxide being formed. The author finds that this is not the case. Ethyl orthoformate is not acted on by a 10 per cent. alcoholic solution of sodium ethoxide at 100°, nor by dry sodium ethoxide at 146°; when boiled with metallic sodium, a small quantity of a brown substance is formed, but no gas is evolved.

Nitric acid decomposes ethyl orthoformate, forming ethyl nitrate, formic acid, and water; a small quantity of ordinary ethyl formate is also formed. C. F. B.

Ethyl Thioacetoacetate. By A. Michaelis and B. Philips (*Ber.*, 23, 559—561).—Ethyl thioacetoacetate (m. p. 100—101°) is formed when ethyl acetoacetate is treated with thionyl chloride in the cold.

When ethyl thioacetoacetate is treated with phenylhydrazine in cold acetic acid solution, it yields a compound of the composition $C_{20}H_{22}O_4N_4S$. This substance separates from hot alcohol in colourless crystals, melts at 185°, and is converted into phenylmethylpyrazoloneazobenzene, identical with the compound described by Buchka and Sprague (this vol., p. 28), when it is warmed with phenylhydrazine in alcoholic solution. F. S. K.

Formation of Lactic Acid from Raffinose and from Cane-sugar. Raffinose not formed from Cane-sugar by the Action of Calcium or Strontium Hydroxide. By K. Beythien, E. Parcus, and B. Tollens (*Annalen*, 255, 222—228).—Lactic acid (0·6 gram) is formed when raffinose (40 grams) is boiled for about 24 hours with a solution of crystalline strontium hydroxide (90 grams) in water (1 litre). Cane-sugar under the same conditions gives the same quantity of lactic acid.

When cane-sugar (1 part) is boiled with calcium hydroxide (1 part) and water (20 parts) for 48 hours, it yields about 1 per cent. of its weight of lactic acid; raffinose is not formed when cane-sugar is boiled with calcium or strontium hydroxide, as is shown by the fact that after separating the alkaline earth and oxidising the residual sugar with nitric acid, not a trace of mucic acid is obtained.

F. S. K.

Lactic Acid from Molasses. By K. BEYTHIEN, E. PARCUS, and B. TOLLENS (*Annalen*, **255**, 228—229).—Molasses contains variable quantities of lactic acid, sometimes as much as 0·5 per cent. The authors examined four different samples and found lactic acid in every case; two of the samples were obtained from works where the elution process and the strontia process are not employed.

F. S. K.

New Synthesis of Bibasic Carbon Acids. By A. CRUM BROWN (*Proc. Roy. Soc. Edin.*, **17**, 53—54).—The electrolysis of salts of the general formula COOK·R″·COOEt has produced potassium hydroxide, hydrogen, and carbonic anhydride at the cathode, and salts of the formula COOEt·R·R·COOEt at the anode. See next abstract.

E. W. P.

Electrolysis of Potassium Ethyl Malonate and of Potassium Ethyl Succinate. By A. CRUM BROWN and J. WALKER (*Proc. Roy. Soc. Edin.*, **17**, 54—56).—Avoiding heating and high concentration, potassium ethyl malonate was subjected to electrolysis; and after the passage of the current for some time, potassium carbonate was deposited, and from the aqueous solution ether extracted ethyl succinate (b. p. 216°).

Ethyl adipate was obtained in a similar manner from potassium ethyl succinate.

E. W. P.

Lactonic Acids, Lactones, and Unsaturated Acids. By R. FITTIG (*Annalen*, **255**, 1—18; compare Abstr., 1886, 47, and 1888, 251).—The condensation of aldehydes with dicarboxylic acids of the succinic series is a reaction which can be employed with advantage for the preparation of lactonic acids, lactones, and unsaturated mono- and di-carboxylic acids, the constitution of which is known from their method of formation.

All aldehydes hitherto investigated in this direction react readily with succinic acid and with pyrotartaric acid; other dicarboxylic acids have not yet been tried.

The usual method of procedure is to heat an intimate mixture of the anhydrous aldehyde (1 mol.), anhydrous sodium succinate (1 mol.) or sodium pyrotartrate (1 mol.), and freshly distilled acetic anhydride (1 mol.), at a temperature varying from 80 to 120°.

In the case of succinic acid, the first product is probably a sodium salt of the constitution OH·CHR·CH(COONa)·CH$_2$·COONa; this compound, on treatment with water, is decomposed by the acetic acid into the free acid or the sodium hydrogen salt, with subsequent formation of a single lactonic acid. The yield of this product is only approximately quantitative, owing to the formation of resinous products, especially when the aldehyde employed is prone to polymerisation.

In the case of pyrotartaric acid, two isomeric lactonic acids of the constitution  $\begin{array}{l}\text{CHR·CH·COOH}\\ \;|\qquad\;\;|\\ \text{O·CO·CHMe}\end{array}$ and  $\begin{array}{l}\text{CHR·CMe·COOH}\\ \;|\qquad\;\;|\\ \text{O·CO·CH}_2\end{array}$, respectively, are formed; the acid of higher melting point is produced in by far the larger quantity, and has probably the constitution represented by the first of the two formulæ.

Salicylaldehyde and succinic acid yield a *dicoumarin* of the constitution $C_6H_4<\substack{O\cdot CO\\ CH}>C\cdot C<\substack{CO\cdot O\\ CH}>C_6H_4$, whilst salicylaldehyde and pyrotartaric acid give *coumarinpropionic acid*,

$$C_6H_4<\substack{O\cdot CO\\ CH}>C\cdot CHMe\cdot COOH,$$

and small quantities of a *hydroxyphenylmethylisocrotonic acid*, which has probably the constitution $OH\cdot C_6H_4\cdot CH\colon CMe\cdot CH_2\cdot COOH$.

Anisaldehyde and succinic acid condense together, forming *anisylisocrotonic acid*, $OMe\cdot C_6H_4\cdot CH\colon CH\cdot CH_2\cdot COOH$, *dianisylpentolic acid*, $OMe\cdot C_6H_4\cdot CH\colon CH\cdot C(COOH)\colon CH\cdot C_6H_4\cdot OMe$, and *dianisyltetrylene*, $OMe\cdot C_6H_4\cdot CH\colon CH\cdot CH\colon CH\cdot C_6H_4\cdot OMe$.

The distillation-products of the monosubstituted paraconic acids are in every case (1) a monocarboxylic $\beta\gamma$-unsaturated acid formed by the elimination of carbonic anhydride; (2) small quantities of a saturated lactone isomeric with this $\beta\gamma$-acid; and (3) one, or in the case of methylparaconic acid several, unsaturated dicarboxylic acids isomeric with the original paraconic acid; in every case, except in that of phenylparaconic acid, some of the acid passes over unchanged, especially with rapid distillation.

The lactonic acids obtained from aldehydes and pyrotartaric acid yield, on distillation, unsaturated hydrocarbons; only very small quantities of unsaturated monocarboxylic acids and lactones being produced; at the same time, some of the lactonic acid is decomposed into pyrotartaric acid and the aldehyde from which it was prepared.

F. S. K.

Acetaldehyde and Succinic Acid. By R. FITTIG and I. FRÄNKEL (*Annalen*, **255**, 18—42; compare Abstr., 1886, 47, 1888, 251).—*Methylparaconic acid*, $\begin{array}{l}CHMe\cdot CH\cdot COOH\\ \,|\qquad\quad\ |\\ O\cdot CO\cdot CH_2\end{array}$, is obtained when a mixture of sodium succinate, acetic anhydride, and acetaldehyde ($1\frac{1}{2}$ mols.) is heated for 12 hours at 100°, and then for 24 hours at 115—120°. The product is mixed with water, the supernatant oil, which consists of paraldehyde and resinous products, separated mechanically, the residual solution distilled with steam to free it from aldehyde, and then concentrated by evaporation; after acidifying with hydrochloric acid, the methylparaconic acid and succinic acid are extracted with ether, dissolved in water, the filtered solution evaporated to dryness, and the lactonic acid extracted with chloroform. It crystallises from benzene in slender needles or plates, melts at 83—84°, and is very readily soluble in most ordinary solvents, but only sparingly in benzene and light petroleum, and almost insoluble in carbon bisulphide. This acid seems to have been previously prepared by Gantter (compare Bischoff and Rach, Abstr., 1886, 1012) by the reduction of ethyl acetosuccinate with sodium amalgam. The *barium* salt, $(C_6H_7O_4)_2Ba + 3\frac{1}{2}H_2O$, prepared by neutralising a cold aqueous solution of the acid with barium carbonate, is very readily soluble in water, from which it separates in small needles; it loses its water at 100°, and is insoluble in alcohol. The *calcium* salt (+ $2\frac{1}{2}H_2O$) separates from very concentrated aqueous solutions in ill-defined, crystalline aggregates. The *silver* salt, $C_6H_7O_4Ag$, crystallises in prisms, is very stable, and dissolves freely in hot water.

Barium methylitamalate, $C_6H_8O_5Ba + 3H_2O$, is produced when methylparaconic acid is boiled with baryta-water; it is not easily obtained in crystals. The *calcium* salt (+ $3H_2O$), prepared in like manner, crystallises from water in small needles, and is more readily soluble in cold than in hot water. The *silver* salt, $C_6H_8O_5Ag_2$, is a colourless, flocculent compound, only sparingly soluble in water.

When methylparaconic acid is heated, carbonic anhydride commences to be evolved at 200°, and at a somewhat higher temperature, a yellow oil distils, leaving a small quantity of carbonaceous matter. The distillate is a mixture of valerolactone, ethylidenepropionic acid, methylitaconic acid, methylcitraconic acid, and unchanged methylparaconic acid; the five compounds are isolated as follows:—The distillate is treated with water, rendered alkaline with sodium carbonate, and the valerolactone extracted with ether; the solution is then acidified with sulphuric acid, the acids extracted with ether, and the mixture submitted to distillation with steam. Methylitaconic acid and methylparaconic acid remain, and can be separated by evaporating the solution and extracting the lactonic acid from the crystalline residue with chloroform. Ethylidenepropionic acid and methylcitraconic acid distil over, and can be separated by converting them into the barium salts and evaporating, whereon the sparingly soluble salt of methylcitraconic acid separates from the hot solution.

Ethylidenepropionic acid, $CH_3\cdot CH\colon CH\cdot CH_2\cdot COOH$, is a colourless oil boiling at 193—194°; it is soluble in 10—12 parts of water, but separates from the solution on the addition of sodium chloride. It is moderately easily volatile with steam, and has an odour recalling that of hydrosorbic acid. This acid is possibly identical with the compound obtained by Zincke and Küster (Abstr., 1889, 599) from catechol and orthamidophenol, and named by them propylideneacetic acid. The *barium* salt, $(C_5H_7O_2)_2Ba$, separates from water in small, anhydrous needles, and is more sparingly soluble in hot than in cold water. The *calcium* salt (+ H_2O) crystallises in plates, and is readily soluble in water and alcohol. The *silver* salt, $C_5H_7O_2Ag$, crystallises from water in nacreous plates, and is slowly decomposed by boiling water, but is moderately stable in the light.

γ-Bromovaleric acid, $CH_3\cdot CHBr\cdot CH_2\cdot CH_2\cdot COOH$, is obtained when ethylidenepropionic acid is treated with ice-cold concentrated hydrobromic acid. It is a colourless oil, and is readily decomposed by boiling water, yielding valerolactone.

Dibromovaleric acid, $CH_3\cdot CHBr\cdot CHBr\cdot CH_2\cdot COOH$, prepared by brominating ethylidenepropionic acid in cold carbon bisulphide solution, is a thick, yellowish syrup; it is not identical with the dibromo-derivative of allylacetic acid.

Methylcitraconic acid, $COOH\cdot CH\colon CEt\cdot COOH$, crystallises from water and chloroform in large, compact prisms, and from benzene in needles, melts at 100—101°, and is readily volatile with steam; it probably distils as anhydride, because even when dried at 70° it is converted into the anhydride, which remains as an oil. The *calcium* salt, $C_6H_6O_4 + H_2O$, separates from hot water in plates, and is more readily soluble in cold than in hot water. The *barium* salt ($+ 4H_2O$) separates from its aqueous solutions, on heating, in slender needles, and loses its water only at a high temperature. The *silver* salt, $C_6H_6O_4Ag_2$, crystallises from hot water, in which it is only very sparingly soluble, in colourless needles, and is very stable.

Methylitaconic acid, $COOH{\cdot}CH_2{\cdot}C(COOH){:}CHMe$, crystallises from hot water in prisms, melts at 166—167°, and is only sparingly soluble in cold ether and cold water, and almost insoluble in chloroform. It is not volatile with steam, and is much more sparingly soluble than methylcitraconic acid, to which it stands in the same relation as itaconic does to citraconic acid. The *calcium* salt, $C_6H_6O_4Ca + H_2O$, crystallises from water in plates, and is more readily soluble in cold than in hot water. The *barium* salt ($+ \frac{1}{2}H_2O$) separates from water in prismatic crystals. The *silver* salt, $C_6H_6O_4Ag_2$, is a crystalline powder, very sparingly soluble in water, and very stable.

Methylcitraconic acid is converted into methylitaconic acid when it is heated with water at 150° for 6—8 hours; when methylitaconic acid is distilled, it is partially converted into methylcitraconic acid. Methylitaconic acid and methylcitraconic acid, on reduction with sodium amalgam, are both converted into ethylsuccinic acid (m. p. 98—99°) identical with the compound obtained by Huggenberg (Abstr., 1878, 782).

An acid melting at 194—196°, and sparingly soluble in hot water, is formed when methylcitraconic acid is heated with dilute (1 : 4) nitric acid; this compound is probably methylmesaconic acid.

Chloral and Succinic Acid. By R. FITTIG and H. E. MILLER (*Annalen*, **255**, 43—55; compare Abstr., 1888, 252).—Trichloromethylparaconic acid is prepared by treating chloral with sodium succinate and acetic anhydride, and, as soon as the first energetic reaction is at an end, heating the mixture at 110—120° for three to four hours. The product is mixed with warm water, the filtered solution strongly acidified with sulphuric acid, extracted with ether, and the ether evaporated; the acid is then purified by repeatedly dissolving in water and evaporating the filtered solution, and finally it is dissolved in chloroform to free it from traces of succinic acid. The yield of the pure acid is about 60 per cent. of the theoretical quantity. It crystallises in slender needles, melts at 97°, and is very readily soluble in ether, alcohol, and chloroform, but less readily in warm benzene, and almost insoluble in carbon bisulphide. The *calcium* salt, $(C_6H_4Cl_3O_4)_2Ca + 2H_2O$, prepared by neutralising a cold aqueous solution of the acid with calcium carbonate, crystallises in prisms. The *barium* salt, $(C_6H_4Cl_3O_4)_2Ba$, is a colourless, crystalline, hygroscopic compound. The *silver* salt, $C_6H_4Cl_3O_4Ag$, crystallises from hot water in slender needles.

Calcium trichloritamalate, $C_6H_5Cl_3O_5Ca$, separates as a colourless powder when a neutral solution of calcium trichloromethylparaconate is evaporated on the water-bath; the *barium* salt cannot be obtained in this way.

When a solution of trichloromethylparaconic acid is boiled with bases, salts of isocitric acid are formed.

Isocitric acid (*loc. cit.*) is obtained by boiling the paraconic acid with baryta. The barium salt, which separates on prolonged boiling as an insoluble, amorphous powder, is extracted with boiling water until free from chlorine, decomposed with boiling acetic acid, the barium precipitated with sulphuric acid, and the filtrate repeatedly evaporated with water. The residue solidifies, after some weeks, to a yellowish, very hygroscopic mass which consists of a mixture of isocitric acid and βγ-butyrolactonedicarboxylic acid. Salts of isocitric acid can be prepared from this mixture by neutralising the aqueous solution with a carbonate in the cold, and purifying the salt by repeatedly dissolving it in water and reprecipitating with alcohol. The *calcium* salt, $(C_6H_5O_7)_2Ca_3 + H_2O$, is a colourless, amorphous compound, sparingly soluble in hot water. The *barium* salt ($+ H_2O$) is more sparingly soluble than the calcium salt. The silver salt, $C_6H_5O_7Ag_3$, is a light-brown, amorphous powder.

Lactoisocitric acid (*βγ-butyrolactonedicarboxylic acid*),

$$CO<\begin{matrix}O-CH\cdot COOH\\ CH_2\cdot CH\cdot COOH\end{matrix},$$

is formed when isocitric acid is kept over sulphuric acid under reduced pressure, or heated at 100°. The *calcium* salt, $C_6H_4O_6Ca + 3H_2O$, prepared by neutralising a cold, aqueous solution of the acid with calcium carbonate, crystallises in colourless needles, and is sparingly soluble in cold, but more readily in hot water. The *barium* salt, $C_6H_4O_6Ba$, and the *silver* salt, $C_6H_4O_6Ag_2$, are amorphous.

Dichloromethylparaconic acid,  $CO<\begin{matrix}O-CH\cdot CHCl_2\\ CH_2\cdot CH\cdot COOH\end{matrix}$, is obtained when the trichlorinated acid is dissolved in glacial acetic acid, and zinc-dust gradually added to the warm solution. It crystallises from water in prisms, melts at 142°, and is soluble in ether and alcohol, but only sparingly in cold chloroform and benzene, and is almost insoluble in light petroleum. When boiled with baryta, it yields a colourless compound melting at about 222°, which still contains chlorine; this substance is being investigated.

When trichloromethylparaconic acid is distilled, about one-third passes over unchanged, the remainder being completely decomposed.

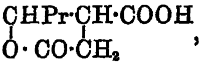
Propaldehyde and Succinic Acid. By R. FITTIG and A. DELISLE (*Annalen*, **255**, 56—68).—Ethylparaconic acid,  $\begin{matrix}CHEt\cdot CH\cdot COOH\\ O\cdot CO\cdot CH_2\end{matrix}$, is obtained by heating a mixture of propaldehyde, sodium succinate, and acetic anhydride for 25—30 hours at 110—120° (compare Abstr., 1886, 47). The product is distilled with water to free it from neutral oils, the filtered solution strongly acidified and extracted with ether; on evaporating the ether, there remains a mixture of ethylparaconic acid and succinic acid, from which the lactonic acid is extracted with chloroform. It crystallises from water in needles, melts at 85°, and is very readily soluble in chloroform, ether, and water, but only moderately easily in light petroleum, and almost insoluble in carbon bisulphide. The *silver* salt, $C_7H_9O_4Ag$, crystallises from boiling water in needles. The *calcium* salt, $(C_7H_9O_4)_2Ca + 2H_2O$, prepared by neutralising an aqueous solution of the acid with calcium carbonate in the cold, crystallises in needles, and is readily soluble in water. The *barium* salt $(+3H_2O)$ crystallises in well-defined prisms.

Calcium ethylitamalate, $C_7H_{10}O_5Ca + 5H_2O$, is obtained by boiling ethylparaconic acid with lime-water; it crystallises in needles, and is insoluble in alcohol, and more sparingly soluble in hot than in cold water. The *barium* salt $(+3H_2O)$ resembles the calcium salt, and is more sparingly soluble in hot than in cold water. The *silver* salt, $C_7H_{10}O_5Ag_2$, is amorphous.

Ethylparaconic acid is decomposed when heated, with evolution of carbonic anhydride, and between 200° and 300° almost the whole distils, the distillate consisting of caprolactone, hydrosorbic acid, $C_6H_{10}O_2$ (b. p. 208°), and unchanged ethylparaconic acid.

F. S. K.

Butaldehyde and Succinic Acid. By R. Fittig and H. Schmidt (*Annalen*, 255, 68—86).—*Propylparaconic acid*,



$\begin{array}{l} CHPr\cdot CH\cdot COOH \\ |\qquad\quad | \\ O\cdot CO\cdot CH_2 \end{array}$, is prepared by heating a mixture of normal butaldehyde, acetic anhydride, and sodium succinate at 100° for 12 hours, and then for 24 hours at 120—125°, and purifying the product as described in the case of ethylparaconic acid (compare preceding abstract). The yield is 45 to 50 per cent. of the aldehyde employed. It crystallises in waxy plates, melts at 73·5°, and is readily soluble in chloroform and hot water, but only very sparingly in light petroleum, and insoluble in carbon bisulphide. The *calcium* salt, $(C_8H_{11}O_4)_2Ca + 2H_2O$, prepared in the usual manner, separates from cold water in crystalline crusts. The *barium* salt, $(C_8H_{11}O_4)_2Ba$, is a colourless, amorphous powder, readily soluble in water. The *silver* salt, $C_8H_{11}O_4Ag$, crystallises in long needles, is soluble in water, and is very stable.

Calcium propylitamalate, $C_8H_{12}O_5Ca + 5H_2O$, prepared by boiling the paraconic acid with lime-water, crystallises from water in moss-like needles, and is more readily soluble in cold than in hot water. The *barium* salt $(+2H_2O)$ forms crystalline scales, and resembles the calcium salt in properties. The *silver* salt, $C_8H_{12}O_5Ag_2$, is almost insoluble in hot water and rather sensitive to light.

When propylparaconic acid is heated, carbonic anhydride is evolved, and at 230—240° a yellow oil distils; this distillate consists principally of heptylenic acid, but contains also small quantities of propylitaconic acid (or its anhydride) and heptolactone, together with variable quantities of unchanged paraconic acid. After isolating the lactone in the usual manner, the residual alkaline solution is acidified and the heptylenic acid distilled with steam; the residue contains propylitaconic acid and propylparaconic acid, which can be isolated by extracting with ether, and separated by means of chloroform, in which the lactonic acid alone is readily soluble.

Heptylenic acid, $CHPr\colon CH\cdot CH_2\cdot COOH$ (Abstr., 1888, 251), has the peculiar odour of unsaturated acids, and is rather sparingly soluble in water. The *barium* salt, $(C_7H_{11}O_2)_2Ba$, crystallises from hot water in plates. The *calcium* salt $(+H_2O)$ is rather more soluble in cold than in hot water, crystallises in plates, and is readily soluble in alcohol. The *silver* salt, $C_7H_{11}O_2Ag$, separates from boiling water, in which it is readily soluble, in small needles, but considerable decomposition occurs.

γ-Bromoheptylic acid, $CHPrBr\cdot CH_2\cdot CH_2\cdot COOH$, prepared by dissolving heptylenic acid in cold hydrobromic acid, and keeping the solution for several days in the cold, is a thick, heavy oil; it is slowly decomposed by water at the ordinary temperature yielding heptolactone.

Heptolactone (γ-propylbutyrolactone) boils at 234·5—235·5° without decomposition (compare Abstr., 1888, 252).

Barium hydroxyheptylate, $(C_7H_{13}O_3)_2Ba$, prepared by boiling heptolactone with baryta, crystallises from hot alcohol in microscopic needles which deliquesce on exposure to the air. It is decomposed when heated at 100° or when boiled with water, the odour of heptolactone being perceptible. The *silver* salt, $C_7H_{13}O_3Ag$, is partially decomposed by boiling water, from which it separates in moss-like crystals; it quickly darkens on exposure to the light.

Hydroxyheptylic acid can be obtained by decomposing a well-cooled solution of the barium salt with 1 per cent. hydrochloric acid, extracting with ether, and evaporating the ethereal solution at 0°; it is a strongly acid syrup, soluble in water, but it very readily changes into the lactone.
